Expected impacts of chemical substances on aquatic ecosystems can be described and predicted well by means of toxic pressure modeling. Uncertainty in model output has remained an issue. Recent studies in the framework of the EU project SOLUTIONS have convincingly demonstrated that uncertainties and variabilities of model parameters, and of modeling assumptions can be adequately dealt with in toxic pressure modeling. It has been shown that state-of-art environmental impact modeling by means of toxic pressure calculation can be carried out for all chemicals that are currently used in the EU. \n This paper focuses at the newly gained insight that toxic pressure modeling using the Van Straalen-Aldenberg convolution integral (i) intrinsically accounts for variances in model output that arise from uncertainty and variability, and (ii) intrinsically deals with simultaneous presence different chemicals. Results from earlier studies are revisited. \n These results are used to demonstrate how increased parameter uncertainty and variability automatically yield greater probability that exposure concentrations exceed critical effect concentrations, and how additive mixture toxic pressure automatically results from integration across all possible values of toxicologically standardized concentrations. It has become evident that the Van Straalen-Aldenberg integral yields uncertainty- and mixture-inclusive modeling results. These results also explain the often observed phenomenon of having Pareto-distributed toxic impacts: overall (mixture) toxic pressure originates from a few chemicals only, namely those in right tail of the concentration distribution. For C_W exceeding *HC50*, Pareto ratios are found to be generally (much) greater than the often-quoted ‘80/20 rule’, namely > 95/5.\nThis means that toxic pressures of chemicals in the environment, even those calculated under relatively great uncertainty and/or variability, can serve well as a scientific basis for regulatory decision making, notably for the REACH regulation, where, in order to allow a chemical on the market, ‘safe use of chemicals’ needs to be demonstrated by registrants. This can be understood entirely from the sensitivities of the Van Straalen-Aldenberg convolution integral to uncertainties and variabilities of model parameters.

MO181

Assessment factor and SSD methods: which one provides more protective threshold for the ecosystem against adverse effects of toxicants?

K. Sorgog, National Institute of Advanced Industrial Science / Research Institute of Science for Safety and Sustainability; M. Kamo, Y. Iwasaki, National Institute of Advanced Industrial Science and Technology AIST Japan / Research Institute of Science for Safety and Sustainability; W. Naito, AIST Tsukuba West / Research Institute of Science for Safety and Sustainability

In general, a predicted no effect concentration (PNEC) is extrapolated by given information of toxicity tests in two ways: applying assessment factor (AF) and using species sensitivity distribution (SSD). AF-method is a conventional way which derives PNEC by dividing the lowest no observed effect concentration (NOEC) by AF. SSD-method, which is increasingly used in EU and USA, firstly estimates the mean and variance parameters based on given NOECs and derives PNEC by dividing a concentration leading to a protection of 95% biological species (HC5) by AF (1 - 5). To date, little is known about which one is more reliable to achieve a protection goal in ecological risk assessments. In this study, we compared which method could more likely to achieve the protection goal. We hypothetically assumed a toxicity distribution for species, and carried out random sampling from the distribution. This process corresponds to the toxicity tests supposing no toxic information about the species in advance, and the sampled values correspond to NOECs. The protection goal is defined as HC5 of the hypothetically assumed distribution. PNECs are determined by dividing the lowest NOEC by AF (fixed at 10 in our study) in AF-method. In SSD-method, HC5s are firstly estimated based on given randomly sampled NOECs and then divided by AF to derive PNEC. The AF is not a fixed value, but is contrived to vary depending on variations in species sensitivity. In both methods, determinations of PNECs are carried out for 10,000 times, and the occurrence of PNECs which are higher than HC5 (this corresponds to the failure of PNEC determination) is counted to compute the probability of failure to achieve the protection goal. In AF-method, the probability of failure is very low when the species sensitivity is low, but high when the sensitivity is high. Contrary, the probability of failure in SSD-methods is almost constant for any variations in sensitivity, and hence the probability of failure in SSD-method is higher than that in AF-method when variation in sensitivity is low, but is lower when the variation is higher. Our results imply that there are no silver bullets; one is superior than the other at a condition, but inferior in the other case. It should be recognized that the variance of the SSD is the key factor for the deriving PNEC.

Flooded Rice Pesticide Risk Assessment: the "orphan" cereal in current Guidance Documents

A. Caffi, ICPS International Centre for Pesticides and Health Risk Prevention / Public Health; F. Marchetto, ICPS / Public Health; S. Ubbiali, A. Riva, F. Galimberti, ICPS International Centre for Pesticides and Health Risk Prevention / Public Health

European Pesticide Registration requires a Risk Assessment for non-target organisms which has to be performed according to EU Regulation (Reg. 1107/2009 EC). Through the years European Authorities developed Guidance Documents (GD) for risk assessment considering exposure scenarios for the required organisms typical for terrestrial crops. GDs do not include scenarios for pesticide applications on rice: paddy is characterized by flooded cultivation conditions, typical of semi-aquatic environments and wetlands, representative of a unique exposure scenario, not comparable to the terrestrial ones. The current and available GD could be considered not adequate and sufficiently representative to describe and evaluate the risk in rice paddy during flooded periods. Aim of this work is to identify the main critical issues raising from the GD application for the mandatory categories of organisms: terrestrial vertebrates, aquatic organisms, non-target arthropods, soil organisms, non-target terrestrial plants. A selection of possible exposure scenarios will be suggested for each group of organisms to define an appropriate approach for the development of a reserved risk assessment for pesticide applications in rice cultivation.

MO184

Identification of terrestrial vertebrate species in rice paddy

F. Marchetto, ICPS / Public Health; A. Caffi, F. Galimberti, ICPS International Centre for Pesticides and Health Risk Prevention / Public Health; L. Bani, V. Orioli, Università degli Studi di Milano Bicocca

Pesticide registration in EU (Reg. 1107/2009 EC) requires appropriate risk assessment for non-target organisms including birds and mammals. The European Food Safety Authority developed a Guidance Document (GD) which doesn’t include scenarios for pesticide applications on rice; nowadays risk assessment is generally performed considering rice as the other cereals. Rice paddy is characterized by flooded cultivation conditions, typical of semi-aquatic environments and wetlands, representative of a specific exposure scenario. The avian and mammal community in rice area is composed by species and feeding guilds which are different from the one of a general cereal exposure scenario. The present work has considered the rice area growing in the North of Italy (Lombardy Region). For birds, data from monitoring program were processed through a Generalized Additive Model (GAM) to draw probability presence maps, while for mammals information related to species autoecology were used to draw suitability maps. The obtained maps were then integrated with land use maps to delineate the rice cultivation area (GIS approach). The aim of this work is to identify focal species, in relation to the specific feeding guilds, that will be proposed for the lower tiers of the ecotoxicological rice paddy Risk Assessment and suggested as potential model for the Southern European Zone involved in rice cultivation.

MO185

Comparison of endpoints from laboratory test and mesocosm studies for risk assessment of pesticides

H.S. Schuster, Cambridge Environmental Assessments (CEA) / Aquatic Ecotoxicology; M. Allen, Cambridge Environmental Assessments (CEA); A. Contreras-Garces, Cambridge Environmental Assessments / Aquatic Ecotoxicology; N. Taylor, Cambridge Environmental Assessments (CEA) / Ecotoxicology

For the aquatic risk assessment of plant protection products (PPPs) a tiered approach is used to estimate effects on non-target taxa in the natural environment. To extrapolate from single species laboratory studies (tier 1) to the effects expected in the 'real world', assessment factors (AF) are applied to the endpoints to achieve a regulatory acceptable concentration (RAC). In the regulatory framework more realism can be introduced by performing higher tier (tier 3) experiments, e.g. mesocosms are used as a proxy for natural surface water bodies. The tiered system is designed so that tier 1 is protective of tier 3, and by moving to higher tiers experiments progress from controlled systems in the laboratory to less controlled and realistic environments. This approach has been criticised as unrealistic at tier 1 and accompanied by high uncertainty at higher tiers and thus as either overprotective or not protective enough. The move from tier 1 to tier 3 can be viewed as an experimental extrapolation and the increased realism is reflected in the EFSA Aquatic Guidance by the use of lower AF's to calculate the ecological threshold option (ETO)-RAC. Here, we compare the endpoints derived from mesocosm studies to those determined in standard tests for the same compounds. Using this approach, we can not only assess if the tier 1 assessments are protective for aquatic ecosystems, but also explore how the introduction of dynamic and complex structures affect endpoints. To facilitate extrapolation (with the ultimate aim to extrapolate to the natural environment), we a) compare the RAC between the tiers by the means of case studies for insecticides, herbicides and fungicides; b) investigate similarities and differences of community responses within the groups of plant protection products; and c) explore future steps. The comparison of the RACs between tiers shows that laboratory study endpoints are more conservative than mesocosm endpoints, however, there is a risk that sensitive organisms are overlooked. Investigating community responses within each discussed PPP group shows that crustaceans are among the most sensitive species, and a decrease in crustaceans results in increases in competitive groups less affected by exposure. Knowledge of these community responses can help to inform models and extrapolate effects to the natural environment, but can also enable standard laboratory studies to be customised to be more relevant to the effects of certain compound groups.

MO186

Validation of a stream ecosystem model: Available data - challenges - future perspectives

K. Rakel, Research Institute gaiac / gaiac- Research Institute for Ecosystem Analysis und Assessment; S. Classen, Research Institute gaiac; K. Weiss, RWTH Aachen University / Institute for Environmental Research; M. Hammers-Wirtz, T. Strauss, Research Institute gaiac / gaiac - Research Institute for Ecosystem Analysis and Assessment

Ecosystem models are powerful tools for predicting species population dynamics for different environmental scenarios under consideration of natural and anthropogenic stressors. In developing such complex models, simplified assumptions have to be made about the relevant processes to be represented in the models. While effect models such as the TKTD model GUTS are at least conceptually easy to parametrize, it is much more effort to parameterize the sensitive ecosystem properties, such as e.g. the food availability for the various feeding types of macroinvertebrates. However, for all models it should be demonstrated that the model is able to reproduce relevant ecological scenarios with sufficiently high accuracy, what is known as "model testing" or "validation". Furthermore in this context it is of importance what type of data is available and of suitable quality for this step. One possibility is to explore macroinvertebrate dynamics over time which is available from monitoring data. In this study the concept of validation of an aquatic stream ecosystem model (STREAMcom) will be demonstrated. The STREAMcom simulates the population dynamics depending on spatial explicit habitat maps as well as temporal information on abiotic factors like temperature, food availability and chemical exposure. Additionally functional trait data bases, dynamic energy budget based population models and process based effect models are included in the STREAMcom model. The usability of available monitoring data for small streams as data set for validation of macroinvertebrate population dynamics in the model as well as associated challenges and future strategies for model applications will be discussed.

MO187

Predicting the sensitivity of invertebrate assemblages to toxic chemicals

T. Sinclair, University of Sheffield / Animal and Plant Sciences; P. Craig, Durham university / Mathematical Sciences; A. Boxall, University of York / Environment and Geography Department; R. Williams, Centre for Ecology & Hydrology Maclean Building; L. Maltby, The University of Sheffield / Dpt. of Animal & Plant Sciences

Biodiversity varies across natural ecosystems, with each being composed of different species assemblages. Yet current environmental risk assessments (ERAs) for chemical exposure are associated with two issues around predicting the sensitivity of natural ecosystems. Firstly, ERAs are generic, and a single regulatory acceptable concentration is utilised across Europe. This is irrespective of spatial variation in sensitivity that arises from differences in species composition. Secondly, standard laboratory toxicity tests for ERAs are only performed on a limited selection of standard test species. Consequently, the sensitivity for most species in natural ecosystems is also unknown. Combined, these issues mean that the spatial variation in predictions and the data with which to calculate such predictions are unknown. To address these issues, the hierarchical species sensitivity distribution (hSSD) approach has been taken to predict a toxicity threshold value. As the hSSD method predicts sensitivity for specified assemblages of species, varying assemblage composition can reflect different natural ecosystems. The hSSD method utilises phylogenetic relatedness and known toxicity data to predict toxicity to a chemical for each species of an assemblage, then integrates these predictions into species sensitivity distributions. The hSSD method was applied to a dataset of macroinvertebrate assemblages from 835 minimally impacted river sites across the UK to quantify variation in the hazard concentration affecting 5% of species (HC_5) derived from hSSD curves. Six chemicals of multiple types and modes of action were tested, including pesticides, down-the-drain chemicals and biocides. The predicted HC_5 values exhibited patterns based on different chemical types. Assemblage sensitivity was also related to the river typology of the sites. As the species present at each site depended on the river typology, the effects observed reflect the influence of species composition on assemblage sensitivity.

MO188

Relevance of systematically screening scientific literature for emerging contaminants - a case study in the Netherlands

I. van Driezum, National Institute for Public Health and the Environment (RIVM) / Centre for Sustainability, Environment and Health; J. Hartmann, Dutch National Institute for Public Health and the Environment / Centre for Sustainability, Environment and Health; S. Wuijts, National Institute for Public Health and the Environment RIVM / Centre for Sustainability, Environment and Health; B. Venhuis, RIVM; A. de Roda Husman, National Institute for Public Health and the Environment RIVM / Centre for Zoonoses and Environmental Microbiology; J. van der Hoek, Delft University of Technology / Water Management

Contaminants in the aquatic environment pose a potential threat to ecosystems and to humans, especially when water resources are used for drinking water production or recreation. Climatological, social and demographic changes as well as the increasing sensitivity of analytical techniques, will result in the augmented detection of contaminants. Thus, effective risk governance of contaminants in the aquatic environment is and will remain very important in order to protect human and environmental health. Here, emerging contaminants are defined as chemical contaminants that pose a new or increased threat to public health or the environment. In recent research, we have shown that the current risk governance of emerging contaminants in the aquatic environment could be improved by more timely identification of contaminants. Therefore, we propose a methodology using scientific literature text mining for picking up the first signal of the detection of a chemical contaminant in the aquatic environment. This first signal is a scientific article that reports the first identification of chemical contaminants in the aquatic environment. Once the first signals are determined, an assessment of the identified signals can be performed to elucidate the national relevance of the contaminant. A longlist of potential contaminants was screened using criteria such as 'source presence', 'persistence in the environment' and (when available) potential 'toxicity'. The resulting short-list was then distributed amongst Dutch authorities and drinking water companies in order to evaluate non-target screening data on the presence of these contaminants. Consequently, a monitoring study for the contaminants was carried out at relevant locations throughout the Netherlands. The locations were chosen taking into account for example specific usage information of the contaminant (e.g. for pharmaceuticals), potential production locations (e.g. for industrial contaminants), hydrological information of the receiving waters and the catchment and proximity to a drinking water intake point. In this study, an assessment of the national relevance of the results of an automated textual screening of the scientific literature was carried out for the Netherlands. The Dutch case study showed that systematic screening of the existing universal scientific literature and determining local relevance can give new insights into aquatic contaminants.

MO189

Putting the TKTD modelling Scientific Opinion of EFSA into practice – the GUTS model

L. Azevedo, BASF SE, Agrarzentrum Limburgerhof / Global Toxicology; S. Braaker, BASF France S.A.S.; P. Dohmen, BASF SE / Environmental and Consumer Safety, Ecotoxicology; P. Thorbek, BASF SE Limburgerhof

The European Food Safety Authority (EFSA) published a Scientific Opinion in toxicokinetic/toxicodynamic (TKTD) effect models for regulatory risk assessments for aquatic organisms in 2018. There, the EFSA Panel on Plant Protection Products and their Residues (PPR) scientific committee concluded that a TKTD model for survival (i.e., the General Unified Threshold models of Survival – GUTS) is ready for use. This is a major step for the regulatory community since it provides clear guidance how to apply as well as for how to evaluate TKTD models for the registration of chemicals in Europe. Furthermore, this Scientific Opinion identifies existing gaps and further regulatory and research needs in existing TKTD models. Although the Scientific Opinion was devoted to the aquatic environment, the linking of GUTS to other areas of the risk assessment is possible. Here we present a case study employing GUTS for assessing the toxicity of a fungicide on honeybees. The objective of this presentation is to identify the expected deviations from the guiding principles of the EFSA Opinion if GUTS is used for honeybees. These deviations will be discussed with respect to the robustness and reliability of GUTS beyond aquatic risk assessment.

MO190

Comparison of Ecotoxicological Endpoints: National Risk Assessments versus Commercially Available Databases

R. Gauch, M. Mathis, Agroscope; A. Aldrich, Agroscope / Ecotoxicology; L. de Baan, Agroscope / Institute for Plant Production Sciences IPS

To calculate indicators of environmental risks for multiple co-occurring pesticides at landscape scales, researchers mostly rely on commercially available databases, which give information on ecotoxicological endpoints. A full coverage of all pesticides and the comparability of study types is important to get suitable endpoints for the task. Databases such as the Pesticide Properties Database (PPDB) are helpful in this context. Using the PPDB for our own purposes, we occasionally came across differences between endpoints from this database and those used for registration of plant protection products by Swiss national authorities. To better understand these differences, a comparison between the endpoints reported in the PPDB and the endpoints used for the registration of plant protection products was conducted. In the majority of cases the endpoints were similar. However, in some cases significant differences even by more than a factor of 10'000 were found. Possible reasons behind largely differing endpoints were investigated and endpoints to be used for risk indicators for co-occurring pesticides are suggested. The comparison illustrates the importance of challenging endpoints provided by databases, and integrating the experience and knowledge of national authorities on single active ingredients to improve indicators of environmental risks.

Criteria and Methods for Identifying Chemicals of Greatest Concern (P)

TOXMIC: TOXicants monitoring chamber for MICrocontaminants

R. Carafa, TECNATOX, URV / AGA; J. Sierra, University of Barcelona / Faculty of Pharmacy, Soil Science Unit; N. Exposito, URV, Tecnatox group; A. Munné, Catalan Water Agency ACA; T. Galle, Luxembourg Institute of Science and Technology; M. Schmitt-Jansen, Helmholz Centre for Environmental Research-UFZ / Bioanalytical Ecotoxicology; M. Schuhmacher, Universitat Rovira i Virgili / Chemical Engineering

There is no doubt that water is a necessary resource for life and that human activity depends on water quality and availability. In spite of the efforts made in the last decades for improving waste water treatment and for the implementation of the Water Framework Directive, water pollution is still a main cause of water quality deterioration. Ecological quality standards for single substances and for mixtures have been established but uncontrolled release of chemicals in waters will continue until the water diagnosis capacity will be incremented. In particular, in EU about 71000 Waste Water Treatment Plant outflows need to be constantly checked, especially during water scarcity periods and the traditional monitoring, based on grab samples, is not economically affordable. The aim of TOXMIC project is to deliver an innovative low-cost in-situ monitoring device able to check in continuous water quality of rivers and capable of being widely taken up by WWTPs and water agencies, ensuring in this way a positive impact on the ecosystem and human health and on business growth. The monitoring chamber has been developed in laboratory and tested in selected sites in Catalan rivers in collaboration with the Catalan water Agency. The chamber combines two existing techniques with an innovative integrated sensor: 1. Passive sampling Polar Organic Chemical Integrative Samplers POCIS, for polar organic compounds, and Diffusive Gradient in Thin film DGT, for trace metals; 2. Pulse-amplitude modulated PAM fluorometry applied to river biofilm structural and functional indicators; 3. Micro-PAM sensor for data transmission in continuous. A local reference is obtained with a reference chamber where river water is filtered by charcoal. The link between contaminants and effects on biofilm is analysed using advanced modelling techniques (mixture effects models and classification tools).

MO192

Do we need new chemical assessment criteria? - Consideration of the recent proposal for application of persistent, mobile and toxic (PMT) criteria.

P.C. DeLeo, Integral Consulting Inc.; S. Hartigan, American Chemistry Council / Regulatory and Technical Affairs

Recently, there have been discussions surrounding new screening criteria based on a chemical having inherent properties of being persistent, mobile and toxic (PMT) or very persistent and very mobile (vPvM). The European Chemicals Agency (ECHA) has also received a proposal to identify a potential Substance of Very High Concern (SVHC) under its regulation concerning the Registration, Evaluation, Authorisation and Restriction of Chemicals (REACH) based on being vPvM, which was purported to be of an equivalent level of concern to already established criteria for persistent, bioaccumulative and toxic (PBT) substances, and very persistent and very bioaccumulative (vPvB) substances. The purpose of the proposed assessment criteria was the protection of drinking water sources. The utility of a new set of assessment criteria for identifying chemicals of greatest concern was examined in the context of existing chemical management regulations in Europe and North America. In addition, the historical development of assessment criteria was considered particularly with regard to the assessment tools at the disposal of regulatory authorities in those geographies at the time of their development. Finally, given the demands on both regulators and the regulated community in the implementation of a new set of assessment criteria, recommendations are provided regarding appropriate steps for its proper evaluation. \n

MO193

Version 2.0 of the Ecological Risk Classification (ERC) Approach for Prioritizing Organic Chemicals in Canada

M.A. Bonnell, C. Inglis, M. Jagla, J. Prindiville, B. Shore, Environment and Climate Change Canada / Ecological Assessment Division

In 2016 Environment and Climate Change Canada (ECCC) published the Ecological Risk Classification (ERC), a computational approach used to re-prioritize 640 organic chemicals originally prioritized in 2006 as persistent or bioaccumulative and inherently toxic. The ERC is a risk-based approach developed to optimize the use of new approach methods (NAMs) in ecotoxicology and novel exposure descriptors for chemical prioritization. The second version of the ERC (ERC2) is under development by ECCC for the prioritization of approximately 12200 organic chemicals on the DSL not prioritized in 2006 as BT or PT chemicals. It will provide ECCC with one approach (substance-by-substance) for determining chemicals of most concern for post 2020 chemical's management work planning. The ERC approaches establish chemical profiles for hazard and exposure. Each profile contains several descriptors that define both the toxicological and exposure spaces used for classification. Logic rules developed for these spaces classify organic chemicals for hazard, exposure and ultimately risk at three levels. Overall risk is determined using a matrix approach. As with ERC1, ERC2 remains an evidence driven rule-based prioritization system, but expands on the toxicological and exposures space from ERC1. ERC2 also addresses key areas of uncertainty identified in ERC1 by better accounting for model domain of applicability and improving on the *consensus* within and among*in silico, in chemico, in vitro, in vivo and in situ* data to classify hazard, exposure and risk. ERC2 also provides an assessment of confidence at all levels of data and for final, hazard, exposure and risk classification based on the degree of data consensus. ERC2 also employs the AOP concept to organize hazard data to provide plausible causal relationships that link chemistry with biology (i.e., mechanistic reasoning for adverse outcomes). Biological read-across is used to incorporate data from laboratory mammalian studies and models given the high degree of conservation of pathways across species. In addition to risk classification of 12200 organic substances, ERC2 will also provide ECCC with data to respond to various regulatory questions such as identification of potential endocrine active substances, regrettable alternatives, high hazard or exposure concerns, potential research and monitoring priorities, etc.).

MO194

The new Microimpedance Sensor System© (MSS) for online biosensing of water quality with microcrustaceans

A. Gerhardt, LimCo International GmbH

Online biomonitors can be interpreted as whole organism biosensors: a sensitive behavioural or physiological response of a sentinel species is used as biological warning system for pollution stress. Continuous biological monitoring of the toxic potential generated by pollutant cocktails in surface waters is already established, e.g. along large transboundary rivers in Europe. Frequently used animal test species for online biosensing have been *D. magna*, mussels and *Gammarus* spp. Based on the Multispecies Freshwater Biomonitor© (MFB) for animal sizes of > 5 mm, we developed the Microimpedance Sensor System© (MSS) to continuously record the quantitative behavioural pattern of small crustaceans and young life stages of epigean and hypogean invertebrates (size ca. 1 mm). These tiny organisms are often additionally transparent, hence difficult to observe with optical tools. Interstitial and sub-surface habitats are inhabitated predominantly by small organisms, such as copepods. These species have a high potential as toxicological test species and online biomonitors of groundwater and drinking water, provided they are more sensitive, easier to handle and generate longer stand-alone times of online biomonitors, to sense also chronic pollutant stress. The MSS has successfully been tested and calibrated with *Eucyclops serrulatus* (Copepoda). *E. serrulatus* detected acute pulses of copper and nitrate. Ease of culture and handling additionally opt for *E. serrulatus* as new indicator in biomonitors.

MO195

WATER TREATMENT PROCESSES AND THE POTENTIAL FOR SUBSTANCES OF CONCERN TO ARISE FROM CROP PRODUCTION PRODUCTS

D. Howes, Envigo Consulting Limited / Envigo Consulting Limited

In 2015, a new requirement was introduced for active substance submissions (including submissions for renewal) in the EU to consider the effect of water treatment processes on pesticides in drinking water. The requirement forms part of the approval criteria for active substances as detailed in Article 4.3(b) of Regulation (EC) No 1107/2009 where they: *...shall have no harmful effect on human health, or animal health, directly or through drinking water (taking into account substances resulting from water treatment), food, feed or air, or consequences in the workplace or through other indirect effects, or on groundwater.* In the absence of any guidance, or indeed information on the actual water treatment processes to be considered, this review provides an overview of current water treatment technologies, the principles behind them and the common side reactions often encountered. This information is then used to suggest potential unwanted harmful by-products that could arise from purification of abstracted water containing pesticide residues. Finally, previous submissions are evaluated to see how applicants have approached Article 4.3(b) to date, and whether or not a consistent approach has been adopted.

MO196

Comparing Mode of Action (MoA) classification using body residues, membrane concentrations and chemical activity for chemical prioritization

J.M. Armitage, AES Armitage Environmental Sciences, Inc / Physical and Environmental Sciences; J.A. Arnot, ARC Arnot Research & Consulting / Adjunct Professor, Department of Physical & Environmental Science/Department of Pharmacology and Toxicology; M.A. Bonnell, Environment and Climate Change Canada / Ecological Assessment Division

In 2016, Environment and Climate Change Canada (ECCC) released the first version of an IATA-like Ecological Risk Classification system (ERC1) for prioritizing the organic substances on the Canadian Domestic Substances List (DSL) remaining to be assessed before 2020. One of the key considerations for assessing toxicity in ERC1 is a Mode of Action (MoA) classification which aims to distinguish between baseline toxicants ("narcotics") and specifically-acting toxicants in a given test organism/receptor. As part of the MoA classification for aquatic organisms (fish), ERC1 used an estimate of the Critical Body Residue (CBR) corresponding to an empirical or QSAR-based lethal concentration (LC50). Two alternative/complementary metrics for MoA classification that have been advanced recently are i) Critical Membrane Concentration (CMC) and ii) (lethal) chemical activity (La50). At the screening level, the CBR, CMC and La50 approaches rely on different physical-chemical properties to "translate" the LC50, namely octanol-water partitioning (K_{OW}), membrane-water partitioning (K_{MW}) and water solubility respectively. The main objective of this study was to generate CBRs, CMCs and La50s for a set of 929 neutral organic chemicals with empirical LC50 data and compare the MoA classifications across the three metrics and to the MOA classification based on another approach applied in ERC1 (structural alerts). Complete agreement in the screening level MoA classification using CBR, CMC and La50 was observed for 719 of 929 chemicals (599 baseline toxicants, 120 specifically-acting). Complete agreement in the screening level MoA classification using CBR, CMC, La50 and structural alerts was observed for 585 of 929 chemicals (522 baseline toxicants, 63 specifically-acting). Explanations for the apparent discrepancies include uncertainties in property measurements/estimates, problematic toxicity data (e.g., LC50s greater than water solubility) and the domains of applicability for all approaches (including MoAs based on structural alerts). The findings of this exercise will be used to inform version 2.0 of the ERC, which is being developed as one approach to determine chemical priorities for post 2020 chemicals management in Canada.

MO197

Biological module bioluminescent biosensor for environmental risk assessment

I.G. Torgashina, Siberian Federal University / Biophysics; E. Esimbekova, Institute of Biophysics SB RAS; V. Kratasyuk, Siberian Federal University / Biophysical

Bioluminescent enzyme systems based on bacterial luciferases offer a unique and general tool for assays of the many analytes in the environment, research and clinical laboratories and other fields. The goal of the study is to develop a biological module bioluminescent biosensor based on bioluminescent enzyme systems for environmental risk assessment provided an alarm detection and quantitative measurement of integral toxicity levels caused by chemical threats. The biological module for the enzyme-based biosensors includes co-immobilized into dried starch gel bacterial coupled enzymatic system: NADH:FMN-oxidoreductase and luciferase and their substrates (mirystic aldehyde and NADH). The bioluminescent biosensor controls the effect of the sum of toxicants. It was shown that starch gel has some stabilizing effect on the enzymes of bioluminescent bacteria. The biomodule maintains the high enzymatic activity in a wide range of temperatures, pH and ion concentration. The effect of toxicants (phenols, quinones and heavy metal salts) on immobilized coupled enzyme system NADH:FMN-oxidoreductase – luciferase has been analyzed. We determined I?$_{50}$constituted 50 % of the loss of biomodule's luminescence for each of the analyzed substances. Biomodule has been shown to be more sensitive to quinones. The sensitivity of detection for naphtoquinone, benzoquinone, tolyquinone and timoquinone were less than their maximum permissible concentration.There is a good correlation between the results obtained and chemical analyses of the industrial waste waters of pulp-and-paper plant (Krasnoyarsk, Russia). Thus, co-immobilized bacterial coupled enzymatic system: NADH:FMN-oxidoreductase and luciferase and their substrates into starch gel is stable and sensitive. Bioluminescent assays based on co-immobilized bacterial coupled enzymatic system are fast (analysis time is 2-6 minutes), simple, sensitive, and accurate. The immobilized bacterial coupled enzymatic system may be use as biological module bioluminescent biosensor for environmental risk assessment was shown. The reported study was funded by Russian Foundation for Basic Research, Government of Krasnoyarsk Territory, Krasnoyarsk Regional Fund of Science, to the research project No 18-44-242003.

Detection and killing of Staphylococcus aureus by specific peptides-conjugated-vacuoles in yeast

N. Nguyen, Chonbuk National University / Bioprocess Engineering; B. Kim, Chonbuk National University / Graduate School of Semiconductor and Chemical Engineering; J. Lee, Graduate school of Semiconductor and Chemical Engineering; Y. Kim, Chungbuk National University / Department of Microbiology; J. Min, Chonbuk National University / Department of Bioprocess Engineering

Staphylococcus aureus is a major human pathogen causing healthcare-associated and communitu-associated infections. In this study, we provided a novel system that is available to detect and kill *S. aureus* specifically based on the conjugation of phage display library technique and yeast vacuoles. Here, a phage clone displaying peptide able of specific binding to *S. aureus* whole cell was selected from a 12mer phage peptide library (peptide sequence: AAHRVGGFNYHM). The ability of selected phage to bind specifically with *S. aureus* was confirmed by using enzyme linked immuno assay (ELISA), and then the chosen peptide was synthesized and conjugated with the Dynabeads M-270 Carboxylic acid to demonstrate its specific binding ability with *S. aureus*. The results showed that the synthesized peptides displayed high affinity with *S. aureus* but low binding ability with other strains including gram negative and positive bacteria, such as *Salmonella* sp., *Shigella* sp., *Escherichia col*i and *Corynebacterium glutamicum*. After that, the peptide was conjugated with our yeast vacuoles, which was proved in previous studies that possess antimicrobial activity. Finally, the novel system containing specific peptides for *S. aureus* and yeast vacuoles showed the high ability to recognize and kill *S. aureus*. This work was carried out with the support of "Cooperative Research Program for Agriculture Science & Technology Development (Project No:PJ01267701)' Rural Development Administration, Republic of Korea.

MO199

An Analytical Method for Screening and Quantification of Pyrrolizidine Alkaloids-Natural Toxins in Surface Water

J. Hama, University of Copenhagen / Department of Plant and Environmental Sciences; B.W. Strobel, University of Copenhagen / Plant and Environmental Sciences

Phytotoxins are natural toxins produced by plants, and they have been produced and loaded into environment in high doses. They are not distinguished as contaminants of possible concern for environment and water. Thus, environmental fate and content of such natural toxins are largely unknown. The purpose of this study to show an analytical method to screen and quantify Pyrrolizidine Alkaloids (PAs) in water and environmental samples, without requiring all corresponding standards. PAs were found in many plant species of families: Asteraceae, Boraginaceae and Fabaceae. Until now, more than 660 PAs have been found in nature. UPLC- MS/MS method developed by a Waters Acquity UPLC I-Class module, equipped with a 2.1 × 50 mm, 1.6 µm Cortecs C18 column (Waters, Milford). MS was operated on a Waters Xevo TQD MS with positive ion mode. In the method, LC mobile phase was composed of A (water + 0.01% FA) and B (acetonitrile + 0.01% FA). Gradient conditions were: 0−4 min 10% B, 7 min 20% B, 10 min 50% B, 15 min 90% B, 15−17 min 90% B. The column was equilibrated for 6 min, and the total run time is 23 min. The flow rate was 0.45 mL/min. The method is quick, robust and validated for quantification of PAs in wide range complex matrixes and environmental samples such as plant, soil and water. The fragmentation pattern of PAs used in the method to characterize product ion: for retronecine and heliotridine types *m/z* 138.09 and 120.08 and for otonecine types *m/z* 168.10 and 150.09 are selected and characterized. The LoD ranged 2-6 μg/L. For application of the method, a surface water close to Ragwort (Plant as a source of PAs) catchment in Vejle-Denmark sampled, as a result 10 toxic PAs analysed in a surface water with a concertation up to 500 μg/L. This research project is part of European Training Network–NaToxAq, which has received funding from the European Union's Horizon 2020 research and innovation programme under the Marie Sklodowska-Curie grant agreement No.722493(NaToxAq).

An approach to systematically evaluate and utilize Molecular Initiating Events (MIE) for chemical classification

M. Sapounidou, M.T. Cronin, J. Madden, Liverpool John Moores University / Pharmacy and Biomolecular Sciences; S. Gutsell, Unilever / SEAC; G. Hodges, Unilever Research / Safety and Environmental Assurance Centre

Mode of Action (MoA) determination is an important part of understanding toxicity to aquatic organisms in the context of risk assessment and as part of regulatory schemes to enable read-across, chemical categorisation and prioritisation. With a lack of harmonisation of current chemical -fragment based approaches to be able to adequately classify the full commercial chemical space coupled with a shift towards mechanistic based approaches, there is a need to better define classification approaches. The Adverse Outcome Pathway (AOP) concept has gained significant traction as a means to interpret apical toxicity endpoints mechanistically. An AOP is a systematic approach that links molecular and biochemical interactions to individual or population responses and thus provides an opportunity to base classification schemes around this framework. A first key component in AOPs is the Molecular Initiating Event (MIE), where both chemistry and biology are integral components. There is a recognised need to evaluate the confidence of all parts of the AOP notably the MIE, Key Events (KEs) and Key Event Relationships (KERs); whilst schemes are in place, for KEs and KERs, they have not been applied to MIEs. The aim of this study was to develop a scheme for classifying chemicals in MIEs relevant to aquatic toxicity. Prior to collation of MIEs a framework was established to evaluate the 'quality' of MIEs in terms of the underlying evidence. Information on structural qualities of the MIE target; the interaction; associated chemistry; taxonomic applicability; along with the sources and the type of data (e.g. in silico, in vivo, in vitro) corresponding to MIE/MIE target of interest were documented, leading to 78 identified MIE and MIE targets. The MIEs were organised in 3 classes based on the type of interaction. This facilitated the utilisation of the chemical domain of MIE/MIE targets as building units for the chemical space per class. The chemical structural criteria for class assignment along with transparency in taxonomic applicability, data source and quality, were coded in a KNIME workflow. This approach provides the user with an informed MIE prediction that can be potentially used in the application of the AOPs to better understand chemical classification and to predict toxicity across aquatic species.

MO201

Cytotoxicity assessment of the emissions to indoor air of a CdTe quantum dot based fluorescent ink

M. BLAZQUEZ, INKOA SISTEMAS / RTD; I. Nelissen, VITO NV / Health; E. Frijns, Flemish Institute for Technological Research VITO; J. Van Laer, J. An, VITO; E. Fernández-Rosas, A. Vilchez, V. Pomar-Portillo, D. González-Gálvez, LEITAT; A. Antipov, PLASMACHEM; S. Vázquez-Campos, LEITAT / Human & Environmental Health & Safety

The fluorescent properties of CdTe quantum dots (QDs) have led to novel products and applications in the ink and pigment industry. From a life cycle perspective, the toxic effects of the emissions to indoor air associated to printing ink during the use phase might differ from those of conventional formulations which do not integrate engineered nanomaterials as CdTe QDs might be emitted. Such chemicals can, thus, be regarded as emerging contaminants for which several authors have reported toxicological effects^[1],^[2]. Within this work, a water soluble fluorescent ink containing polyethyleneglycol-coated Cadmiun Telluride (PEG-CdTe) QDs (3.2 nm, 3.6 nm with coating) at a theoretical concentration of 8 mg/mL has been selected. Such ink is a prototype of a Nano enabled Product (NEP) that has been formulated to be used in household printers. Emissions of the printing process have been characterized under different simulation scenarios. Subsequently, released particles have been evaluated in terms of their cytotoxicological potential in contrast to the solvent ink. The pulmonary cell line BEAS-2B has been selected both for *in vitro* air-liquid interface cell exposure and in submerged conditions. Preliminary results indicate that the Cd2+ concentration determines the toxicity observed.

Using the Multispecies Freshwater Biomonitor to assess the potential impact of the antidepressant Venlafaxine on the amphipod Gammarus pulex

G. Consolandi, University of Portsmouth; A. Ford, University of Portsmouth / Biological Sciences; A. Gerhardt, LimCo International GmbH; M. Bloor, University of Portsmouth / School of Earth and Environmental Science

The Serotonin and Norepinephrine Reuptake Inhibitor (SNRI) Venlafaxine (VEN) is an antidepressant that is often prescribed to treat depression and anxiety. VEN has been frequently detected in aquatic environments where its possible effects are still widely unknown. The aim of this study was to investigate the potential impact of VEN at environmentally realistic concentrations (20 ngl^{-1}, 2 μgl^{-1} and 20 μgl^{-1}) and identify if it effects the behaviour of the freshwater amphipod *Gammarus pulex*. River water and specimens of *Gammarus pulex* were collected from a non-polluted stream in Allensbach, Germany (47°42'27.6'' N, 9°06'26.5''E) during September 2017. The organisms were acclimated for 14 days at 18°C in aerated stream water in the dark. *Gammarus pulex* were provided with *Alnus glutinosa* leaves. In order to test the effects of the antidepressant VEN a serial exposure was undertaken. Specimens of *Gammarus pulex* (n=30) were used for each concentration (20 ngl^{-1}, 2 mgl^{-1} and 20 mgl^{-1}) and a control. 5 x 250 ml glass beakers were filled with 100 ml of each VEN concentration. 6 *Gammarus pulex* were put into each beaker with a 3 cm Ø *Alnus glutinosa* leaf disc. Behavioural analyses were carried out using the Multispecies Freshwater Biomonitor (MFB).The MFB is a device that tracks and records the behavioural activity of different aquatic organisms through a quadruple impedance conversion technique. Each organism was placed in a small plastic chamber in a 4 L aquarium. The presence of electrodes inside the chamber enables an organism's movement to be recorded as a change in the electrical field. A movement generates specific frequencies which in the case of *Gammarus pulex* are from 0.5 to 2.5 Hz. *Gammarus pulex* swimming behaviour was recorded 5 times over a period of 12 days. The data was analysed with a general linear effects model and it was found that there was a significant difference in their behaviour over time (F=4.107; p=0.004) and that there was a significant different in their behaviour between treatments (F=4.364; p=0.006), but there was no interaction between treatments and time (F=1.092; p=0.372). Pairwise comparisons showed a significant difference between the lowest concentration (20 ngl^{-1}) and the control (p=0.011) and the median concentration (2 μgl^{-1}),(p=0.012). Overall, VEN does have an impact on the behaviour of *Gammarus pulex,* but this effects is not related to time.

MO203

Identification of novel PMT compounds of potential concern to water resources - The case of natural plant toxins

B. Soerensen, Helmholtz centre for environmental research - UFZ / Effect-Directed Analysis; D. Kühnel, Helmholtz-Centre for Environmental Research - UFZ / Bioanalytical Ecotoxicology; M. Krauss, W. Brack, Helmholtz Centre for Environmental Research UFZ / Effect-Directed Analysis

Recent work has highlighted the potential risk of persistent, mobile and toxic (PMT) compounds to water resources, including drinking water. Focus is often on anthropogenic pollutants, however a large number of natural toxins, produced by plants as e.g. defense compounds against herbivores and microbes, have similar properties in terms of mobility, persistency and toxicity. Plants occur abundantly in the environment and thus even small amounts released per plant, continuously or in high rainfall events, may become substantial overall. The present project, part of the European Union ETN network 'Natural Toxins and Drinking water Quality - From Source to Tap', focuses on the identification of novel natural toxins that could leach from source (plant) to tap, and cause detrimental effects in the aquatic environment in between. In this study, we sampled 20 invasive plant species based on four non-exclusive criteria – local abundance, high distribution, proximity to water resources and likelihood of toxin content – and employed effect-directed analysis (EDA) in order to identify novel toxins of concern. Secondary metabolites were extracted with water and dosed on *Daphnia magna* as a model organism for acute toxicity and neurotoxicity. Fractionation (reverse-phase HPLC) was performed on extracts with high effect levels, and current activities focus on the identification of causative compounds in active fractions (LC-HRMS).

MO204

The FET and behavioral assays under flow-through conditions - evaluation of a biowellplate utilizing zebrafish embryos

C. Neuser, Institute of Environmental Research-RWTH Aachen / Department of Ecosystem Analysis ESA; L. Nuesser, RWTH Aachen University, Institute for Environmental Research / Department of Ecosystem Analysis; E.M. Wielhouwer, Syntecnos Screening Technologies BV; T. Kouts, Tallinn University of Technology Tartu College; H. Hollert, RWTH Aachen University / Institute for Environmental Research; T. Seiler, RWTH Aachen University / Ecosystem Analysis

Whole-organism bioassays, such as the fish embryo toxicity test (FET), are often applied in biological, biomedical and ecotoxicological research. However, they are mostly performed within discontinuous conditions i.e. static or semi-static exposure regimes in small units, such as multiwell plates for prolonged incubation periods. In order to improve exposure conditions of whole-organism bioassays, we tested the performance of a biowell plate-prototype (BWP) designed for the exposure of organisms within flow-through conditions. The aim was to provide a testing system that reduces labour intensity, invasiveness to the tested organisms caused by manual exchange of the exposure medium and that improves the stability of the concentration of the tested chemical in the exposure medium as well as the oxygen concentration by a continuous flow. The prototype provides a constant exchange of the exposure medium combined with a controlled temperature within the 8 wells which have dimensions comparable to those of a 96-well plate. Prolonged FETs until 96 hours post fertilisation (hpf) utilizing zebrafish embryos (*Danio rerio*) were conducted in order to assess the general performance of the BWP and the influence of the flow-through conditions on the stability of exposure concentrations and consequential the determined effect concentrations for a set of model compounds (cadmium dichloride, ethanol, permethrin, sodium hypochlorite). Implications for testing strategies of single substances in whole organism-bioassays will be discussed. Monitoring of zebrafish embryo behaviour emerges as new, sensitive method to study adverse effects of compounds. We propose to use behavioral changes of zebrafish embryos for the detection of sudden contamination events in a water stream. The applicability of the BWP as a biosensor in environmental monitoring was evaluated utilizing assays that examine the behavioural reaction of hatched embryos (96 hpf) towards acute exposure to different compounds relevant for surface waters. In this study, the zebrafish embryos were incubated in the BWP in formulated water under flow-through conditions until 4 dpf. Subsequently, they were exposed to a set of model compounds in low concentration ranges and monitored for avoidance behaviour which results in an increased activity. This first proof of concept study evaluated the general performance of the BWP in the FET and the potential application as biosensor in environmental monitoring.

MO205

Toxicological Council and SamTox - A Swedish initiative to establish an organisation of an early warning system in order to identify new, potential chemical threats

L. Wendt-Rasch, E. Westerholm, B. Lund, Swedish Chemicals Agency

In order to improve the coordination between national authorities, in 2016 the Swedish government decided to establish a coordination group to deal with new and emerging chemical threats (SamTox). The Toxicological Council was formed in order to improve the systematic monitoring and use of scientific information and to provide updated and relevant information to SamTox. The Council includes representatives from Swedish governmental authorities and universities. The Toxicological Council identifies and evaluates signals of new, potential and emerging chemical risks and reports its findings to SamTox. The purpose of this organisation is to ensure a structure for the rapid and systematic transfer of information and knowledge between responsible authorities and other actors, as well as cooperation in the event of the detection of a serious chemical threat. In order to develop a methodology for the joint evaluation of signals aimed at identifying potential NERCs (New Environmental Risk Chemicals) or insufficiently managed chemical risks, three areas in which multiple signals had been compiled were selected for additional work from 2017–2018. After gathering additional data, the Toxicological Council decided to raise two areas of concern with SamTox. The first, PFAS accumulating in landfills potentially resulting in a (future) source of contamination can be regarded as a potential NERC based on new information becoming available. The second, non-decreasing exposure levels of cadmium in the general population can be regarded as a known but insufficiently managed chemical risk. The Toxicological council has established a successful working procedure in order to identify NERCs. However, identifying new potential chemicals threats require more cooperation and exchange of information at the EU level and internationally. The presentation is a step to initiate such cooperation.

Difficult to Test Substances and Wastes: Regulatory Status, Testing Challenges, Interpretation of Data and Fulfilling Information Requirements (P)

MO206

Testing poorly water-soluble test chemicals according to the updated OECD Guidance Document 23 on aqueous-phase aquatic toxicity testing of difficult test chemicals

C. Fassbender, G. Stoddart, PETA International Science Consortium Ltd.; M. Halder, European Commission Joint Research Centre / DG Joint Research Centre IHCP EURL ECVAM; E. Salinas, BASF SE / Eperimental Toxicology and Ecology; A. Wigh, BASF SE / Experimental Ecotoxicology; W.S. Hunter, U.S. Food and Drug Administration / Center for Veterinary Medicine

Aquatic toxicity testing of poorly water soluble test chemicals presents unique challenges as it may be difficult to create dosing solutions and to maintain constant aqueous concentrations of these chemicals in exposure systems. Solvents are sometimes employed to facilitate dissolution of poorly water soluble test chemicals; however, the use of solvents may have an impact on the study results, particularly in chronic studies. Furthermore, the use of solvents increases the number of animals used per test by up to 14-25% depending on the study, because an additional solvent control group is recommended by the Test Guidelines. For these reasons, efforts are made to avoid the use of solvents in aquatic toxicity tests wherever possible. In recent years, new methods have become available for aquatic toxicity testing of chemicals considered to be difficult-to-test, including poorly/sparingly water-soluble. Therefore, through the Organisation for Economic Cooperation and Development (OECD) Test Guidelines Programme, the European Commission, United States, and the International Council on Animal Protection in OECD Programmes worked with leading experts to update OECD Guidance Document (GD) 23 on aqueous-phase aquatic toxicity testing of difficult test chemicals. The GD was expanded to discuss the state-of-the science approaches for testing a broad range of difficult-to-test test chemicals including poorly/sparingly water-soluble chemicals and was adopted in 2018. This poster describes state-of-the-art approaches for testing poorly or sparingly water-soluble chemicals including additional guidance on creating exposure systems using direct addition, the use of generator systems including saturator columns and passive dosing as well as flow-through exposure systems. For illustration, this poster compares water solubility and saturation concentrations in different media from studies run using saturation columns, liquid-liquid saturators, solid-liquid saturators, and passive dosing. The updated GD 23 will help government agencies, industry, and contract research organisations to conduct valid and reliable aquatic toxicity studies on difficult-to-test chemicals while minimising both the number of animals used and the need to repeat studies. *The views, conclusions and recommendations are those of the authors and do not necessarily represent the policies or positions of the organisations to which the authors are affiliated.*

MO207

Help, we've measured the wrong active!

M. Reed, HSE; M. Clook, HSE Health and Safety Executive / Chemicals Regulation Directorate; C. Taylor, C. Elphick, HSE Health and Safety Executive; L. Samuel, CRD, HSE; M. Fryer, HSE Health and Safety Executive

When testing mixed active substance plant protection products in aquatic toxicity studies at least one active substance needs to be measured in order to confirm dosing. Often only one of the active substances has been measured which can make it difficult or impossible to use the study in an aquatic risk assessment according to EFSA (2013). In order to conduct a mixture assessment it is first necessary to determine whether the plant protection product is higher, lower or of similar toxicity than would be predicted by the active substances based on additive toxicity. This is done by calculating the model deviation ratio (MDR) using the calculated and measured toxicity. In order to do this it is important that the product and active substance studies are equivalent, which means the concentrations in the studies should be known or at least confidently predicted. When an active substance is known to be stable in water, confirming the targeted concentration was achieved might be enough for this, but where it is unstable it is necessary to have measurements of that active substance over time. This poster explores what can be done in a variety of situations if all active substances in a formulation study have not been measured at least at the beginning and end of the study. There is a particular focus on fish because of the need to avoid additional vertebrate testing unless it is essential. A risk assessment method is presented where only initial measurements are available and the study is on fish, to allow the use of an old study that doesn't meet modern requirements for test substance analysis. Proposals are also made for deciding which active substance is more important to be measured if only one has been and how these endpoints can potentially be used in the risk assessment. The decision scheme presented can be used both by people conducting studies to help them decide whether all active substances need to be measured and by regulatory authorities when deciding if and how a study can be used for the risk assessment.

MO208

How to assess the aquatic toxicity of cationic polymers?

A. Brun, Aarhus University, Department of Environmental Science / Environmental Science; H. Sanderson, Aarhus University; S.E. Belanger, Procter & Gamble Company / Global Product Stewardship; J. Rawlings, The Procter Gamble Company / Global Product Stewardship; J. Brill, Procter & Gamble Company / Environmental Stewardship and Sustainability; M. Lam, Procter & Gamble Company / Global Product Stewardship; K.A. Connors, Procter & Gamble Company / Environmental Stewardship and Sustainability Organization

Cationic polymers are widely used across the world. They are large, charged surface-active compounds and since they are polymers they are currently exempt from the REACH-framework. The exemption is based on the assumption that polymers due to their large size will be toxic and thereby not pose any risk to the aquatic environment. However, reduced registration requirements for polymers may lack scientific justification. Scientifically-based methods to support assessments and registration will need to be established in the future for these compounds. Cationic polymers bind to negatively charged surfaces, such as the surface of an organism or certain forms of aquatic organic substances. The bound complex may not cause direct toxicity but can indirectly harm or impair aquatic organisms. This mode of "toxicity" challenges our understanding of what causes toxicity and how we describe, test and model environmental interactions. When dealing with cationic polymers known effect-predictors as hydrophobicity may not describe physical-chemical influences on toxicity. Instead, alternative physicochemical properties as charge-density, molecular weight, polydispersity and viscosity may be more suitable to predict effects. This research will investigate how to describe and assess the aquatic toxicity of cationic polymers in a realistic way that would assist future aquatic environmental risk assessment (ERA) of these compounds. Our initial focus is on four model cationic polymers that are selected due to their representative differences in physicochemical properties: Polyquaternium-6, -7, -10 and -16. We will present our plan for this CEFIC LRI project, as well as our current findings: main points from a literature review and screening results of the acute aquatic toxicity of algae, daphnia and bacteria caused by various Polyquaternium-10's. The results are determined by tests following the guidelines ISO 11348-3, OECD 201 and OECD 202 to represent the current frame of acute toxicity testing in ERA. The results will give an indication of what physicochemical properties are driving the toxicity but also point toward current deficiencies when using standard tests to describe the effect of what could be called non-standard molecules. By discussing the results, we will present how adjustments to the current test guidelines, of e.g. the test water, will make the description of the acute aquatic toxicity realistic and applicable for modelling and ERA in a regulatory setting.

MO209

PBT Testing Strategies for Difficult Substances under REACH

J. Caley, European Chemicals Agency - ECHA / Evaluation; A. Kapanen, European Chemicals Agency - ECHA; F. Pellizzato, European Chemicals Agency; M. Sobanska, European Chemical Agency; L. Walker, European Chemical Agency ECHA; L. Wollenberger, European Chemicals Agency

Suspected PBT (persistent, bioaccumulative, toxic) substances are often difficult to test in aqueous systems due to high lipophilicity and low water solubility. In addition, many are adsorptive, leading to problems such as adsorption to glassware and formation of NER (non-extractable residues). PBT testing and assessment of multi-constituent and UVCB (unknown or variable composition, complex reaction products or of biological materials) substances can create additional problems when deciding on the most appropriate test material and testing strategy. The standard approach under REACH is to test for P first, by measurement of the half-life in soil, sediment or water, followed by fish bioaccumulation testing and toxicity testing. This can minimise the need for vertebrate testing. We will present and discuss the following examples of the PBT testing strategy used for suspected PBT substances with 'difficult to test' properties under REACH. For a UVCB containing five constituent groups, a dietary fish bioaccumulation test was used first to assess the B properties of the constituents. For another complex UVCB, degradation testing was performed on a purified fraction to assess its persistency. For an adsorptive substance, a simulation test in water was requested first to minimise the potential for formation of NER by minimising the amount of particulate matter in the test system. For a multi-constituent substance, testing was requested on a specific constituent of the substance which screened to be of most concern using QSAR predictions. **Key words: PBT (persistent, bioaccumulative, toxic), testing strategy, UVCB, REACH**

MO210

Challenges of Testing Chemical Mixtures in Aquatic Toxicology Studies

H.O. Krueger, EAG Laboratories / VP Regulatory and Scientific Affairs

A key component of any aquatic toxicology test is the delivery of the test substance in the test system. This is difficult with a single chemical and is even more complicated with mixtures. The more chemicals in the mixture the more difficult it becomes to design a test that maximizes exposure for each chemical. But before one even begins testing, it is important to know 1) how the toxicity of the mixture is to be expressed, 2) physical and chemical properties of the chemical(s), 3) the suitability of a particular test type, and 4) proper analytical methodology. While it is appealing to test at nominal concentrations and not measure each of the components in a mixture, it is also desirable to know which component(s) are causing toxicity or if there is an interaction between chemicals. It is uncertain as to whether the toxicity should be expressed based on the toxicity of the entire mixture, key components, or surrogate measures such as TOC. Most regulatory tests require maintaining concentrations in water between 80 and 120% of nominal for the duration of the test. What does that mean for mixtures? Do all chemicals in the mixture need to be maintained in that range or only the ones suspected to be toxic at concentrations of concern? For a single chemical or mixture it is important to understand the physical and chemical properties of the chemical(s) in order to design a proper test. Prior to testing it is desirable to know if the chemical is volatile, stable in water, its water solubility, whether it adsorbs to components of the test system, or reacts to light. That will determine if the test can be run as a static, static-renewal, or flow-through test. Closed systems can be used for volatile materials, water accommodated fractions were developed for petroleum products and are also useful complex materials with low solubility, saturator columns or passive dosing systems are newer techniques that also are useful. There are other options for bioaccumulation tests in which the test material can be delivered via diet instead of a water exposure or sediment tests in which test materials are added to the sediment for testing. The more chemicals in the mixture the more difficult it becomes to design a test that maximizes exposure for each chemical. Choices and trade-offs based on regulatory concerns will be necessary in designing aquatic toxicology studies for mixtures.

MO211

World distribution of test species for ecotoxicology of antifouling biocides

S. Martins, FURG / Instituto de Ciências Biológicas; G. Fillmann, FURG Universidade Federal do Rio Grande / Instituto de Oceanografia; K.V. Thomas, QAEHS The University of Queensland; A. Lillicrap, NIVA Norwegian Institute for Water Research / Ecotoxicology

Toxicity tests have been used for setting environmental quality standards in many countries and results are important for toxicity evaluation in ecological risk assessments. However, environmental authorities usually require that standard species be used for regulatory purposes. These species distribute mainly in temperate waters, in spite that most of the megadiverse countries in the world are located in the tropics. In order to investigate the representativeness of test species in different continents, this study compiled the world distribution of 92 marine species - of which 15 are standard species for toxicity tests, that have been used to determine the toxicity of 13 antifoulants under lab conditions. GBIF, WoRMS, Algaebase, Molluscabase and Fishbase were used as databases for checking the distribution of each test species, which were categorised by taxonomic groups (microalgae, macrophytes, invertebrates and fish). The occurrence of test species in different continents was analysed compared to the total number of test species. The percent of test species (out of 92) that have been registered for each continent are as follows: Europe and North America 70.7%, Asia 63%, Oceania 45.7%, South America 42.4%, Africa 41.3%, Central America 27.2%, and Antarctica 8.7%. When only standard species are taken into account, the occurrence is reduced in all continents as follows: North America 13%, Europe and Asia 9.8, Oceania 6.5%, South America 8.7%, Africa 7.6%, Central America 2.2%, and Antarctica 0%. Results also show that microalgae test species are usually widely distributed; more than 50% of invertebrate test species are registered for Asia, Europe, North America; and more than 50% of fish test species occur in Europe and North America. In spite of great biodiversity, representativeness of fish and invertebrate test species was low in Central America, South America and Oceania. The results show that the use of native species greatly contributes to increase ecotoxicity datasets and may reduce uncertainties for the establishment of PNECs by increasing representativeness of the ecosystem threatened by antifoulants.

MO212

Investigation of the effect of macronutrients on ecotoxicity evaluation of sewage treatment water to algae

I. Tamura, Okayama University / Integrated Environmental Risk Research Section; k. Shigemoto, H. Hino, Faculty of environmental science and technology, Okayama University; K. Kawamoto, Graduate school of environmental and life science, Okayama University

Whole effluent toxicity test is a method to evaluate ecological effects of samples containing various chemical substances such as industrial wastewater. It is possible to evaluate wastewater without pretreatment.However, that method has a problem that the ecotoxicity of a sample containing a high concentration of nutrient salt such as sewage treated water is masked by effect of nutrient. In this study, the influence of a macronutrients on the ecotoxicity evaluation of sewage treated water using algae was investigated. We conducted toxicity test using the organisation for economic co-operation and development (OECD) TG 201 and short-term test kit including algal cell. In the test-kit including algal cell, 9.6 ml of a medium was dispensed to a culture measuring tube. After that, the frozen algae kit was thawed with a thawing apparatus, and the thawed concentrated algae suspension 400 ?L was added, sealed with a ventilation seal, and cultured for 1 hour in a culture apparatus was used for the test. After completion of the recovery culture, initial value measurement was carried out to ascertain whether recovery culture was normally performed with a high sensitivity luminometer. After the initial value measurement, we dispensed 9.5 mL of the sample to each culture measurement tube, added a total of 18 culture measuring tubes algae suspension by 0.5 ml, sealed with a ventilation seal, a set was incubated in a culture device. After that, the culture was rotated at 24 ± 1 ° C, and the delayed fluorescence after 6 hours and 24 hours was measured. It was conducted the toxicity test at nitrogen concentration 4, 7, 12, 24, 47 mg/L using potassium nitrate. As a result, it was observed growth inhibition at 24 mg/L at test kit. However, it was not observed the increase of growth rate by nitrate, and the masking effect of toxicity was considered to be low. While, it was observed the increase of growth rate by nitrate at TG201. In the test with the addition of dipotassium hydrogenphosphate, Potassium dihydrogenphosphate, or iron fulvate was not confirmed significantly different on both algae growth inhibition test and algae delayed fluorescence inhibition test. In addition to this, the results of evaluating treated water / effluent water at the sewage treatment plant will be reported.

MO213

Interlaboratory comparison test on soil improver quality

L. Maunuksela, Finnish Food Safety Authority Evira; K. Björklöf, Finnish Environment Institute SYKE / Reference Laboratory; M. Kartio, Finnish Food Safety Authority Evira; M. Leivuori, Finnish Environment Institute SYKE / Reference Laboratory

The recycling of nutrients and organic material from waste material helps create a closed nutrient cycle and reduces the need for additional nutrients from non-renewable sources. To increase the market potential for bio-based fertilizer products we need reliable quality assessment tools. Soil improver quality is commonly determined using a test battery of chemical, biological and ecotoxicity tests. An interlaboratory comparison test was organized for determining the quality of two green waste and sewage sludge soil improver samples. The performed analysis were: Germination and root growth of cress, nitrate-N/-ammonia-N ratio, self-heating and CO_2-production. In addition, chemical parameters like dry weight, pH, electrical conductivity, bulk density and organic matter content of samples were measured. These tests are used for determining composition, phytotoxicity, stability and maturity of soil improvers which can be caused for instance by ammonia, ethylene oxide or short chain fatty acids. In total 11 participants took part, of which eight were from Finland. The interlaboratory comparison test was carried out in accordance with international guidelines and the performance of the participants was evaluated by using z scores. Altogether 50 % of the participants used accredited analytical methods at least for a part of the measurands and 100 % of their results were satisfactory. In this proficiency test, 96 % of the results were satisfactory when deviation of 1 pH units and 25–80 % (for other determinations) from the assigned value was accepted. Maturity assessment of these samples, according to criteria from Finnish legislation and results from the laboratories that performed at least three maturity tests, showed that both samples were mature and stable. According to the results, many participants had good practices and manage these analyses well. Other laboratories still need more experience. More detailed guidance on procedures that may affect the results is needed.Further harmonization is recommended e.g. by training courses and updating existing method description to harmonize procedures that affect the results.

MO214

Automatic counting and evaluation in Ecotoxicology assays

S.N. Abreu, Aveiro University & CESAM; F. Jesus, University of Aveiro / CESAM Department of Biology; F. Baptista, University of Aveiro; A.M. Soares, University of Aveiro / department of Biology & CESAM; R.E. Martins, M. Oliveira e Silva, University of Aveiro / DETI IEETA

In ecotoxicology assays, reproduction rate, involving the counting of offspring, is often one of the endpoints most frequently evaluated. The counting of organisms has been performed by piking manually every single organism (against a backlight to improve the contrast) in all replicates, which may totalize tens or hundreds of flasks. As stated before, other possible approaches could involve image digital processing but it would involve substantial modifications to present established guidelines, counting extrapolations, and also time consuming. Automatic counting minimizes human error, serializing all the organisms under exposure and providing a chromatic data set for every single organism based on both absorption and scattering light signals. The device forces the passage of all the organisms through a group of optical sensors. The acquired digital signals are then processed in real-time by a computing system in order to automatically count, and to evaluate body length and chromatically characterize each organism. The light absorption from the exposure medium can also be simultaneous registered and it is a relevant feature for ingestion bioassays assessing feeding rates. All the acquired data is stored allowing it to be reprocessed using different detection and characterization criteria and also to be exported in common data processing applications, such as Excel. The device can replace the traditional counting method, hence assuring a greater reliability, making the counts, or its repetition, a much easier and faster process. It can also contribute for diminishing human errors as well as to preserve visual acuity of the technicians, caused by the repetitive use of the traditional counting method. Given the simplicity of the device, this can become an important tool for the automatic counting of organisms, regarding that this are put on a suspension, including evaluating new model species. Concerning the chromatic characterization, this device allows the chromatic characterization of both medium and organisms simultaneously, due to the presence of both receptors and emissaries on top of the collector recipient. This functionality is particularly useful in ecotoxicological studies for the evaluation of the ingestion of the organisms, through determination of the concentration of algae in the medium. The device can also be used in bioassays involving exposure of mixed species hard to differentiate by naked eye.

MO215

Impact of the use of sugar cane vinasse as fertilizer over the years: Terrestrial toxicity bioassay and soil physics study

J. Evangelista Correia, Unesp - Institute of Biology / Biology; C.M. Sousa, São Paulo State University UNESP / Biology; C.P. de Souza, R. Souza, Sao Paulo State University - UNESP / Biology; C.A. Christofoletti, Fundacao Herminio Ometto / Environmental Mutagenesis; K.L. Grecco, Escola Superior de Agronomia Luiz de Queiroz - USP; J.H. de Miranda, Escola Superior de Agricultura Luiz de Queiroz - USP; C.S. Fontanetti, Sao Paulo State University - UNESP / Biology

Vinasse is the main liquid residue from the processing of sugarcane in ethanol. Over the last 35 years the practice of fertigation of vinasse in sugarcane crops has been carried out as a way of discarding this residue. This study aimed to evaluate the impact that vinasse can cause in areas that receive it for approximately 5, 15 and 30 years, using Rinochricus padbergi as a bioindicator and soil physics tests to determine the mobility of potassium and nitrate ions. The soil samples were collected in sugarcane crops that received vinasse for 5, 15 and 30 years and two control areas (S5, S15, S30, SC and SS, respectively). The bioassay was performed in triplicate, each terrarium containing 7.5 kg of soil and 20 animals with exposure for 21 and 42 days. After exposure, three individuals from each terrarium were dissected for midgut collection for histopathological analysis and labeling of HSP70 heat shock protein. In order to verify the mobility of the ions in the soils, the vinasse was percolated in segmented columns. In the terrestrial toxicity bioassay there was a high mortality of the diplopods exposed to the soil S30 in 21 days; after 42 days of exposure all individuals exposed to the soil S30 died and only four survived in the soil S15. Midgut histological analyzes revealed a significant thickening of epithelial cells brush border, as well as loss of adhesion and presence of cytoplasmic vacuoles in epithelial cells in some animals. There was also an increase in spherocrystals in hepatic cells. From analysis of the HSP70 labeling, there were statistically significant differences in individuals exposed for 21 days in soil S5 and S15 and after 42 days in soil S5 when compared to controls. In the soil physics tests it was observed that potassium presented low mobility in soils, due to its high adsorption, being present in higher concentrations in the upper rings of the columns. For nitrate, the highest concentrations were found in the lower rings, since it is an anion being easily carried along the column. Considering the results of soil physics studies, it is noted that the prolonged use of fertirrigation in soils may be related to the mobility of the compounds and the adsorption of potentially toxic compounds. The results obtained through terrestrial toxicity bioassay suggest toxic action of the soils that received vinasse as fertilizer, being verified significant effects even in soil that received vinasse for only 5 years.

MO216

Sugarcane vinasse treated for neutral pH adjustment reveals low toxicity in millipedes

C.M. Sousa, São Paulo State University UNESP / Biology; R. Souza, C.P. de Souza, Sao Paulo State University - UNESP / Biology; J. Evangelista Correia, Unesp - Institute of Biology / Biology; A. Yabuki, São Paulo State University UNESP / Biology; C.S. Fontanetti, Sao Paulo State University - UNESP / Biology

One of the main final destinations of sugarcane vinasse has been fertirrigation. Legislation for its adequate use has been developed in order to respect the characteristics and limits of the soil to receive this residue. Its use as fertilizer shows numerous benefits, however several researchers have revealed that vinasse causes damage to representatives of soil edafic fauna. As one of the major problems presented by vinasse is its acidic pH, this study proposed to treat vinasse with lime (CaO) in order to adjust its pH to 7,0 (neutral) in an attempt to reduce its toxicity for later use in crops. For this purpose, millipedes of the species *Rhinocricus padbergi,* well established animals for soil ecotoxicological tests, were used as biondicators organisms. In order to analyze the toxicity of treated vinasse, morphological alterations in the cells of millipede midgut were observed. The animals (n=30 per treatment) were exposed to five treatment groups: a control group (animals exposed to soil from the site where the animals were collected); a group of animals exposed to vinasse in its raw form, prior the treatment with lime, in the concentration established by the Brazilian legislation; a group exposed at double concentration allowed by the legislation, simulating a situation of super dosage; a group exposed to treated vinasse with lime (pH adjusted to 7,0) in the concentration established by the legislation; a group exposed to treated vinasse at double concentration allowed by the legislation. The animals were exposed for 30 days. After this period, millipedes were dissected for removal of the midgut, which was processed for analysis in Transmission Electron Microscopy (TEM). The animals exposed to the control group presented the midgut with morphological integrity, as expected. The animals exposed to the raw vinasse, at both concentrations, presented several morphological changes in the cells of the midgut, as nuclear alteration, reduced microvilli and loss of plasma membrane integrity. The animals exposed to the treated vinasse, at both concentrations, presented less cellular damages when compared to the animals exposed to the raw vinasse. According to the results, the treatment of the vinasse with lime is a viable alternative to reduce its toxicity.

MO217

Experimental membrane-water partition coefficients are becoming available to aid ionogenic surfactant risk assessment

S. Droge, University of Amsterdam/IBED Institute / IBED

Surfactants are important ingredients in various household products, personal care products and many different industrial processes. They are often used and applied in relatively high concentrations on a daily basis, which leads to relatively high concentrations in waste water streams, of which resilient fractions may drive a constant emission into aqueous environments receiving (treated) waste water. A first aim of this study was to provide an overview of surfactant substances registered in REACH. Over 150 substances were retrieved, covering different types of polar headgroups (e.g. sulfonates, sulfates, amines, ethanolamines, diamines, amine-oxides, quaternary ammonium compounds) and different hydrophobic tails (e.g. petroleum origins, naphthalene structures, tallow based origins). Many registered surfactants are complex technical mixtures of ionogenic head groups and linear or branched hydrophobic alkyl chain lengths ranging between C_{12}-$C_{>18}$. \n As for many ionogenic compounds, the environmental fate assessment of ionogenic surfactants is complicated because it is not clear how to parameterize critical partition coefficients such as K_{ow}, K_{oc}, or how to model uptake in organismal tissue. Various techniques to derive logP for surfactants are described in these REACH dossiers, with conflicting argumentations on which is most relevant. It is well known that K_{ow} is a problematic parameter for surfactants, and that only experimental soil-water partition studies or bioconcentration studies provide adequate insight. To avoid and/or reduce costly and unethical numbers of animal tests, insight in the key parameters of pure surfactant components driving uptake in biota is highly needed. The phospholipid-water partition coefficient (K_{MW}) is considered to be the dominant contributor to the overall tissue-water partition coefficient for ionogenic surfactants, because membranes lipids allow for both ionic interactions at the zwitterionic head groups and hydrophobic interactions at the membrane core. Therefore, the second aim of this study was to provide an overview of 56 surfactant substances for which K_{MW} values have been reported, as an already available, consistent and meaningful partition data set for surfactants. The third aim of this study was to provide an overview of the preliminary K_{MW} data set generated for 40 additional surfactants during the CEFIC ECO37 project.

MO218

Effects of produced water components on early life stages of cold-water marine fish

B. Hansen, SINTEF Materials and Chemistry / Environment and New Resources; T. Størseth, L. Sørensen, SINTEF Ocean / Environment and New Resources; R. Nepstad, SINTEF Ocean / Monitoring and Modelling; S. Meier, Institute of Marine Research / Environmental Chemistry; D. Altin, BioTrix; D.F. Krause, T. Nordtug, SINTEF Ocean / Environment and New Resources

Regular discharges of produced water from the offshore oil and gas industry represents the largest direct discharge of effluent into the marine environment worldwide. Produced water contains an aqueous mix of formation water, oil and/or gas from the reservoir, injected freshwater or brine water and added production chemicals. Organic compound classes typically reported in produced water include saturated hydrocarbons, monoaromatic and polyaromatic hydrocarbons (MAHs, PAHs) as well as oxygenated compounds, such as phenols, acids and ketones. Total (for the year 2016) produced water releases from activities on the Norwegian continental shelf alone was estimated to include 1 600 tons of crude oil, 2221 tons BTEX (benzene, toluene, ethylbenzene and xylenes), 576 tons phenols, 28 438 tons organic acids and 126 tons PAHs. This forms a cocktail of known and suspect compounds causing acute adverse effects, but limited knowledge is yet available on the sub-lethal toxicity of produced water to marine species. In the present work, we conducted a 4-day exposure of embryos of Atlantic cod (*Gadus morhua*) and haddock (*Melanogrammus aeglefinus*) to produced water extracts equivalent to 1:50, 1:500 and 1:5000 times dilutions of raw produced water in natural sea water. During exposure, embryonic heart rate was significantly reduced for both species at the highest exposure concentrations. After exposure, eggs were transferred to and kept in clean sea water and kept until 3 days post hatch. No significant reduction in survival or hatching success was observed. However, the exposed cod eggs hatched earlier in a concentration-dependent manner. After hatch, larvae exposed to produced water extracts were smaller. Furthermore, the larvae displayed signs of cardiotoxicity, jaw and craniofacial deformations in a concentration-dependent manner. In a follow-up study, we extracted and fractionated produced water into 12 fractions with different component groups. Experiments are currently on-going to identify and determine which specific component groups are the main drivers for the observed fish toxicity.

MO219

Optimising the feeding of the Mayfly Cloeon dipterum under laboratory conditions and the influence of diet on growth and emergence

Z.L. Jones, Cambridge Environmental Assessments (CEA) / CEA; E. Jefferys, Cambridge Environmental Assessments CEA / Aquatic Ecotoxicology; N. Taylor, Cambridge Environmental Assessments (CEA) / Ecotoxicology

The pre-adult stages of mayflies (Ephemeroptera) reside in freshwater habitats such as ponds, streams, rivers and lakes. Recent studies have found that, in some instances, mayfly larvae can be more sensitive to Plant Protection Products (PPPs) than other benthic macroinvertebrates. One common issue with the use of mayfly larvae in chronic toxicity testing has been the optimisation of larval diet to ensure successful growth through to emergence. Attempts have been made to develop a standardised toxicity test method for non-European species such as *Neocloeon triangulifer* (US) and *Hexagenia limbata* (US, Canada); however, little progress has been made using European species. The mayfly species, *Cloeon dipterum* is highly abundant throughout the British Isles and across Europe. In their natural environment they would feed upon available detritus and algae. Using wild-caught mayfly to maintain a culture in a laboratory environment can be problematic, in terms of what diet to feed them and also being able to culture algae or diatoms for feeding purposes. In this poster we will present our development work identifying different food types that *Cloeon dipterum* larvae can be fed, including algae (*Desmodesmus*), crushed alder leaves, and vegetarian fish food, and describe what impact the different diets have on development, growth and emergence rate.

MO220

Non-standard biotests - Intelligent testing to combine different needs and requirements for experimental and modelling approaches

M. Hammers-Wirtz, T. Strauss, S. Classen, Research Institute gaiac / gaiac - Research Institute for Ecosystem Analysis and Assessment

In recent years biotests differing from standard procedures become more and more important for the environmental risk assessment of plant protection products. For higher-tier testing test designs are adapted to frequently complex issues in order to contribute to a more realistic risk assessment if applied for instance in SSDs or in the context of effect modelling. In addition to variations in exposure (e.g. peak scenarios) non-standard species as e.g. mayfly, stonefly and caddisfly larvae, isopods or gammarids are increasingly being tested. Historically the design of experiments used for classical higher tier risk assessment has other requirements than experiments used for modelling purposes (e.g. number of observation times, number of replicates). However, to minimize the testing effort in this context it is of particular importance to define certain basic test requirements to ensure the best possible use of the generated data for other issues (intelligent experimental design). Thus, we aim to use standard experimental data for the parameterization or validation of TKTD effect models and vice versa. In addition, it would be useful to design the test conditions in such a way that the experimental results can also be used for mechanistic population modelling. To ensure multi-usable and comparable test results, the selection of the test species and their origin, the developmental stage of the test species, the toxicological endpoints (lethal and sub-lethal), the number of replicates and the number of observations as well as the test duration must be clearly defined. Furthermore, adapting the test conditions to the ecological requirements of the specific test species (e.g. in terms of the selection and characterization of food, selection of test temperature) minimizes the laboratory stress for the organisms, and thus results in increased validity, and allows an easier integration into more advanced model applications. We will present basic requirements for biotests with non-standard species and discuss the data needs in particular for the context of different effect modelling approaches.

MO221

Occurrence and environmental risks of pharmaceuticals and personal care products in Guanting Reservoir and its upstream rivers

h. zhou, P. Zhang, China Institute of Water Resources and Hydropower Research IWHR

Abstract: Eighteen selected pharmaceuticals and personal care products (PPCPs), consisting of five non-antibiotic pharmaceuticals (N-APs), four sulfonamides (SAs), four tetracyclines (TCs), four macrolides (MCs), and one quinolone (QN) were detected in surface water and sediments from Guanting Reservoir (GTR) and its upstream rivers in north China. Acetaminophen, caffeine, chlorotetracycline, and ofloxacin were detected with 100% frequency in the surface water of GTR and its upstream rivers, while diltiazem was also detected with 100% frequency in surface water from the reservoir's upstream rivers. Acetaminophen and caffeine were detected with 100% frequency in sediments from GTR and its upstream rivers, while high concentrations of ofloxacin in GTR, and carbamazepine, tetracycline, and chlortetracycline in upstream rivers were also detected in 100% of samples. Five N-Aps, especially acetaminophen and caffeine, were prominent pollutants. The mean concentrations of acetaminophen were 155 and 302 ng•L^{-1} in surface water and 529 and 202 ng•g^{-1} in sediments from GTR and upstream rivers, respectively. The mean concentrations of caffeine were 208 and 338 ng•L^{-1} in surface water samples and 1430 and 1020 ng•g^{-1} in sediments from GTR and upstream rivers, respectively. The geographical differences in PPCP concentrations were largely due to anthropogenic activities. Sewage discharged from Zhangjiakou City and human activities around the GTR basin were the main sources of PPCPs in this area. An environmental risk assessment for the worst-case scenario was undertaken using calculated risk quotients, which indicated a medium risk from erythromycin in GTR and a high risk in its upstream rivers.\nKey words: Occurrence, environmental risks, pharmaceuticals and personal care products (PPCPs), Guanting Reservoir (GTR)

MO222

TOXICITY TESTING OF WASTEWATER WITH GREEN ALGAE RAPHIDOCELIS SUBCAPITATA (=PSEUDOKIRCHNERIELLA SUBCAPITATA)

P. Arh, Slovenian Environment Agency; B. Hajnzic, The National Laboratory of Health, Environment and Food; J.V. Valh, Faculty of Mechanical Engineering; M. Spacapan, M. Kos Durjava, National Laboratory of Health, Environment and Food

In accordance with the provisions of the Slovenian General Emission Regulation, it is necessary to determine concentrations of selected chemical parameters as well as the toxicity for the aquatic organism Daphnia magna (small planktonic crustacean, water flea) in industrial wastewater. In the case where herbicides are present in wastewater, it would be more appropriate to test the toxicity of organisms from first trophic level such as green algae for a more realistic environmental risk assessment. In this research we discussed the effect of various wastewaters and herbicide terbutylazin on the aquatic ecosystem. Our intention was to investigate and justify the introduction of the toxicity test with the green alga Raphidocelis subcapitata into Slovenian legislation.

Raphidocelis subcapitata was formerly known as Pseudokirchneriella subcapitata or Selenastrum capricornutum. Aquatic toxicity test with water flea was carried out in accordance with the standard method OECD TG 202, and the freshwater algae growth inhibition test was carried out using the standard method OECD TG 201. We have determined that wastewaters have a different effect on the water flea mobility and on the growth of green algae. Herbicide terbutilazin, even at the highest concentrations used, did not exhibit toxic effects on daphnids, whereas in the case of algae concentrations were inhibitory at all levels used in tests.

MO223

Harmful substances from reclaimed asphalt and their effect on living organisms

R. Licbinsky, V. Jandova, M. Buckova, J. Huzlik, Transport Research Centre

The composition of reclaimed asphalt (RA) is an important issue due to its further use for renovations or construction of new roads. All these materials must meet the conditions required for environmental protection. The occurrence of pollutants in RA is related to the actual composition of the original material (e.g. the presence of tar in the binder) and the formation of pollutants during road traffic (exhaust gases, abrasion of the tire and brake lining). The paper discusses an experiment whose aim was to assess the leaching of harmful substances from the RA repository under real conditions and comparing the acquired data with the results of the leaching tests of these materials in laboratory conditions. The experiment consisted of determining the contents of polycyclic aromatic hydrocarbons (PAHs) and metals in four types of samples - the RA material, laboratory-prepared water leachate from this material, seeping water obtained from the repository under real conditions and rainfall from the repository site. Chemical analyses of these samples were supplemented by ecotoxicological tests that characterize the effect of the material on living organisms. Seeping water was found not to have significant negative effects on living organisms, although it was relatively polluted by selected compounds (metals and PAHs). Laboratory prepared water leachate of the material have revealed the greater negative effect on living organisms than the seeping water, although the concentrations of analyzed substances were much lower there. Thus, the leachate could contain "unknown" substances from the leaching process in the laboratory that were not analyzed and could occur in high concentrations and are responsible for toxic effects on living organisms. The presented experiment shows the benefits of ecotoxicological tests for evaluation of hazardousness of RA materials for freshwater ecosystems. Using only chemical analysis in assessing the possible harmful effects of RA materials could provide misleading information. The results of the experiment further indicate the importance of determining the pollutants in the water leachate of a material rather than just determining the content of harmful substances in the dry matter. The reason is the contact of the material with rain or underground water under real conditions, in which foreign substances can be released into the environment.

MO224

Time-course of coiling activity in zebrafish (Danio rerio) as an endpoint for developmental neurotoxicity - hidden potential and underestimated challenges

F. Zindler, F. Beedgen, D. Meißner, M. Steiner, D. Stengel, T. Braunbeck, COS University of Heidelberg / Aquatic Ecology and Toxicology

First locomotor activity in zebrafish embryos is characterized as spontaneous one-sided tail coils that originate from a single neural circuit in the spinal cord. According to literature, this coiling activity is driven by periodically depolarizing spinal neurons independent of light or touch stimuli. Throughout the embryonic development until late pharyngula stage, coiling movements become more complex (e.g., modifiable by external stimuli), and multiple neural circuits are integrated. Early tail coiling in zebrafish has been subject to numerous studies assessing developmental neurotoxicity (DNT). Many of these have been criticized for bearing considerable limitations in terms of methodology and result interpretation, and only a handful of studies have examined coiling activity with regard to its actual suitability as DNT endpoint. Therefore, effects of five neurotoxic compounds (ethanol, cadmium, dichlorvos, fluoxetine, and citalopram) on coiling activity of zebrafish embryos until the late pharyngula stage (47 hpf) were investigated. Coiling activity in zebrafish was analyzed on an hourly basis under infrared illumination with a common day/night light cycle (14/10 h). Substantial new insights were gained concerning the development of first locomotor activity in the zebrafish embryo. Results were evaluated against the background of substance-specific embryo toxicity (fish embryo toxicity test, OECD 236). Findings revealed distinct effects on coiling activity by the test compounds, which differed with respect to their neurotoxic mode of action. Effects on coiling activity could not be interpreted separately from substance-specific embryo toxicity. To the best of our knowledge, the present study is the first of its kind investigating the development of coiling activity in zebrafish embryos by means of non-visual light. On the basis of an enhanced test protocol, various challenges could be identified which may arise during the examination of coiling activity as an endpoint for DNT in zebrafish embryos. On the other hand, results highlight the potential of an improved coiling assay to distinguish between chemicals with different neurotoxic modes of action. The present work is part of the project “Effect Network in Water Research” and has been funded within the framework of „Wasserforschung Baden-Wuerttemberg".

Effects of CaCO3 mine tailings on the marine copepod Calanus finmarchicus

J. Farkas, SINTEF Ocean / Environment and New Resources; I. Øverjordet, B. Hansen, SINTEF Materials and Chemistry / Environment and New Resources; T. Nordtug, SINTEF Ocean / Environment and New Resources; L. Svendheim, T. Kristensen, Nord University; D. Altin, BioTrix; R. Nepstad, SINTEF Ocean / Monitoring and Modelling; E.J. Davies, SINTEF Ocean / Environment and New Resources; T. Jager, DEBtox Research / Dept of Theoretical Biology; P. Olsvik, Nord University

The rapidly increasing demand for mineral resources is driving mining activities worldwide. Mining generates extensive quantities of waste that needs to be disposed of. In Norway, mine tailings are disposed directly in fjords in several locations. During marine mine tailing disposal large quantities of fine inorganic particles, associated metals and processing chemicals can be introduced into the marine environment. Exposure to mine tailings, especially to inorganic particles, does not necessarily cause acute toxicity and mortality, but can cause physiological stress and reduced food intake impacting organisms' energy budget. In this study we investigate the effects of tailings deriving from a $CaCO_3$ processing plant on different life stages of the marine filter feeding copepod *Calanus finmarchicus*: eggs to nauplii stage 3 (N3), N3 to N5/N6, and adult individuals. The tested tailings contain a large fraction of very fine particles as well as floatation and flocculation chemicals. The tailing stock dispersions were prepared as 1g/L wet weight (30% dry mass) in seawater, were left for settling of larger particles for 20 min and subsequently decanted. Decanted dispersions were used as high (H) exposure concentration (approximately 2 million particles/mL), or diluted to middle (M; 1:1) and low (L; 1:10) exposure concentrations. Exposure (96 h) to $CaCO_3$ tailings did not significantly reduce hatching success and survival up to N3 life stages. However, when deprived of food, all tailing exposures caused an almost 100 % mortality in the first feeding stage nauplii (N3), with tailings found in the guts of dead nauplii. Such mortalities were not observed in nauplii (N3) and N5/6 that were additionally provided with algae during tailing exposure, even though uptake of tailings together with algae occurred in 70 – 96 % of the exposed individuals. Similarly, short term exposure (72 h) did not lead to acute mortality in adult copepods, however, 86±11% of the exposed individuals had taken up tailings into their guts. Impacts of tailings on oxygen consumption, developmental rates, size and activity levels are currently ongoing. All obtained data will be integrated into energy budget models in order quantitatively test the hypotheses that mine tailing particles can exert sublethal effects through reduced energy intake versus increased costs for maintenance.

Antimicrobial Resistance in the Environment (P)

Rauseo, National Research Council / Institute of Water Research IRSA-CNR; F. Spataro, Italian National Research Council / Water Research Institute; L. Rolando, Water Research Institute - Italian National Research Council / Water Research Institute; L. Mariani, Italian National Research Council / Water Research Institute; A. Barra Caracciolo, National Research Council / Water Research Institute

Antibiotics are emerging contaminants with two-fold main impacts: they can affect some microbial populations interfering with biogeochemical cycles and can act as micropollutants active in the transmission of resistance genes. For these reasons, antimicrobial resistance has become an emerging threat for human, animal and ecosystem health. Huge amounts of the produced antibiotics are used in livestock farms and the persistence of antibiotics in the cattle manure can be cause of environmental contamination considering that it is often spread on the land as a fertilizer. Moreover, owing to the practice of energetic biomass wastes valorization, manure is increasingly used to feed biogas plants. The presence of antibiotics into the digesters can affect the performance of the anaerobic digestion process leading to sub-optimal biogas productions, and in the case of their persistence, a compost of low quality is obtained. The AZeRO antibiotics Project (*AZeRO Antibiotici Prot. N.ro 85-2017-15065" – LAZIO INNOVA - Progetti di gruppi di ricerca*) relies on a joint collaboration between the Italian Ecology lab of IRSA-CNR and the Biomass and Biotechnologies for Energy Lab of ENEA. It aims at: assessing the presence of antibiotics in manure and digestate at a regional scale (Lazio, Italy) considering farms that own biogas plants; studying the kinetics of antibiotic degradation, in the anaerobic digestion process (anaerobic condition) and in the storage and spread phases of digestate (aerobic condition). Preliminary studies showed that the genes of resistance can be transferred from digestate bacteria to microbial communities of agricultural soil. The three-year Project also aims to find green solutions to manage antibiotics and resistance genes spreaded in the environment. Key words: Antibiotic resistance, manure, anaerobic digestion, digestate.

MO227

Methods for the risk assessment of antibiotic resistance and related genes in the environment

M. Virta, University of Helsinki / Department of Microbiology

The origins of antibiotic resistance in the environment is relevant to human health because of the increasing importance of zoonotic diseases as well as the need for predicting emerging resistant pathogens. Antibiotics are used in diverse settings for food production. Domestic animals are treated with antibiotics for both curing disease and promoting growth. Moreover, aquaculture relies on antibiotics to manage infectious disease. Wastewater treatment plants receive sewage from various sources, including hospitals and households which are both important sources of antibiotics and their residues, and antibiotic resistant bacteria. Risk assessment of antibiotic resistance is complex. It should include at least quantitative information of the gene, sequence of the gene, host cell of the gene and genetic environment of the gene (e.g. presence in mobile DNA element). We have used the combination of different methods for obtaining that information: Parallel quantitative PCR array for high throughput quantification (1), epicPCR(2) for host information and Inverse-PCR(3) for analysis of the genetic environment. Inverse-PCR and epicPCR combined with DNA sequencing resolve also the sequence of the resistance gene. Our results demonstrate that human activities results to the increase to the abundance of antibiotic resistance genes. In many cases the genes are located in mobile genetic elements with increases the probability of transfer of the them between bacterial species. The host range information obtained by epicPCR revealed wide diversity on the host range of the antibiotic reistance genes in different environments. Our results can be used for the development ecotoxicological risk analysis for antibiotic resistance. MO228

Detection of low levels of antibiotic resistance genes in aquatic environments

A. Rahman, Orebro University / Microbiology; F.A. Khan, J. Jass, Orebro University / SCHOOL OF SCIENCE AND TECHNOLOGY

Detection of low levels of antibiotic resistance genes in aquatic environments
Aminur Rahman†, Faisal Ahmad Khan†, Jana Jass † Contributed equally The Life Science Center - Biology, School of Science and Technology, Örebro University, SE-701 82 Örebro, Sweden Abstract Low levels of antibiotics and pharmaceuticals are regularly released into natural aquatic environments via wastewater, thus there is a concern that these anthropogenic practices may serve to create hotspots for antibiotic resistant bacteria. Although it is important to study antibiotic resistant bacteria, antibiotic resistance genes (ARGs) associated with clinically relevant human pathogens are considered an emerging environmental contaminant. There are several methods to detect ARGs in the environment, including, metagenomic analysis and various PCR methods. However, it is difficult to detect very low levels of ARGs with these methods from environmental samples. The aim of this study was to develop a sensitive and efficient method to detect ARGs of culturable coliforms and Gram-negative bacteria in aquatic environments where there are low levels of ARG. Water samples were collected from a river up-stream and down-stream of a wastewater treatment plant in Örebro, Sweden. The water was filtered using 0.45 μm cellulose filter and incubated overnight at 37ºC on coliform selective chromocult agar to enrich the growth of Enterobacteriaceae. A comparison was made between DNA isolated directly form the waters and from enriched bacteria growing on chromocult agar for the presence of 84 ARGs using DNA qPCR arrays. Different classes of beta-lactamase, fluoroquinolone, tetracycline, aminoglycoside resistance genes and multidrug resistance efflux pump genes were detected in both enriched and non-enriched samples. However, there was a significantly higher number of ARGs detected in enriched samples than that observed in non-enriched samples. The results indicate that the enrichment of Enterobacteriaceae and Gram-negative bacteria can provide a more accurate indication of the distribution of environmental contamination by ARGs. **Key words:** Enterobacteriaceae, Coliform bacteria, Antibiotic resistant bacteria, DNA qPCR array

Wiberg, Swedish University of Agricultural Sciences / Department of Aquatic Sciences and Assessment; L. Ahrens, Swedish University of Agricultural Sciences SLU / Dept. of Aquatic Sciences and Assessment

The presence of antibiotic resistance genes (ARGs) in aquatic environments poses a threat to human and environmental health. Water bodies which receive effluent discharge of wastewater treatment plants (WWTPs) are an important media to evaluate ARGs entering the environment. A few European studies have reported ARGs in recipient waters, but such data remains very limited in Sweden. The key objective of this study was to assess the prevalence of ARGs in the Swedish surface water environments. Specially, it aimed to (a) collect recipient water samples, downstream of the municipal wastewater treatment plants, as well as upstream water samples where possible, and (b) screen for a wide range of ARGs in the target water environment. Various ARGs and other genes in the samples were identified and quantified using a high-throughput quantitative polymerase chain reaction (qPCR) method with 384 primer sets. A total of 152 ARGs were detected in all the samples, conferring resistance to aminoglycoside, amphenicol, β-lactam, genes classified as multidrug resistance, macrolide lincosamide streptogramin B, sulfonamide, tetracycline, trimethoprim and vancomycin. Additionally, integrase genes of class 1, 2 and 3 integrons as well as six other resistance genes were found in the samples. More genes were detected in the downstream than the upstream samples, particularly for the Uppsala's County site. Our results showed that antibiotic resistance was ubiquitous in the studied water bodies and WWTP effluents were an important impact source for ARGs. Since the recipient water eventually connects to the largest drinking water reservoir in Sweden, there is a potential risk of spreading antibiotic resistance genes to the source of drinking water. Overall, our finding provided a new insight into the occurrence and abundance for a wide range of ARGs and other genes in the Swedish aquatic environment. This could assist to select specific sites for assessing temporal changes of ARGs in such a context of Sweden in the future. **Keywords:** river water, antimicrobial resistance, antibiotic resistant bacteria, qPCR **Presentation preference:** platform presentation

Presence and fate of antibiotics and antibiotic resistant genes in Finnish wastewaters

A. Kruglova, I. Levchuk, Aalto University / Department of Built Environment; A. Mikola, Aalto University / Department of Civil and Environmental Engineering

The constant release of antibiotics (even in very small concentrations of nanograms and micrograms per litre) in natural waters not only cause toxic effect on aquatic organisms but also spread antibiotic resistant genes (ARGs) to the environment threatening the future therapeutic efficiency of existing antimicrobial drugs. Urban wastewater treatment plants (WWTPs) are among the main sources for the release of antibiotic resistance into the aquatic environment. At the same time, the data on the removal of antibiotic resistant genes (ARG) are very limited and there is a big gap of knowledge on dynamics of antibiotic resistant bacteria (ARBs) and ARGs during wastewater treatment process. In this study, wastewaters of seven Finnish WWTPs are studied in order to gain the total profile of the antibiotics and antibiotic resistance genes (ARG) in influent and effluent wastewaters.The target antibiotics are analyzed by ultra-performance liquid chromatography mass spectrometry. The presence of ARGs is studied by *SmartChip* Real-Time PCR System. The data on antibiotics usage, persistence in wastewaters, removal efficiency are compared with the spread of ARGs in treated wastewaters. The results demonstrate the collective data on presence and fate of 49 antibiotics and 216 ARGs in Finnish wastewaters. This knowledge can be used for the assessment of the commonly used antibiotics environmental safety.

Field-compatible protocol for detecting bioavailable antibiotic contamination without pipetting steps

J. Muurinen, University of Helsinki / Food and Environmental Sciences; A. Pasupulate, University of Helsinki / Department of Microbiology; J. Lappalainen, ABOATOX; M. Virta, University of Helsinki / Department of Microbiology

The discovery of antibiotics has had a crucial influence on our civilization, but their efficiency is compromised by accelerating evolution of antibiotic resistance that seems to be a consequence of rampant use of antibiotics. Antibiotics are used in treatment of infections in humans and animals, but also as growth promoters in livestock production and against plant pathogens in crop production. As a result of the high use in agriculture and in humans as well as wastewater discharges from pharmaceutical factories, antibiotic contamination has been found from various foodstuffs, soils, sediments and watercourses. The role environmental of antibiotic contamination in the emergence of antibiotic resistance is yet to be defined and an important question is if the antibiotic residues in the environment can select resistance in bacterial communities, i.e. if the contaminants are bioavailable for bacteria carrying resistance genes. Whole-cell bioreporters are living organisms that produce measurable signals in the presence of target chemicals. Thus, using bioreporters for detecting environmental contaminants would reflect biological effects of these pollutants. However, bioreporters are not widely used in field studies. One possible explanation for this is that many of the bioreporter field protocols are suitable only for liquid samples or include pipetting steps, which is a demanding task outside laboratory. We present a bioreporter protocol for detecting tetracycline contamination without pipetting steps or sample type requirements. The protocol utilizes polyester swabs that are commonly used in cleanroom technology. For testing the applicability of the protocol, we generated test samples in Milli-Q water, milk and soil matrixes with known tetracycline concentrations up to the maximum tetracycline residue limit of milk set by the EU regulation. The swabs were first dipped to the bioreporter cell cultures and then to test samples, following incubation and luminescence measurements. The standard deviation of measurements from ten replicate swabs ranged 4-19 %, which can be expected also with pipetting protocols. The test samples with lowest tetracycline concentration (5 ng ml^{-1}) could be distinguished from the control samples (0 ng ml^{-1} tetracycline). Our results show that swabs can be used together with luminescent whole cell bioreporters, enabling rapid screening for contaminated foodstuffs and making it possible to conduct the measurements in field conditions

MO232

Study of Antimicrobial Resistance in pristine area

A. Navarro-Cuenca, EU Commission JRC / Directorate D Sustainable Resources Water and Marine Resources Unit; I. Sanseverino, R. Loos, H. Skejo, T. Lettieri, European. Commission - Joint Research Centre / Directorate D Sustainable Resources Water and Marine Resources Unit

Nowadays the antimicrobial resistance (AMR) is a European and global concern which has been highlighted as a catastrophic threat for human health. Several studies had pointed out that the aquatic environments may play an important role in the AMR acting as a reservoir and spreading the resistant bacteria and antimicrobial resistant genes (ARG). Although it has been shown the presence of resistant bacteria and ARG in highly anthropogenic areas such as the effluents from the waste-water treatment plants, the AMR is also a natural phenomenon, which is not fully investigated. The aim of the current study is to characterise the natural background of the AMR in a pristine aquatic environment and in microcosm studies to assess the minimal antibiotics' concentration that might induce resistance. In this study, water samples were collected from an alpine river, Rio Variola in Monte Ossolano (Domodossola, Italy) during July, September and October in 2018. To investigate the natural background, a small water volume was plated on agar plates in presence of antibiotics and without antibiotics as a control. The other volume was used to perform microcosm studies. The microcosms were exposed to low concentrations (0-100ng/L) of three antibiotics: erythromycin, amoxicillin, and tetracycline. For the background study, the water from Rio Variola, showed bacteria resistant to ampicillin, amoxicillin, kanamycin, and erythromycin in July and November and only to erythromycin and kanamycin in September. For the microcosm study, after 7 days of exposure, it was observed changes in the occurrence of antimicrobial resistant bacteria on agar plates. Cell number also showed differences after 11 and 13 days of exposure to erythromycin and tetracycline at concentrations of 50ng/L and 100ng/L respectively. This change on the microcosm could explain the variations of bacterial resistance during the experiment. This study demonstrates that resistance to antibiotics occurs naturally in the environment. Furthermore, the low concentrations of antibiotics can have an effect on the bacteria communities and may help in the maintenance of antimicrobial resistance in the environment. Further experiments using the Next Generation Sequencing will allow to characterise the bacterial community changes and to identify the resistance genes.

MO233

Selective potential of sulfamethoxazole in natural microbial communities

J. Rauseo, National Research Council / Institute of Water Research IRSA-CNR; N. Ademollo, National Research Council of Italy / Water Research Institute; A. Barra Caracciolo, Italian National Research Council / Water Research Institute; W. Gaze, University of Exeter / Medical School; P. Grenni, T. Pescatore, F. Spataro, Italian National Research Council / Water Research Institute; I. Stanton, University of Exeter / Medical School; L. Patrolecco, Water Research Institute-National Research Council / Water Research Institute

Antibiotic large-scale production and use in human and veterinary medicine, agriculture and aquaculture practices result in a flow of antibiotics, antibiotic-resistant organisms and antibiotic-resistance genes into the natural environment. Recent studies using single species assays showed that selection for antibiotic resistance occurs at very low antibiotic concentrations, suggesting a correlation between the environmental antibiotic concentrations and the spread of antibiotic resistance. Currently, there are few data about selection for and mobilisation of resistance genes in complex natural microbial communities representing real conditions. Sulfamethoxazole (SMX) is a frequently prescribed and consumed antibiotic worldwide, leading to its ubiquitous presence in the natural environment. Thus, the evaluation of the relationship between SMX concentration and the selection for antibiotic resistance in a real community context is necessary for environmental risk assessment. The aim of this study was to investigate the selective potential of SMX in natural systems containing natural microbial communities from different environmental compartments. Initially, different week-long evolution experiments were performed by exposing the microbial community from municipal wastewater to different SMX concentrations (2, 20, 200, 2000 and 20000 µg/L), in order to determine the minimal selective concentration (MSC) of SMX that caused positive selection for resistance. The selection coefficients were calculated based on changes in the class 1 integrase (*intI1)* gene prevalence over time. Results showed that the selective effect of SMX occurred when the antibiotic concentration was between 2000 and 20000 µg/L. However, it is worth to highlight that this range value was higher than that usually found in natural environments. In addition, different SMX biodegradation experiments were conducted in microcosm studies by adding SMX to natural river water (500 µg/L SMX) or to agricultural amended soil (20 mg/kg) both containing the indigenous microbial communities. In these experiments, the correlation between the change in *intI1* prevalence and SMX degradation was evaluated. The results confirmed the role of the SMX in selection for resistant microorganisms at the study concentrations.

MO234

Modelling environmental antibiotic-resistance gene abundance: a meta-analysis

D.d. Silva Tavares Duarte, A. Ragas, R. Oldenkamp, Radboud University / Environmental Science

The successful treatment of infectious diseases heavily relies on the therapeutic usage of antibiotics. However, the overreliance on the use of antibiotics in humans and animals leads to increasing pressure on bacterial populations in favour of resistant phenotypes. Antibiotics reach the environment from a variety of emission sources and are being detected at relatively low concentrations. Given the possibility of selective pressure to occur at sub-inhibitory concentrations, the ecological impact of environmental antibiotic levels on microbial communities and resistance levels is vastly unknown. Quantification of antibiotic-resistance genes (ARG) and of antibiotic concentrations is becoming commonplace. Yet, these two parameters are often assessed separately and in a specific spatiotemporal context, thus missing the opportunity to investigate how antibiotics and ARGs relate. Furthermore, antibiotic (multi)resistance has been receiving ever growing attention from researchers, policy-makers, businesses and civil society. Our aim was to collect the limited data on antibiotic concentrations and ARG abundance currently available to explore if a relationship could be defined in surface waters, sediments and wastewaters. A metric of antibiotic selective pressure, as measured by the concentration and effect of antibiotics, was used to correlate the presence of antibiotics in the environment to total relative abundance of ARG while controlling for basic sources of non-independent variability, such as country, year, study, sample and antibiotic class. The results of this meta-analysis show a significant effect of antibiotic pressure and type of environmental compartment on the increase of ARG abundance even at very low levels. If global environmental antibiotic pollution continues, ARG abundance is expected to continue as well. Moreover, our analysis emphasizes the importance of integrating existing information particularly when attempting to describe complex relationships with limited mechanistic understanding.

MO235

Improved marine environmental risk assessment for pharmaceuticals in marine aquaculture

J.H. Heseding, C. Floeter, Hamburg University of Applied Sciences / Environmental Engineering

Pharmaceuticals are detected in waterbodies all over the world. Antibiotics are of special concern for the environment (e.g. specific activity against prokaryotes, possible formation of microbial resistance). For the approval of pharmaceuticals in marine aquaculture, no marine prokaryotic test system is standardised and implemented in the risk assessment. Moreover, the question, if marine cyanobacteria can act as transfer factor for antimicrobial resistance is so far neglected in research. The akute marine sediment test with the amphipod *Corophium volutator* according to ISO EN DIN (16712) is applied in the European environmental risk assessment, but a more holistic approach considering effect on its microbiom and sublethal parameter are missing. Marine cyanobacteria are of high importance for the nitrogen cycle and primary production especially also in respect of climate change. In order to assess the effects of antibiotics to marine cyanobacteria, a marine cyanobacteria growth inhibition test (72h) with the species *Anabaena spec.* was developed. To investigate the potential of antibiotic resistance in marine cyanobacteria a multi generationtest with repeated exposition was developed. These results were compared to results from a standadized marine eukaryotic algae test. Antibiotics applied in aquaculture reach directly or indirectly not only the waterphase but also sediments. For the environmental risk assessment of single substances and sediments the acute amphipod test with *Corophium volutator* (EN ISO 16712) is an important test system. But the parameter mortality seems not reflect the effects to the species sufficiently, sublethal effects and effects of on the microbiom are of environmental importance and thus investigated in this study. Due to its environmental relevance, seven antibiotics were selected for both test systems. Environmental concentrations of antibiotics ($\mu g\ L^{-1}$) have an impact on ecosystem relevant non-target organisms. Marine cyanobacteria are more sensitive than marine eukaryotic algae to antibiotics in bioassays. The LC_{50} value for *C. volutator* and antibiotics is not sensitive enough to reflect the effects of antibiotics to the sediment dwelling amphipod Sublethal parameters are more suitable for an environmental risk assessment of antibiotics in the marine (sediment) environment. A underestimation of ecotoxicological risk in both cases is possible.

MO236

Antibiotics and antibiotic resistances in the environment - Options for action

U. Kuehnen, Federal Environment Agency; K. Westphal-Settele, German Environment Agency UBA / Section IV.2.2 Pharmaceuticals; S. Konradi, Federal Environment Agency (Umweltbundesamt) / Section IV 2.2 Pharmaceuticals; J. Schoenfeld, German Environment Agency UBA / IV 2.2 Pharmaceuticals

Large quantities of antibiotics are used in both human and veterinary medicine [1, 2]. Once partially metabolised and excreted by humans or animals, antibiotics are transported into the environment via wastewater, the spreading of sewage sludge or manure. Antibiotics can also enter ground or drinking water from surface waters and soils. In Germany, antibiotics have been regularly detected in all environmental compartments in recent years. In this context, antibiotics can inhibit the growth of cyano- and soil bacteria as well as plants and thus damage both aquatic and terrestrial ecosystems. Studies demonstrated that environmental bacteria are resistant to a variety of antibiotics and that this reservoir of antimicrobial resistances (AMR) is steadily increasing in the environment. In fact, there is evidence that at least some clinically relevant resistance genes from bacterial species originate from the environment. Manure and their digestates, for example, are often contaminated with antibiotic-resistant bacteria (ARB) and constitute as a "hotspot" for the transmission of resistance genes. In particular, the combination of various factors, such as large quantities of antibiotics and / or heavy metals (zinc and copper) and high bacterial densities has been shown to promote the spread of AMR. For precautionary reasons, a broad package of measures is needed to reduce the potential risks of the spread of ARB and antibiotic resistance genes in the environment. We proposing seven options for action – including the technical upgrade of wastewater treatment plants, linking the quantities of antibiotics used in the animal house with the documentation of manure parameters, the transfer of this information from manure production via fermentation to application on soils, as well as systematic monitoring of antibiotics and AMR in the environment [3]. Thus, the occurrence and dissemination of AMR in the environment, in terms of the "One-Health" approach, can be limited. MO237
The accessibility of data on environmental risk assessment of pharmaceuticals - the marketing authorization procedure in conflict with the international right of access to environmental information
K. Oelkers, HAW Hamburg / Department of Environmental Engineering; C. Floeter, Hamburg University of Applied Sciences / Environmental Engineering
The study examines the availability of environmental information on pharmaceuticals from the point of view of the active and passive information obligation established in the Aarhus Convention. In the EU, since 1998 (veterinary) and 2006 (human) pharmaceuticals have to be assessed for their environmental risks in the context of the marketing authorization. Nevertheless, most of the active pharmaceutical ingredients (API) on the market are authorized before this time ("old" APIs), thus there is a data gap on environmental risk assessments. For some years now, parts of the environmental information generated during the procedure of marketing authorization have also been published as part of the Public Assessment Report (PAR). This publicly accessible information does not sufficiently reflect the information from environmental risk assessments. The environmental risk assessments including their effect data are not publicly available. They are treated as confidential commercial or industrial information. Therefore, even environmental authorities, like the German Environment Agency, can't use the environmental information generated by the pharmaceutical companies to compile environmental quality standards. This is incompatible with Article 4 of the Aarhus Convention and the European and national implementing provisions for this article, which require access to such environmental information for everyone. The study concludes that this contradiction can only be resolved through a publicly accessible database of active pharmaceutical ingredients and their environmental risk assessment (including effect data). This would be the basis for a monograph system, as under the EU REACH Regulation and the Biocidal Products Regulation. The database should also be extended to "old" APIs for which environmental risk assessments have not yet been carried out.

The Overlooked Hazard of Small Creeks - Elucidating the Input and Fate of Organic (Micro-)pollutants in Streams (P)

MO238
How to design sampling approaches for deriving valid degradation rates of organic micropollutants in rivers
C. Glaser, Center for Applied Geosciences / Center of Applied Geoscience; C. Zarfl, University of Tuebingen / Center for Applied Geoscience; M. Werneburg, Center for Applied Geoscience (ZAG), Eberhard-Karls-University Tübingen / Center for Applied Geoscience; M.E. Müller, University of Tubingen; C. Zwiener, Environmental Analytical Chemistry, Center for Applied Geoscience, University of Tuebingen / Geosciences; M. Schwientek, Eberhard Karls Universität Tübingen / Center for Applied Geoscience
Anthropogenic organic micropollutants enter river systems mainly via wastewater treatment plants (WWTP). The characterization of turnover processes and fate of these compounds including also hydrological processes remains challenging in the field. This study will show the significant influence of the chosen sampling concept on derived degradation rates of organic micropollutants in river systems. Field investigations took place at two sequential reaches of the Ammer River close to Tübingen (Germany) in the southwest of Germany. Time-series measurements of the electrical conductivity (EC), conservative ions and organic chemical compounds (target screening) were conducted over a period of 24 hours, capturing the diurnal cycle of an upstream WWTP. A lumped parameter model approach including hydrological transport processes (advection and dispersion) was applied to derive degradation rate constants from comparing the same water parcel upstream and downstream of one reach. Calculating degradation rates from arbitrary grab samples entering and leaving the same reach led to different results. Dilution caused by tributaries and groundwater inflow was considered in both approaches. The difference in estimated degradation rates underlines their dependence on identifying and including hydrological boundary conditions of river systems and input dynamics of WWTPs.

MO239
Impacts of hydrological dynamics on the fate of pharmaceuticals in a small river - a model-based analysis
Y. Liu, University of Tubingen / Center for Applied Geoscience; C. Zarfl, G. Guillet, M. Schwientek, Eberhard Karls Universität Tübingen / Center for Applied Geoscience; N.B. Basu, University of Waterloo / Department of Civil and Environmental Engineering; O.A. Cirpka, Eberhard Karls Universität Tübingen / Center for Applied Geoscience
In recent years, emerging micropollutants, e.g. pharmaceuticals, at concentrations in the range of nano- to micrograms per liter have become a major concern for river water quality in industrialized countries. Since the fate and effects of these compounds in the environment are not completely understood model-based analysis of field experiments can help to elucidate their accumulation and attenuation processes in rivers. We thus developed a one-dimensional reactive solute transport model coupled with transient storage and applied it to the Steinlach River, a small river impacted by a WWTP in southwest Germany, to investigate the fate of representative pharmaceuticals and the effects of transient storage on pollutant removal. Taking advantage of tracer experiments and a Lagrangian sampling campaign performed both at day and night, the change of transient storage with changing flow rates was quantified and attenuation mechanisms for different pharmaceuticals were differentiated. Results show that transient storage plays a significant role for flow and solute transport in rivers, especially under low-flow conditions. The increase in transient storage ratio increases the travel time and thus affects solute transport. However, when river discharge is high, transient storage can be negligible. The studied river segment of the Steinlach River is 1310 meters long. While carbamazepine is relatively conservative along this section, sulfamethoxazole which is biodegradable shows a daily mean removal of around 13%. Metoprolol and venlafaxine undergo both photo- and bio-degradation leading to a daily mean removal of 23-26%. Degradation processes are substantially affected by local conditions, e.g. pollutant removal decreases with increasing flow rates. This influence is especially significant for pollutants that undergo biodegradation only. The model presented in this study provides a good tool to understand the fate of emerging contaminants and identify impacts of hydrological conditions on pollutant attenuation along rivers.

MO240
NAWA SPEZ 2017: Chemical and bioassay based risk assessment of pesticide mixture in Swiss streams for aquatic plants
M. Langer, Oekotoxzentrum Eawag-EPFL / Aquatic Ecotoxicology; M. Junghans, Swiss Centre for Applied Ecotoxicology EAWAG - EPF / Ecotox Centre; E. Vermeirssen, Swiss Centre for Applied Ecotoxicology EawagEPFL / Aquatic Ecotoxicology; I. Werner, Swiss Centre for Applied Ecotoxicology / Department of Anatomy Physiology and Cell Biology
Small streams represent 75% of the Swiss river network, but information about pesticide contamination as well as possible ecotoxicological effects in agricultural areas is still limited. To investigate the situation in Swiss streams, a special monitoring program (SPEZ) was conducted on five streams as part of the National Surface Water Quality Monitoring Network (NAWA) from March to October 2017. Composite 3.5-day water samples were taken continuously from March to October 2017 using automated sampling devices. Samples were extracted using solid phase extraction (SPE) and were subsequently analysed for over 200 organic pesticides using HPLC-HRMS. Additionally water samples or SPE extracts were analysed with bioassays to complement the chemical risks assessment. In a first step, we calculated acute mixture risks for aquatic plants based on the measured concentration (MEC) and the corresponding environmental quality standard (EQS). To calculate mixture risks we added the risk quotients (RQ= MEC/EQS) of all substances for which effect concentrations of aquatic plants were within a factor of 10 of the most sensitive species. At four out of five sampling sites at least one sample had a mixture RQ > 1, with a maximum RQ of 11. In a second step, we tested the ecotoxicological effects of the water samples using the combined algae assay using a green algal species *Raphidocelis subcapitata*. The Test endpoints were PS II inhibition (after 2h) and algal growth inhibition (after 24 h). Results were calculated as diuron equivalent concentrations (DEQ). Using the EQS for diuron, DEQs can thus be used to calculate bioassay based RQ. The combined algae assay showed elevated mixture RQ at the same sites where RQ >1 based on analytical data. Some of the tested water samples induced very high effects in the combined algae assay, resulting in an RQ of up to 17. In most cases, both methods correlated well, with the combined algae assay indicating slightly

higher risks. At one sampling site, the bioassay based RQ was up to 10 times higher than the chemical based RQ, which suggests the presence of undetected substances. Only when mixture risk was dominated by substances for which aquatic plants other than green algae were most sensitive, the chemical based mixture RQ were higher. Due to the high accuracy and the ease of handling the combined algae test it has proved to be a valuable tool to experimentally assess the mixture risk of pesticides for aquatic plants in environmental monitoring campaigns.

MO241

Spatial and temporal variability of pesticides in an agricultural catchment

M. Heinz, Julius Kühn-Institut - Federal Research Centre for Cultivated Plants / Institute for Ecological Chemistry, Plant Analysis and Stored Product Protection; S. Lorenz, Julius Kühn Institute, Federal Research Centre for Cultivated Plants; M. Stähler, Julius Kühn Institute, Federal Research Centre for Cultivated Plants / Institute for Ecological Chemistry, Plant Analysis and Stored Product Protection; H. Schuster, Niedersächsischer Landesbetrieb für Wasserwirtschaft, Küsten- und Naturschutz

Small streams are highly connected to their surrounding landscape and catchment alterations can immediately propagate to stream environments due to this close connection. As a consequence, pesticide inputs following applications of plant protection products at adjacent fields can pose a serious risk to aquatic organisms in streams that drain agricultural catchments. Inputs of pesticides can vary temporally and spatially within the catchment due to the heterogeneity of crops being cultivated in the catchment and the heterogeneity of bank structure along the stream course. Additionally, depending on the substance properties, in-stream processing of active substances affect their individual fate and transport along the stream course. We performed a two month sampling campaign monitoring 68 active substances of plant protection products to assess how the number and concentration of active substances vary temporally and along the stream in an agricultural catchment (~59 km²). The catchment investigated is characterized by a gradient of increasing agricultural land use intensity and lower contribution of near natural stream reaches from upper to the lower catchment areas. We applied a combined approach including time integrated sampling and high resolution active sampling. At six stations along the stream course passive sampler devices (Chemcatcher housing, SDB-RPS disk, PES membrane) were installed for three sampling intervals (three weeks each) to assess time integrated substance concentrations. Additionally, at two stations along the stream reach daily mixed samples (1 hour sampling interval) were collected using automatic water samplers. Active substances were analyzed with LC-MS/MS in extracts of passive sampler devices and in the water samples. Active substances with different functions (fungicides, herbicides and insecticides) were detected along the stream reach. In extracts of passive sampler devices 34 of 68 substances analyzed were detected. Moreover, the results indicated a tendency of increasing number and an overall increase of sum concentration of active substances, as well as increasing concentration of some individual substances along the stream course.

MO242

Targeted and non-targeted LC-MS workflows for the identification of dominant input sources and transformation processes of emerging pollutants in surface waters of a small but complex river system

M. Werneburg, Center for Applied Geoscience (ZAG), Eberhard-Karls-University Tübingen / Center for Applied Geoscience; C. Glaser, Center for Applied Geosciences / Center of Applied Geoscience; M.E. Müller, University of Tubingen; M. Schwientek, Eberhard Karls Universität Tübingen / Center for Applied Geoscience; C. Zarfl, University of Tuebingen / Center for Applied Geoscience; C. Zwiener, Environmental Analytical Chemistry, Center for Applied Geoscience, University of Tuebingen / Geosciences

Emerging (micro)pollutants and their metabolites are easily overlooked during routine environmental monitoring programs if they are not covered by existing water-quality regulations. The potentially high pollutant concentrations in small river systems due to a limited dilution power in relation to emissions from wastewater treatment plants and diffuse sources may pose a higher risk for living organisms there. Highly sensitive and selective analytical techniques are required for the challenging identification of the large number of mostly unknown compounds, complex matrices and low concentrations in the aquatic environment. For this reason, mass spectrometric (MS) techniques including low and particularly high resolution (HR) mass analyzers coupled to liquid chromatography (LC) are the method of choice to investigate river waters. The study aims to identify dominant input sources of micropollutants and to understand *in-stream* attenuation of micropollutants in a small but complex river system over distance and time. Therefore, surface water of the Ammer River, a tributary of the Neckar River close to Tübingen (South-west Germany), was investigated by Lagrangian sampling. A representative river segment was chosen that combines two reaches with different river morphologies and all existing/identifiable tributaries and ground water inflows. Samples were taken as grab samples or over 24 h at a temporal resolution of 1 h/6 h. A LC-QqQ-MS/MS target method was established and validated for the quantification of about 88 relevant organic pollutants including mainly pesticides and pharmaceuticals as well as their metabolites. Non-target screening data sets were generated by LC-QTOF-HRMS measurements. Generic data evaluation workflows were developed that allow the identification of unique input sources by applying logical correlations. Focusing on persistent pollutant metabolites, a comprehensive screening approach for about 60 abiotic and biotic transformation processes by an HR-mass shift driven procedure and Kendrick mass analysis was designed. In addition, a suspect screening for database-predicted transformation products of possible target analytes was included. In conclusion, an integrated approach of target, suspect and non-target techniques with emphasis on LC coupled to MS and unique workflow strategies revealed dominant input sources and relevant attenuation processes of emerging pollutants in the Ammer River.

MO243

Uptake calibration and modelling of Chemcatcher passive samplers for polar organic compounds

M. Grodtke, TU Bergakademie Freiberg / Institute of Organic Chemistry; D. Kessler, Helmholtz Center for Environmental Research UFZ / Department of Ecological Chemistry; A. Paschke, UFZ - Helmholtz Centre for Environmental Research / Ecological chemistry; G. Schuurmann, Helmholtz centre for environmental research - UFZ / Department of Ecological Chemistry

Passive samplers are easy-to-use and cheap alternatives to grab sampling for monitoring of waterborne micropollutants. The compounds are preconcentrated on a sorbent material and eluted in the laboratory after retrieval from the field. The range of target compounds mainly depends on the sampling phase used. A relatively new sorbent disk, the Atlantic HLB Disk, contains HLB (hydrophilic lipophilic balance) material which is fixed in a glassfibre body. It can be used in the modular designed Chemcatcher. For the calculation of time-weighted average water concentrations from the accumulated amounts of chemicals in the samplers, passive samplers need to be calibrated in the laboratory. Uptake kinetic was measured in a three week calibration experiment in a flow-through tank at 15 °C with polar pesticides and pharmaceuticals. The uptake results were fitted using different models (linear and nonlinear) and the influence of a diffusion limiting membrane was considered. Partitioning coefficients between water and sampling phase could also be derived from the models and were compared with results from batch equilibration experiments.

Micro(Nano)plastic Pollution: Tackling the Plastic Problem by Identifying Sources, Investigating Fate and Novel Approaches (P)

MO244

Emissions and mitigation of synthetic microfibres from machine washings and tumble dryings

M. Sillanpää, Finnish Environment Institute / Laboratory Centre; M. Sepponen, Finnish Environment Institute SYKE / Laboratory Centre

Synthetic microfibres released in cloth washing are assessed to be one of the major sources of primary microplastics into the environment. The annual emission of polyester microfibres from household washing machines has been estimated to be 150,000 kg in a country with population of 5.5×10^6 (Finland). The objectives of this study were 1) to quantify the emissions of synthetic textile fibres discharged from sequential machine washings and tumble dryings and 2) to determine the collection efficiency of two commercially available microplastic traps: washing bag (GuppyFriend) and washing ball (Coraball). The synthetic fabrics were four types of polyester textiles (two fleece fabrics, one softshell fabric and technical T-shirt), one technical T-shirt of polyamide and one jersey of polyacryl. All the fabrics were new/unused and they were separately treated in five sequential washing-drying cycles. For the assessment of microplastic traps, the new/unused and identical polyester technical T-shirts were washed as three replicates with and without the trap under the investigation. The replicate samples from total washing waters were filtrated and subsequently analysed gravimetrically and under an optical microscopy. The fibres released in the tumble drier were collected after each drying and their masses were determined. The number and mass of microfibers released from test fabrics in the first wash varied in the range 1.0×10^5 to 6.3×10^6 kg^{-1}, and 0.038 to 0.22 % w/w, respectively. The corresponding mass range in the first drying was 0.001 to 0.17% w/w. Fibre emissions showed a decreasing trend both in sequential washes and dryings. The ratio of machine washing to tumble drying varied between the fabrics: the ratio was nearly one or lower to polyester fleece fabrics whereas it was much larger to other tested textiles. GuppyFriend washing bag trapped approximately 30 % of the polyester microfibres discharged in washings whereas Cora Ball did not mitigate the emissions of microplastics on a mass basis. The sampling, sample pretreatment and identification/quantification methods have to be developed in order to get reliable information on the occurrence, abundance and environmental fate of these synthetic microplastics.

MO245

Synthetic microfibres and small microplastics in wastewater effluent

N. Kärkkäinen, S. Selonen, Finnish Environment Institute SYKE / Laboratory Centre; M. Sillanpää, Finnish Environment Institute / Laboratory Centre

The domestic washing of textiles is a major source of synthetic microfibres entering a wastewater treatment plant. It has been estimated that the annual emission of the most common synthetic fibre, polyester, from households is approximately 154,000 kg in Finland (population $5.5x10^6$). In earlier studies, wastewater treatment processes have been shown to remove effectively microplastics from wastewater influent to sewage sludge, but the synthetic microfibres have not been in the main focus of the studies due to the large volume samplings and high contamination risk. Consequently, the efficiency of wastewater treatment processes for synthetic microfibres and small microplastics is still poorly known. The objectives of this study are 1) to develop and optimise the sampling and pretreatment methods for low volume wastewater effluent samples and 2) to investigate the temporal variation of small microplastics in the effluent. Particular effort is put to mitigate and assess the sample contamination. The samplings are carried out as three replicates of 2 litre grab samples. The laboratory and field blank samples are handled identically with the effluent samples. The chemical and possible enzymatic sample pretreatment steps are conducted in a laminar flow hood. The sample preparation steps are optimised for an efficient removal of organic matter. Microplastics with the smallest dimension of ≥10 µm are identified by using a Fourier Transformation Infrared microscope (µFTIR; Spotlight 200i, Perkin Elmer). The number concentration of synthetic microfibres and microplastics are shown and the diurnal variation in number concentrations is discussed in the presentation.

MO246

Microplastic fluxes from a Swedish wastewater treatment plant

L.A. Rasmussen, L. Iordachescu, K.B. Olesen, Aalborg University / Department of Civil Engineering; J. Vollertsen, Aalborg University / Department of Civil Engineering, Section of Water and Environment

Waste from households, industries and urban run-off is usually collected in sewer systems. Large quantities of microplastics (MP) can be found in wastewater e.g. from MP in cosmetics or personal care products, release of synthetic fibers from washing of clothes, MP in urban runoff from air deposition or weathering of plastic materials. This creates a concentrated stream that needs to be treated before it can be discharged to a recipient. Recent publications show that wastewater treatment plants are effective in removing microplastics. It is suggested that the treatment processes lead to a concentration of the MPs in the sludge. Due to its high content of organic material, sludge is often used as a fertilizer on agricultural fields leading to a potential spreading of MP to the terrestrial environment. In this study, inlet samples as well as samples from coarse and fine screens (20 mm and 2 mm), digested sludge and effluent water was analyzed using µFTIR-imaging and ATR-FTIR. The grit samples were first sterilized using 10 % H_2O_2. Afterwards plastic-like particles were visually identified and sorted out. Before analysis, all other samples underwent a multistep sample preparation consisting of pre-treatment with SDS and H_2O_2, followed by enzymatic digestion, iron catalyzed oxidation with H_2O_2 (Fentons reaction) and, at last, density separation with $ZnCl_2$ at >1.7 g/cm^3. After sample preparation the samples were split in two fractions according to size: above and below 500 µm. MP particles above 500 µm, as well as those from the grit samples, were analyzed with ATR-FTIR. The smaller size fraction was concentrated in 5 ml of 50% ethanol from which a subsample was deposited on a ZnSe window and analyzed using FPA-µFTIR-imaging. MP was automatically identified from the acquired IR-map using our in-house software, MPhunter.

MO247

Occurrence of microplastics in municipal sewage treatment plant(STPs) in Korea

H. Park, M. Oh, P. Kim, Korea University; H. Kang, Knoell Korea; G. Kim, DongMoon ENT Co.Ltd, Seoul, Korea; B. Ju, D. Jeong, W. Lee, National Institute of Environmental Research; J. Kwon, Korea University / Division of Environmental Science and Ecological Engineering

Municipal sewage treatment plants (STPs) are suspected to be major point sources of microplastics in freshwater systems. In order to know the occurrence of microplastics in Korean STPs, a preliminary nationwide monitoring of microplastics in STP influents and effluents was conducted in 50 STPs covering wide range of treatment capacity over the country. Triplicate samples of 20 mL influents were filtered through 100 µm filter and 1000 L effluents were passed through a custom-made sampling sieve (pore size of 100 µm). Filtrates were further treated using wet peroxidation using hydrogen peroxide and density separation using zinc chloride solution. Isolated particles were identified under a Fourier-transform infrared spectroscopy (FT-IR) and a dissection microscope. Recovery of polyethylene particles added to influent samples was over 85%, supporting that the method is acceptable for monitoring microplastics. Thermoplastics and synthetic fiber were main materials of microplastics in STPs. Typical number concentration ranged 200-1,000 particles per liter in influents and 0.01-0.3 particles per liter in effluents. Daily microplastic flow to STPs was estimated approximately 200,000 particles per capita-day, close to recent assessment in other countries. Removal efficiency of microplastics in STPs were mostly greater than 99.9%. In addition, it was found that typical anaerobic/anoxic/oxic (A2O) processes remove incoming microplastics significantly better than biocube sponge processes. Particle size distribution of isolated microplastics followed a power law relationship down to the cutoff size (100 mm), implying that majority of microplastics are secondary microplastics.

MO248

Microplastics loading estimation from urban areas to sewage treatment plants based from a monitoring campaign in Japan

Y. Kameda, Chiba Institute of Technology / Creative Engineering

One of a main land-based sources of micropalstics (MPs) released to aquatic environment is considered to be human activities such as our daily life, industrial activities, agricultural activities and so on. These MPs are released to wastewater and runoff water from sources and finally flow into sewage treatment plants (STWs). To control the concentration in surface water, it is important to estimate the load from urban areas to STWs and reveal the removal rates at STWs. In this study, a MPs monitoring campaign was performed in order to measure the concentration in raw wastewater samples and effluent water samples at approximately 20 STPs in Japan. The concentration variations in raw wastewater samples during a day were also investigated. MPs in raw wastewater and effluent water samples were analyzed by our novel analytical method “automatic microFTIR with Multivariate Curve Resolution analysis and Correlation analysis”. Each polymer type microplastics less than 100µm are qualified and quantified into each shape types such as fragments, spheres, fibers and so on. Based on these data, microplastics loading per capita to STWs can be estimated statistically. Removal rates are also estimated at Japanese STPs. These data will be used to simulate their concentrations in rivers and bays near large cities by simulation models. This presentation will show some results in this monitoring campaign.

MO249

Microplastic in Biosolids and Agriculture Soils Receiving it as Fertilizer

K.B. Olesen, Aalborg University / Department of Civil Engineering; P. Anderson, Hushållingssällskapet; E. Fältström, Sweden Water Research AB; J. Vollertsen, Aalborg University / Department of Civil Engineering, Section of Water and Environment

Microplastics (MP) have been measured in large abundance in wastewater. Recent studies showed that wastewater treatment plants effectively retain MP, since low MP concentrations are measured in the effluent compared to the influent. However, this indicates that MP likely accumulates in the wastewater sludge. This sludge has a high content of organic material and phosphorous and is hence commonly used as agricultural fertilizer. This use of sludge could potential cause spreading of MP to the terrestrial environment, a process that hitherto has received little attention. This study focuses on the abundance of MP in the size range 5000-10 µm in agriculture soils that have received wastewater sludge as fertilizer (biosolids) for the last 35 years. It presents a protocol of sample preparation as well as field data. In Malmö, Sweden, three fields were sampled. One field had received 3 tons/ha of biosolids, another 1 ton/ha and one had received mineral fertilizer only. From each field, 40 kg of soil were sampled from the top soil layer and brought back to the lab for analysis. The microplastic concentration was in general low. Hence the soil had to undergo extensive treatment to extract the plastic particles, and protocols were developed for this purpose. Upon extraction the MP were analysed on a state-of-the-art FPA-µFTIR-Imaging system (10-500 µm MP) and ATR-FTIR (500-5000 µm MP). The FTIR-analysis showed the following MP concentration-tendency; Soil with 3 tons/ha > soil with 1 ton/ha > soil receiving mineral fertilizer only. However, the detected MP concentration in the soil fertilized with a biosolids load of 1 ton/ha and the soil receiving no biosolids were rather close. Overall, the results showed that more plastic types were found in the soil fertilized with biosolids compared to the soil that received mineral fertilizer only. This indicates that the composition of MP in soil may have been affected by the biosolids load.

MO250

Occurrence of fine microplastics and other emerging debris in Lake Bikal

Y. Kameda, Chiba Institute of Technology / Creative Engineering; M. Yamamuro, Tokyo Unversity; M.V. Moore, Wellesley College; O.A. Timoshkin, Limnological Institute SD RAS

Lake Baikal is the largest freshwater lake by volume in the world. There are many researches about chemical contaminants in the lake such as PAHs, PCBs, Dioxins and so on. However there are few researches about microplastics (MPs). This psesentation will reveal occurrence of MPs in Lake Bikal. The surface water samples were collected and were passed through 10 µm nets. MPs in the collected particles were extracted by H_2O_2 digestion and NaI density separation. The MPs on a membrane were identified and quantified by our novel analytical method “automatic microFTIR with Multivariate Curve Resolution analysis and Correlation analysis”. This presentation will show tha characteristics of MPs in Lake Bikal.

MO251

Occurrence of fine microplastics and other emerging debris from a river in Japanese urban area

Y. Kameda, Chiba Institute of Technology / Creative Engineering

An occurrence of microplastics (MPs) was investigated in contaminated river water located in a Japanese metropolitan area. The surface water samples were collected at 5 sites from the upstream site to the downstream area. The collected samples were passed through 10 µm nets. MPs in the collected particles were extracted by H_2O_2 digestion and NaI density separation. The MPs on a membrane were identified and quantified by our novel analytical method "automatic microFTIR with Multivariate Curve Resolution analysis and Correlation analysis". By our methods, many fine MPs whose sizes ranged from 10 µm to 100 µm were observed. The concentration was over one thousand particles in 1 m^3 which was much higher than those in previous studies. The changes of the each polymer concentration from upstream to downstream were also evaluated as well as the impact of release from sewage treatment plants and runoff water from a city area. In the middle reach site, a large amount of white fibers were found with MPs. These fibers were identified as asbestos by the analysis method. The origin of them was estimated to be building construction site near the river. This presentation reveals environmental behaviors of ordinary large MPs as well as fine MPs and new emerging debris in the polluted river.

MO252
First evidence of microplastics in the sediments of the Limfjord: hydrodynamic modelling-based sampling combined with FPA-µFTIR-Imaging automated analysis

A. Vianello, T.R. Bentzen, Aalborg University / Civil Engineering Department Section of Water and Environment; L. Iordachescu, Aalborg University / Department of Civil Engineering; J. Vollertsen, Aalborg University / Department of Civil Engineering, Section of Water and Environment

Microplastic (MP) pollution is a global concern affecting almost the totality of the water bodies, including transitional environments such as lagoons, salt marshes, and estuarine areas. Monitoring activities are hence paramount to fill knowledge gaps on MP occurrence and spatial distribution. Therefore, we conducted the first MP sediment monitoring survey of the Limfjord, the largest Danish fjord (1500 km^2). Its average depth is 4.9 m, with a freshwater average inflow of 2.7 km^3 y^{-1} and a net flow of 6.8 km^3 y^{-1} passing from west to east due to the wind and tidal impacts. The total catchment area (7600 km^2) includes Aalborg (~130000 inhabitants) and other smaller cities, harbours and shellfish farms along the shores. The sampling locations were selected taking into account the hydrodynamical conditions and considering the bed shear stress induced by the currents as the main parameter for sedimentation, erosion, and resuspension of materials. The shear stress was modelled with a calibrated non-steady hydrodynamic model (MIKE3FM), including both effects of time-varying boundary conditions, stratified conditions due to salinity gradients and wave-induced currents based on a spectral wave calculation. Sampling was conducted in areas with low bed shear stresses, where the light material is expected to settle, also considering potential direct MP sources and sampling both up and downstream of the major city (Aalborg), WWTPs and riverine inputs. Samples were collected with a Van Veen grab, processed by flotation ($ZnCl_2$) and multi-step sample clean-up (enzymatic treatment, Fenton reaction), then analyzed by FPA-μFTIR-Imaging spectroscopy/MP auto-analysis (MPhunter). Preliminary results showed a diffused MP contamination (600-4000 part. kg^{-1} and 50-900 μg kg^{-1}), highlighting higher concentration at the urban stations and downstream the city, but highly depending on the hydrodynamic conditions (location with higher bed shear stress showed a lower MP abundance). The polymer composition showed mainly polyethylene (25%), polypropylene (26%), polyester (17%), and polystyrene (17%). Although the MP concentration cannot be directly correlated to the mud % and to the shear bottom stress in a dynamic environment like the Limfjord, the combination physical systems' understanding (e.g. throughout modelling) and unbiased analytical measurements provides powerful tools to improve data quality and, therefore, a better understanding of MP spatial distribution.

MO253
Occurrence of fine microplastics and other emerging debris in aquatic biota at a contaminated bay compared with those in Japanese tropical area

Y. Kameda, Chiba Institute of Technology / Creative Engineering

An occurrence of microplastics (MPs) was investigated in oysters in a polluted large bay, Tokyo bay compared to beaches in Okinawa, tropical island in Japan. The oyster samples were collected at several points along the Tokyo bay and several areas at Okinawa. The collected samples were digested by KOH and extracted by NaI density separation. After the separation, H_2O_2 digestion was performed. Finally the particles were collected on a membrane. The MPs on a membrane were identified and quantified by our novel analytical method "automatic microFTIR with Multivariate Curve Resolution analysis and Correlation analysis". By our methods, many fine MPs whose sizes ranged from 10 µm to 100 µm were observed. The MPs profiles were different among sites even in Tokyo bay. These results indicated that some of MPs in oysters might be originated from land-based MPs or those from sewage treatment plants. A large amount of alumina particles and other particles were also identified in oysters by our method. These new particles are not measured in recent researches. Their toxicity and ecological risk assessment will be necessary and this method is a powerful tool for non-target analysis of particles in aquatic organisms.

MO254
Understanding sources and transport of microplastic pollution to the Canadian Arctic

J. Adams, University of Toronto / Earth Sciences; L. Jantunen, Environment and Climate Change Canada / Centre for Atmospheric Research Experiments & Department of Earth Sciences; M.L. Diamond, University of Toronto / Department of Earth Sciences; S.A. Finkelstein, C.M. Rochman, S. Bernstein, University of Toronto; G. Stern, Fisheries and Oceans Canada

Evidence continues to emerge showing the ubiquitous distributions of microplastics in the environment, and there is growing evidence showing their presence in remote Arctic environments. The presence and impact of microplastics in the Arctic may be exacerbated by climate change, due to increased ship transportation through the north-west passage, changing air and ocean circulation, and release of microplastics from melting of multi-year sea ice. Our research aims to determine the extent of microplastic contamination across the Canadian Arctic archipelago and Hudson Bay marine systems, and to evaluate sources and transport pathways of the microplastics. Fourteen surface sediment (0-5 cm) samples were collected between 2014 and 2017 across approximately 3,300 km of the Canadian Arctic archipelago (CAA) marine system. An additional seven surface sediment samples were collected from Hudson Bay in 2018. Sediments were collected from water column depths ranging from 40 to ~1500 m using a box corer, as part of the Northern Contaminants Program during yearly ArcticNet expeditions. Sediments were examined for microplastic particles > 20 μm, specifically particle abundance, distribution and characteristics. Field and laboratory blanks were collected and processed concurrently. Our data indicate the presence of microplastic particles in all 14 CAA samples. However, there was great spatial heterogeneity of abundances; blank-corrected counts varied by an order of magnitude across sites, from 700 to 6,700 particles/kg dried sediment. Blanks contained 0-5 particles/sample, all of which were fibers. The dominant particle type in samples was fibers, ranging from 60 to 100% of particles per sample. The greatest abundances of microparticles were found in the western Arctic offshore of Alaska in the Beaufort Sea, and in the deposition zone of the Mackenzie River, Northwest Territories, as well as in the eastern Arctic surrounding Baffin Island and in the Davis Strait. Our results indicate the ubiquity of microplastics across the Canadian Arctic marine systems, and that microplastics likely undergo long-range transport via oceanic and air currents, and riverine systems to reach the Arctic. In addition, local sources may contribute to microplastic abundance, even in remote environments.

MO255
Occurrence and distribution of metals in plastic litter from Spanish Mediterranean coasts

S. Muniategui, Universidade da Coruña / Analytical Chemistry; C. Moscoso-Pérez, J. Moreda-Piñeiro, V. Fernández-González, Universidade da Coruña; V.M. León, Instituto Español de Oceanografía, Centro Oceanográfico de Murcia

Marine litter is a global problem, and is known to negatively affect the environment in several ways. Less understood, however, is the role of plastics in providing a vector for exposure to and accumulation of chemicals that are adsorbed to or incorporated within the polymeric matrix. Moreover, the majority of studies have targeted persistent organic pollutants, but very little attention has been paid to the occurrence and impacts of metals in marine litter [1]. Once released into the marine environment, plastic litter inmediately begins to undergo a variety of weathering processes. The process is influenced by polymer type and the presence of additive chemicals such as metals and metalloids, currently used as catalysts, biocides, pigments for colour and UV and heat stabilisers [2]. In this study, plastic litter was sampled at three Iberian Peninsula Southeastern beaches (Calblanque, Cape Cope and La Llana), each affected by different predominant anthropogenic activities (tourism, agriculture, urban, etc). Plastic litter was characterized by ATR-FTIR, and RX fluorescence was used as a semiquantitative technique that indicates the main metals contained in the samples. PE and PP were the most abundant polymers present at the plastic litter in two coastal areas (Cape Cope and Calblanque) whereas PA was the predominant one in La Llana. The presence of Ca, Cl, Al, Fe and Ti has been found in most of the analyzed samples. From the results here shown it is clear that plastics present at marine litter constitute a pollution vector, but our findings highlight the need for further studies and because of that we are studing the desorption of these pollutants for the first 24 hours to seawater to estimate their potential transfer to the seawater as it has been previously determined for organic contaminants [3]. MO256
Microplastics in Santa Catarina Island, Southern Brazil: occurrence, distribution and characterization

J. Leonel, Universidade Federal de Santa Catarina / Oceanography Departament;

D.G. Zanetti, C.K. Andreussi, Universidade Federal de Santa Catarina
Once in the marine environment, plastics represent a global concern with ecological, health and economic consequences. Plastics causes entanglements, act as a transport vector for contaminants, and cause large financial costs through lost tourism. In Brazil, several studies reported different-size plastics on sandy beaches, but there is no data regarding microplastics in Santa Catarina Island. Therefore, in the present study microplastics (0.5 - 5 mm) were quantified and characterized by FTIR analyis in ten beaches from Santa Catarina Island, an important area for tourism and mariculture. A total of 572 particles classified as fragments (47%), pellets (37%), fibers (2%) or styrofoam (14)%. Concentrations ranged from no items to 36 itens m-2 and from 1.32 to 126 itens m-2 in the backshore and strandline, respectively. Northern Moçambique was the place with the greater concentrations (126 and 64 itens m-2, respectively). Since Northern Moçambique, located inside a State Park, is neither a popular place for tourism nor for the practice of aquatic sports the highest values of debris could only be explained by physical features and/or beach dynamics. Northern Moçambique was the beach with the largest concentration of mesoplastics, follow by Brava > Pântano do Sul > Lagoinha do Norte > Ribeirão da Ilha > Barra da Lagoa > Joquina> Sanbaqui ~ Solidão. Lagoinha do Norte > Brava > Ribeirão da Ilha > Sambaqui ~ Southern Moçambique > Pântano > Solidão ~Sambaqui. Accumulation of mesoplastic can be affected by physical features, beach dynamics, proximity to urban centers and presence of beach goers. Since Northern Moçambique, located in the northern portion of Rio Vermelho State Park, is neither a popular place for tourism nor for the practice of aquatic sports the highest values of debris could only be explained by physical features and/or beach dynamics. On the other hand, both Solidão and Sambaqui are well protected beaches with low urbanization.

MO257
Characterization of microplastics in sand of the Concepción bay, central Chile
V.G. Aburto, University of Siena / Department of Environmental Sciences; K. Pozo, M. Torres, W. Urbina, Universidad San Sebastián / Facultad de Ingeniería y tecnología; D. Nuñez, Centro de investigación de polímeros avanzados; M. Baini, University of Siena / Department of Physical, Earth and Environmental Sciences; M. Fossi, University of Siena / Department of Physical Sciences, Earth and Environment; P. Oyarzún, Universidad San Sebastián / Facultad de Ingeniería y tecnología
In recent years, there has been increasing concern about "microplastic particles" (MP) (plastic fragments smaller than 5 mm) in the environment. Due to their small size, MP are considered bioavailable for organisms throughout the food chain and for humans. In Chile, recent studies have detected microplastic in abiotic matrices along the Chilean coast. In this study we assess the occurrence of MP in sand samples from Concepcion Bay which is a coastal ecosystem with a vital role in the economic sustainability of the Biobío region of central Chile. The bay holds several beaches, along the coast, used for recreational activities by the population during the summer period. In this study we have characterized MP, in sand, of the beaches of Concepción bay, in central Chile, during two years in different seasons in order to preliminary assess population exposure to MP. Samples of MP were collected and analyzed physically and chemically. Samples (250 g) were collected in four location of the bay, six beaches: i) Dichato, ii) Coliumo, iii) Tome (Bellavista, Morro, Estación) and iv) Penco, during four seasons (September 2015 (winter) - March 2018 (Summer)). Samples were taken in glass bottles and analyzed using a saline solution (NaCl 1.2 kg/L) and filtered using a filtration system under vacuum, with glassfiber filters (Whatman GFF). Then, the samples were analyzed physically (size, colour and shape) using optical microscope with an integrated camera, Leica DM 750 and chemically screened under a FT-IR spectrometer Agilent Cary 630. The preliminary results of MP in sand samples showed, in general, an average abundance of 0.07 ± 0.04 MP items/g, showing greater abundance in summer season. The physical characterization showed the predominance of MP < 0.5 mm in the different sampling sites as follow: Coliumo beach (67%), Tome - Estación (50%) and Dichato (67%)); the most abundante MP shape was fiber (Bellavista (72%), Estación (50%) and in the Morro beach (54%)); solid MP pieces accounted for 34% for Coliumo and 67% for Dichato. The colour with the highest frequency of detection was red colour (detected at Coliumo (50%), Bellavista (43%), Estación (50%) and Dichato (38%)), and black colour (Penco (60%) and Morro (46%)). The polymer analysis showed that the most frequent plastics identified were polypropylene. These data are the first information of MP in Concepción Bay and are consistent with other studies in the scientific literature.

MO258
Occurrence of fine microplastics and other emerging debris in seawater from Japanese tropical area
Y. Kameda, Chiba Institute of Technology / Creative Engineering
An occurrence of microplastics (MPs) was investigated in seawater in a contaminated bay, Tokyo bay compared to that in Okinawa, a tropical island in Japan. The seawater samples were collected and passed through 10 µm nets . MPs in the collected particles were extracted by H_2O_2 digestion and NaI density separation. The MPs on a membrane were identified and quantified by our novel analytical method "automatic microFTIR with Multivariate Curve Resolution analysis and Correlation analysis". Amount of large plastics debris comes to Okinawa coastal area from China and other Asian countries. But many MPs in seawater at beach were black fibers in a beach. These MPs were identified polyvinyl alcohol and similar to nets used by fishermen. Many particles were identified as salt of stearic acid, whose log Kow is 4.13. This method could detect many small MPs which were not identified by visual inspection.

MO259
Investigating the effect of urbanisation on microplastic pollution, water quality and pollutant sensitivity of Daphnia magna: a case study in pond surface waters of Birmingham, UK
R.M. Adams, The University of Birmingham / Geography, Earth and Environmental Sciences; K. Reilly, S. Supian, University of Birmingham / geography earth and environmental sciences; I. Lynch, University of Birmingham / Geography Earth Environmental Science; J. Sadler, The University of Birmingham / Geography Earth Environmental Science
Freshwater habitats have been shown to accumulate concentrations of microplastics (MPs) equalling or exceeding those reported for the marine environment. Due to the variation of potential point (wastewater) and diffuse (road run-off) sources of MPs into the urban aquatic environment, the presence and sensitivity of keystone species to MPs within this ecosystem is of great interest. \n A study conducted at 15 ponds spanning an urban-rural gradient in and around Birmingham, UK aimed to address the following aspects of MP freshwater pollution: (1) the scale and characteristics of freshwater MP pollution by assessing the types and sizes of MPs present, (2) the water quality of the sites determined through parameters such as dissolved oxygen and the presence of macronutrients, and (3) the abundance of *Daphniidae* and their sensitivity to further pollutant exposure following acclimatisation in the lab. Environmental parameters such as pH, temperature, conductivity and flow rate were taken at each pond. \n MPs were classified by morphology (e.g. fragment, fibre, spherule, foam, sheet), size, colour and polymer type using microscopy techniques and Fourier-Transform Infrared Spectroscopy (FTIR). From the invertebrate samples, *Daphnia magna* were identified and counted before being cultured in borehole water for several generations prior to EC_{50} determination following exposure to sodium dodecyl sulfate and 1 μm carboxylate-modified polystyrene MPs individually and as mixtures. These were conducted to ascertain if the daphnids' sensitivity to pollutants varied depending on the level of urbanisation and pre-exposure to MPs in the locations they were collected from. Water quality was assessed and compared to current standard media (e.g. HH COMBO) for daphnids in terms of the macronutrient availability determined using ICP-MS analysis of the major ions. Field parameters combined with suspended solids and ion concentrations allowed further understanding of the variability of water quality across the sampled sites. \n Combining the various elements allows us to hypothesise the links between water quality and growth conditions of *Daphnia* in their natural habitat and how their environmental history can affect their sensitivity to subsequent pollutant exposures even after several recovery generations in clean water.

MO260
Size matters: ingestion of relatively large microplastics contaminated with environmental pollutants posed little risk for fish health and fillet quality
G. Asmonaite, University of Gothenburg / Department of Biological and Environmental Sciences; K. Larsson, I. Undeland, Chalmers University of Technology; J. Sturve, University of Gothenburg / Department of Biological and Environmental Sciences; B. Carney Almroth, University of Gothenburg Sweden / Department of Biology and Environmental Sciences
In this study, we investigated biological effects associated with ingestion of polystyrene (PS) microplastic (MPs) in fish. We examined whether ingestion of contaminated PS MPs (100-400 μm) results in chemical stress in rainbow trout*(Oncorhynchus mykiss)* liver and we explored whether this exposure can affect the oxidative stability of the fillet during ice storage. Juvenile rainbow trout were fed for 4 weeks with four different experimental diets: control (1) and feeds containing virgin PS MPs (2) or PS MPs exposed to sewage (3) or harbor (4) effluent. A suite of ecotoxicological biomarkers for oxidative stress and xenobiotic-related pathways was investigated in the hepatic tissue, and included gene expression analyses and enzymatic measurements. The potential impact of MPs exposure on fillet quality was investigated in a storage trial where lipid hydroperoxides, loss of redness and development of rancid odor were assessed as indications of lipid peroxidation. Although, chemical analysis of PS MPs revealed that particles sorb environmental contaminants (e.g. PAHs, nonylphenol and alcohol ethoxylates and others), the ingestion of relatively high doses of these PS MPs did not induce adverse hepatic stress in fish liver. Apart from a small effect on redness loss in fillets, PS MPs ingestion did not affect lipid peroxidation or rancid odor development, thus did not affecting fillet's quality.

MO261
Ingestion and transfer of microplastics pre-incubated with and without crude oil in the planktonic food web
a. gomiero, International Research Institute of Stavanger / Enviromnent; M.

Arnberg, R. Katrin Beckmann, S. Bamber, NORCE Norwegian Research Centre
Marine debris is a growing problem to which plastic makes a major contribution. Once released in the marine environment large plastic items can undergo several chemical and physical degradation processes. Photooxidation, weathering and mechanical fragmentation from wave action all contribute to the generation of smaller-sized particles, such as microplastics. A decrease in particle size may increase its bioavailability and its potential threat to aquatic life. Recent studies have identified several different adverse effect mechanisms. Plastic fragments can significantly alter the ecophysiology of marine organisms by clogging the gut and digestive system, inducing starvation as well as histological alteration of organs. In addition, there is growing evidence of the ability of microplastics to adsorb and act as carriers for organic contaminants, hence promoting their global distribution and accumulation in marine organisms through trophic levels. The combined effect of microplastic and absorbed contaminants ton aquatic food webs is still poorly understood. To address this, food web transfer experiments were performed by exposing brine shrimp, Artemia salina, to mixtures of artificial and natural particles. The first hypothesis tested was that brine shrimp were unable to discriminate between particle types [hypothesis 1]. The chlorophyceae algae, Dunaniella salina (3-6 μm), and Texas red stained fluorescent microbeads were used to test the hypothesis. A second line of research tested the hypothesis that microplastic particles were able to transfer adsorbed organic pollutants from microplastic to target organisms as well as promote the transfer of chemicals from one food level to another [hypothesis 2]. Northern shrimp (Pandalus borealis) larvae were fed with brine shrimps pre-incubated with microplastics spiked with oil.

MO262

Screening of HBCD Enantiomers Transported by Microplastics in Wastewater Treatment Plants

K. ZHANG, City University of Hong Kong / State Key Laboratory of Marine Pollution; Y. Ruan, The State Key Laboratory in Marine Pollution / State Key Laboratory in Marine Pollution; C. Wu, Institute of Hydrobiology; P.K. Lam, City University of Hong Kong / State Key Laboratory of Marine Pollution

Microplastics are commonly defined as those plastic particles whose diameters are < 5 mm. As a kind of synthetic polymers, microplastics can persist in the environment for a long time. The sorption of environmental contaminants on these microplastics may be a cause for environmental and health concern due to the possible desorption of these contaminants *in vivo*. Hexabromocyclododecane (HBCD), a commonly used flame retardant, exhibits strong hydrophobicity, and thus has a high capacity of being sorbed on hydrophobic particles such as microplastics from the aqueous phase. Despite this, the sorption and desorption behavior of HBCD enantiomers on microplastics is still largely unknown. Wastewater treatment plants (WWTPs) are considered as an important source of microplastic pollution. We have carried out an investigation on microplastics in two typical WWTPs in Hong Kong, with an aim to examine the abundance of microplastics in different treatment stages from the WWTP, and the sorption/desorption behavior of HBCD enantiomers on the microplastics present in the WWTPs. Results showed that the abundances of microplastics in the two WWTP effluents were 0.27 and 0.4 particles/L, respectively, which was in the medium level compared to other studies. The removal efficiencies of microplastics reached 86.9% and 60.4%, indicating that the treatment methods were not efficient for microplastic removal. No obvious trend or tendency was found for that the proportion of different microplastic sizes shifted in different treatment stages, indicating that the removal of microplastics did not have a preference in size. HBCD was detected in two samples from one WWTPs and the total concentrations were as high as 502.3 and 4184.4 ng/g. The concentration of HBCD carried by microplastics in the final effluent was much higher than in the settled sewage, which was opposite to HBCD distribution in the aqueous phase in the WWTP. The enantiomeric patterns of HBCD were different in the sewage and carried by microplastics, which might indicate that the HBCD stereoisomers have different behaviors in the aqueous and solid phases. For the first time, the amount of HBCD carried by microplastics was estimated in the WWTPs of Hong Kong. The study brings new insight into the fate of microplastics and the role of the vector for pollutants transportation.

EXTRACTION AND DETERMINATION OF PERSONAL CARE PRODUCTS ADSORBED ON MICROPLASTICS

R. Guedes-Alonso, S. Mondesdeoca-Esponda, S. Viera, Universidad de Las Palmas de Gran Canaria / Chemistry; Z. Sosa-Ferrera, J. Santana-Rodríguez, Universidad de Las Palmas de Gran Canaria / Department of Chemistry

At present, images of floating garbage and beaches full of plastics have attracted media attention as a real evidence of human impacts on environment. In fact, concern about the presence of plastics in oceans and seas and the effects on aquatic biota is increasing, not only among scientists, but also on policy-makers [1]. From the huge variety of plastics which arrive to water body, microplastics (MPs) have revealed as the most concerning ones. Plastics with a size lower than 5 mm are considered as MPs and they are found, not only in waters but also in sediments or aquatic organisms of all water bodies of the globe [2]. Because of their physicochemical properties, microplastics are considered a new toxic actor for aquatic organisms. In fact, in the last years, many scientific studies have been focused in the quantification of these pollutants. Nevertheless, the possibility that other pollutants as organic molecules could be adsorbed on microplastics have been not studied enough and this phenomenon could produce that the toxicity of microplastics could be even worse. Among the pollutants that have been studied adsorbed in MPs are polychlorinated biphenyls (PCBs), organochlorine pesticides (OCPs) and polycyclic aromatic hydrocarbons (PAHs). To our knowledge, the lack of studies about sorption of pharmaceuticals on MPs makes necessary the study of this topic. In relation to extraction techniques, the use of soxhlet, ultrasounds and solvent soaking stand out [3]. In this work, we propose an extraction method for the extraction of pharmaceutical compounds adsorbed onto MPs with the aim of studying which factor affects the most its adsorption and desorption. T-shirt in a Sandwich: A novel passive sampling approach for analyzing SVOC release from clothing during laundering

S. Athey, University of Toronto / Earth Sciences; J. Urík, Masaryk University / RECETOX Research Centre for Toxic Compounds in the Environment; B. Vrana, Masaryk University, Faculty of Science, RECETOX / RECETOX Research Centre for Toxic Compounds in the Environment; M.L. Diamond, University of Toronto / Department of Earth Sciences

Clothing and other textiles can accumulate chemical contaminants from the environment. Chemical additives are also often added to clothing during production. Clothing has been shown to release brominated flame retardants (BFRs) and organophosphate esters (OPEs) as well as fibres into wash water during laundering. However, the proportion of chemicals bound to released fibres versus solubilized into wash water has not been investigated yet, to our knowledge. Our goals were to address the following questions: (1) What fractions of chemicals released during the washing of clothing are solubilized in wash water vs sorbed to released fibres? (2) Can silicone rubber (SR) passive samplers be used to approximate the maximum chemical fraction in textile that can be easily solubilized during washing? (3) Can the distribution of the fibre-sorbed vs easily solubilizable fraction be predicted based on physical-chemical properties of the textile material and chemicals of interest? SR has been used as an effective passive sampling device for chemical contaminants in a variety of environmental matrices. Here we show the use of a novel contact passive sampling technique to investigate chemical partitioning of BFRs and OPEs between wash water and clothing. The novel method is based on the application of a 'SR sandwich' that consists of a single layer of clothing sandwiched between two layers of SR and allowed to sample over a two-week period. We tested the sandwich using 40 cotton t-shirts worn for 24 hours by volunteers. Four strips were cut from each t-shirt and treated one of the following ways: (a) extraction for total chemical concentration prior to washing, (b) contact passive sampling using the 'SR sandwich' for the portion of the chemical contaminants that are readily releasable from the material, (c) simulated washing followed by extraction of the t-shirt strip and the water for total concentration released into water and residual concentration in the t-shirt strip, and (d) simulated washing followed by extraction of filtered wash water for solubilized chemicals that leached from the material during washing. The fraction of chemicals sorbed to released fibres was estimated by subtracting the concentration of compounds in filtered wash water from the total chemical concentration in wash water (containing fibres). These results provide evidence for the role of microfibres released during washing as conduits for chemical movement from the indoor to outdoor environment.

MO265

Adsorption behaviour of musk fragrances on LDPE microplastics

S. Muniategui, Universidade da Coruña / Analytical Chemistry; C. Moscoso-Pérez, P. López-Mahía, D. Prada-Rodríguez, Universidade da Coruña

Microplastics (MPs) and synthetic musks are organic pollutants of great concern in the marine environment.There are many sources of microplastics, including cosmetic additives, laundry wastewater, and the photolysis of large plastics, and are potential carriers of organic pollutants due to their recalcitrance and high specific surface area. On the other hand, synthetic musks have been widely manufactured and used as fragrance additives in chemical commodities for daily use, such as perfumes, cosmetics or shampoo. [1] Synthetic musks have been detected in several environmental samples and due to they are only partially biodegradable, they are not completely eliminated by wastewater treatment plants (WWTPs). To date, environmental regulatory limits have not been set for these compounds, and it is extremely important to study their occurrence in the environment, in order to determine whether they can be considered hazardous for human health and environment. [2] In this stydy, the adsorption of six synthetic musks (Celestolide, Galaxolide, Tonalide, Musk xylene, Musk moskene and Musk ketone) by low density polyethylene (LDPE) was investigated. The assessment of the changes and processes that MPs suffer during weathering is essential to understand their effects in the environment, and therefore the tests were made with pristine and weathered LDPE. The adsorption experiments were performed at room temperature (20ºC) and at 4ºC using simulated seawater prepared with sea salt. Samples were collected at 24, 48, 96 and 168 hours. The adsorption to the plastic is observed already at 24 hours. Moreover, adsorption capacity was affected by temperature which is explained because the compounds have lower solubility in water at low temperatures, and few differences are observed between the pristine plastic and the weathered one. Soil physicochemical property dependent toxicity of microplastics on nematode species

S. Kim, Konkuk University; D. Kim, Konkuk University / Department of Environmental Health Science; S. Jeong, Kunsan National University / Department of Environmental Engineering; Y. An, Konkuk University / Department of Environmental Heath Science

Problems associated with plastic particles in soil ecosystems have been highlighted, and some studies have started to investigate these problems. Notwithstanding many reliable results in previous studies supported that adverse effects could be induced by nano- and micro-plastic exposure, they may not represent real soil environmental conditions because some of these studies were conducted in non-soil media such as liquid and mixtures of plaster and activated charcoal. In the present study, we conducted nematode bioassay in liquid and soil media to evaluate the media-dependent effects of nano- and micro- plastic particles. Field soil samples were used to assess whether the effects of plastic particles are dependent on particle size and soil physicochemical properties. Polystyrene beads of two different sizes (42 and 530 nm) were chosen as target materials, and the target organism, *Caenorhabditis elegan*s, was exposed to liquid and soil media containing each PS beads. We performed same bioassays using five different field soil samples with different physicochemical properties. The soil media including plastic particles was more toxic system than liquid media, and plastic size-dependent toxicity were only observed in soil media. As result on field soil samples, we also found that soil texture composition can be highly related with plastic toxicity. This is first study reporting reliable quantification of plastic toxicity and its interaction with soil properties, and will provide the important knowledge on plastic toxicity in soil system *This research was supported by Basic Science Research Program through the National Research Foundation of Korea (NRF) funded by the Ministry of Science, ICT and future planning (2016R1A2B3010445; 2017R1A6A3A01005507)*

Investigations of artificial digestion of microplastic spiked with perfluorooctane sulfonate (PFOS) and related toxic effects using pregnane X receptor (PXR) in vitro bioreporter system

F. Borchert, Institute for Environmental Research (RWTH Aachen University) / Department of Environmental Research; B. Cormier, University of Örebro; R. Aro, University of Örebro / Man-Technology-Environment research centre (MTM); B. Holmes, Orebro University; L.W. Yeung, University of Toronto / Man-Technology-Environment (MTM) Research Centre, School of Science and Technology; K. Hylland, University of Oslo / Biosciences; S. Keiter, University of Örebro / Man-Technology-Environment research centre (MTM)

During the past few years, research on microplastic (MP) particles has vastly developed. Several studies have shown that MP may cause either no or only minor toxic effects, and in most of the cases the effects were due to the additives or environmental pollutants sorbed onto the plastics. However, little is known about the desorption of pollutants or additives from plastic during digestion and subsequent effects in fish. For different chemicals the modelled desorption potential is to be expected in a non-toxic dimension. Therefore, the capability of gut surfactants to desorb pollutants from MP still needs to be tested. PFOS is a persistent organic pollutant that is shown to cause several adverse effects. The aims of the present study are 1) to investigate the desorption of perfluorooctane sulfonate (PFOS) from MP under simulated digestive conditions; and 2) to evaluate possible toxic effects of the desorbed toxicants associated with the MP using pregnane X receptor (PXR) *in vitro* bioreporter test system. PFOS was spiked on polyethylene particles (11 – 13 μm, 0.96 g/cm^3) in concentrations of 70 μg per gram of plastic. The prepared MPs were exposed for 4 days in artificial digestion fluid composed of sea salt (35 ‰) and 15 mM of the bile salt sodium taurocholate (NaTC). This solution is used to mimic the intestinal juice of the Atlantic Cod (*Gadus morhua*). NaTC is the main driver in solubilisation of nutrients during digestion in the posterior intestine since it has surface active properties. The simulated digestion over 4 days represents the average gut retention time of food in Atlantic Cod. After exposure, fluids will be analysed for PFOS using LC–MS/MS in order to quantify desorption. The same fluids will be tested using PXR *in vitro* bioreporter systems to evaluate the adverse effects from desorbed PFOS. Preliminary results reveal that less than 10 % of the initial PFOS concentration desorb from the MP particles. However, we expect a cellular response in the bioreporter test system since PFOS is known to cause effects in comparable low concentration ranges. The overall goal of this investigation aims for better understanding of desorption of pollutants from MP under digestive conditions which may also contribute to a more comprehensive environmental risk assessment of MP pollution.

MO268

Assessment of microplastics as a source and carriers of pesticides to earthworms (Eisenia fetida)

A. Rodriguez Seijo, GreenUPorto, University of Porto / Department of Biology; B. Santos, University of Porto / GrenUPorto & Department of Biology; E. Ferreira da Silva, University of Aveiro / Department of Geosciences and Geobiotec Research Centre; A. Cachada, CIIMAR; R. Pereira, University of Porto / GreenUPorto and Faculty of Sciences, Universidade do Porto

Studies addressing the contamination of soils with microplastics (MP) are few and the impacts on soil biota are poorly known. Less than 10% of peer-reviewed publications covering the period between 1972 and 2019 addressed studies related to microplastics and terrestrial environments. Some questions can arise related with this significant environmental issue, and its impacts on soils and terrestrial ecosystems, mainly whether MPs could transport contaminants (e.g. agrochemicals) on the soil matrix and if they could be carriers of pesticides to soil organisms through ingestion. In order to contribute to the understanding of these issues, earthworms (*Eisenia fetida)* were exposed for 14 days to OECD soils containing MPs with two different sizes [large MPs (5 mm) and small microplastics (0.250 -1 mm)], previously sprayed or not with chlorpyrifos following the dose recommended by the supplier (4 L ha^{-1}). This agrochemical is a broad-spectrum organophosphorothionate pesticide with several agricultural applications to a variety of food and feed crops, and it is used worldwide. Acetylcholinesterase activity and thiobarbituric acid reactive substances (TBARs) were measured to track the exposure of earthworms to the MPs alone or combined with chlorpyriphos. The behaviour of earthworms in the test containers was also assessed, as well as the movement of MPs on the soil. The concentration of chlorpyrifos in soil after 14 days differed between treatments with MPs of different sizes [17.9 ng g^{-1} and 2442 ng g^{-1} for large (5mm) and small MPs (1 mm), respectively]. Despite the ability of the MPs to release chlorpyrifos to the soil, the earthworms have firmly avoided the 1mm MPs treatment. At the lowest concentration of chlorpyrifos provided by large MPs, earthworms avoided it, but the contact time with contaminated soil was higher, as shown by the enhanced level of TBARs and acetylcholinesterase inhibition.

MO269

Ecotoxicology testing of microplastics contaminated sediment by oligochaete worm Lumbriculus variegatus.

B. Mekonen Belay, Autonomous University of Madrid / Department of Biology; O. Penttinen, University of Helsinki / Faculty of Biological and Environmental Sciences; S. Pflugmacher, Joint Laboratory of Applied Ecotoxicology, Environmental Safety Group, Korea Institute of Science and Technology Europe (KIST Europe) Forschungsgesellschaft mbH, Universität des Saarlandes Ca

Microplastics have been found in all aquatic ecosystems and environment. While impact of microplastics in marine environment has been widely covered, little is known about the risk in freshwater ecosystem. It is particularly relevant in the case of freshwater benthic organisms which apparently have a higher risk of exposure as a result of sinking microplastics onto sediments. Polyethylene microplastics (MPs) with a 10 µm particle size were spiked into sediment or water in three experiments. Survival, feeding activity, growth and reproduction of worms were used as end-points to evaluate the toxicity of MPs. First, worms were exposed to microplastics in different exposure routes water column, pore-water, and whole-sediment to assess the most harmful pathway. Second, different MPs concentrations ranging from 0 to 50 g/kg of MPs were set to analyse how the established endpoints may be altered with the increasing MPs concentration. Third, a layer of 1 mm MPs were placed at different depths, starting at 1, 4 and 7 cm, to study bioturbation effects of *Lumbriculus variegatus*. Feeding activity and growth was lower in whole-sediment exposure being these differences statistically relevant. Moreover, feeding activity has shown a clear dose-response correlation with increasing MPs concentration, in fact, at the highest concentration was almost zero. Growth showed remarkable decrease in higher concentration compared to controls. At 1 cm deep there was a slight mixing of the microplastics toward the upper layers due to the worms' movement. The worms reached the microplastics located 4 cm deep, however, the worms did not penetrate below that layer and never reached MPs at 7 cm deep. *Lumbriculus variegatus* did not feed on MPs present in the water, only feeding on MPs contained in the ingested sediment, being the main pathway whole-sediment exposure. This study has demonstrated the ability of *Lumbriculus variegatus* to mix MPs in the upper layer. The worm is able to mix MPs in the upper layer very close to sediment surface, but cannot burrow further than 4 cm deep. Indeed, it has shown very low MPs transport capacity. The obtained EC_{50} value (3.29 g/kg) for feeding activity suggests there is not an immediate risk for the worm. However, microplastics concentration are expected to increase, therefore, *Lumbriculus variegatus* and other more sensitive species may be in danger in the near future.

MO270

Effects of microplastic beads and their associated microbial communities on the sea urchin Paracentrotus lividus

C. Murano, Stazione Zoologica Anton Dohrn di Napoli / Biology and evolution of marine organisms; V. Donnarumma, A. Adame Rodriguez, I. Castellano, Stazione Zoologica Anton Dohrn Naples; C. Agnisola, Università di Napoli Federico II; E. Zettler, L. Amaral Zettler, NIOZ; I. Corsi, University of Siena / Physical, Earth and Environmental Sciences; R. Casotti, A. Palumbo, Stazione Zoologica Anton Dohrn Naples

Microplastics (< 5 mm) are a global threat to the marine environment and they are attracting attention of researchers based on the consideration that, despite their documented widespread occurrence, little is known on their effects on the marine biome. In the sea, these particles undergo deep transformations by physical, chemical and biological factors. They also harbour microbial communities which contribute to their transformation and represent the so-called “plastisphere”. In this work we have investigated the uptake of virgin microplastics (fluorescent polystyrene beads) by the sea urchin *Paracentrotus lividus*. Uptake was observed both in the digestive and water vascular systems and was dependent on the size and concentration of the particles. Moreover, fluorescent beads were detected in the coelomic fluid and in the gonads. The number and phenotype of the immune cells, the sentinels of the environmental stress response, was characterized. Markers of oxidative stress, including ROS and RNS determination, enzymatic activities, antioxidant response were examined in immune cells and in tissues containing microplastics. Natural microbial communities adhered on microplastic fragments have been assessed in the Gulf of Naples during several surveys. Scanning electron microscope analyses of fragments collected by manta net show different degrees of colonization and dominant microbes are bacteria and diatoms. Based on the observation that in nature microplastics are always colonized by microbes, we have exposed the sea urchins to beads incubated in natural seawater from different coastal sites for different times to test the hypothesis that microbial communities modulate the effect on the sea urchin in terms of stress response.

MO271

µFT-IR imaging to analyze the effect of antifouling paint leachates on a freshwater microalga

M. Simon, Aalborg University; N.B. Hartmann, Technical University of Denmark / DTU Environment; J. Vollertsen, Aalborg University / Department of Civil Engineering, Section of Water and Environment

We evaluated the effect of the leachate of a mixture of antifouling paints on the growth and physiology of a freshwater microalga (*P. subcapitata*). We applied Fourier Transform Infrared micro imaging spectroscopy (μFT-IR) with a focal plane array (FPA) to examine the related metabolic changes of the organisms. The technique allows examining numerous algae cells individually, therefore provides a detailed view of the effects of environmental stressors. A mixture of antifouling paint particles (20-500 μm) was leached in algae growth medium at 20°C for 72 hours with liquid to solid ratio of 100. A dilution series of 4 with a factor 10 was prepared from the concentrated leachate. A growth inhibition test was performed with modifications according to *Water quality - Freshwater algal growth inhibition test with unicellular green algae, ISO Standard 8692, 2004*. Algae cells were subsequently deposited on a CaF_2 transmission window for μFT-IR imaging. A fraction of the window was scanned to create a mosaic with 1.1 µm pixel resolution on the FPA. The obtained spectra were processed applying baseline correction, standard normal variate correction, and smoothing using the Savitzky-Golay algorithm. The second derivative of the processed spectra was used in the PCA analysis. There was a significant difference in the growth rate among the samples (ANOVA, p=3.82?10^{-9}). The following Tukey HSD-test revealed that the growth inhibition observed in the concentrated leachate and the first dilution was significantly different from the control, while the growth rate of algae incubated in the more diluted leachates was not significantly different from the control. \n PCA analysis with the obtained spectra showed a slight grouping of the spectra by the degree of dilution of the leachate with extensive overlap among the groups. Particularly, spectra of algae exposed to the second dilution (100x) seemed to separate from the spectra of control and other dilutions. The PCA analysis suggests that exposure to the diluted leachates could have caused metabolic changes in some of the algae cells, while it did not affect the growth rate of the population.

MO272

Representative behaviour of nanoplastics in a salinity gradient: a micro-chip to go one step further?

z. venel, EPOC, University of Bordeaux / UMR EPOC 5805; H. Tabuteau, University of Rennes / Institut de Physique de Rennes (IPR) CNRS UMR 6251; M. Baudrimont, Université Bordeaux1 / UMR EPOC 5805; J. Gigault, University of Rennes 1 / Laboratoire Geosciences

Plastic pollution is a global concern as plastic debris are present all around the world and especially in aquatic compartment. Up to now, it is well known that meso-plastics break down into micro and nanoparticles according to physical, physico-chemical and biological processes in aquatic environments. Evaluating nanoplastics toxicity in marine waters is a challenge considering their tendency to aggregate in presence of high ionic strength. Up to our knowledge, relatively few studies have considered nanoplastics aggregation before exposing organisms, whereas fate and toxicity of nanoplastics depends on their aggregation behavior. The aim of this study is to evaluate and understand the behavior of **environmentally relevant nanoplastics** in different salted medium before exposition of organisms. More specifically, we develop unprecedented methods to representatively disperse nanoplastics into a **salinity gradient** by designing and using a **microfluidic device**. \n Micro-channel is filled by NaCl solution or artificial marine water in one inlet, and nanoplastics dispersion in the other. At the two outlets, evolution of size distribution, fractal dimension and stability is investigated using *in situ* dynamic light scattering, static light scattering, laser induced breakdown detection, asymmetrical flow field-flow fractionation and zeta-meter. Different aged nanoplastics (100 to 500 nm) were prepared from pristine polystyrene and polyethylene materials, and also from environmental plastic debris sampled on Caribbean littoral. Standard polystyrene nanospheres (200 nm) are also used as a reference for comparison with aged nanoplastics and literature data. \n Both type of particles aggregates in the centre of the microfluidic channel, at the maximum transition of the salinity gradient. While polystyrene nanosphere creates and homogenous deposit, aged nanoplastics forms scattered large aggregates. This difference can be explained by their polydispersity. The hydrodynamic conditions in the microchannel seem to induce an aggregation pathways governed by Reaction-Limited-Cluster-Aggregation (RLCA) mode for the two types of particles. To the contrary, in the classical batch approach i.e. dropwise addition of NaCl solution into the nanoparticles dispersion and manually stirred, aged nanoplastics and polystyrene nanospheres present a characteristic aggregation pathway of Diffusion-Limited-Cluster-Aggregation (DLCA) mode.

MO273

Screening Method for Microplastics in Beach Samples

A. Reuwer, Institute of Environmental Systems Research, University of Osnabrück / Institute of Environmental Systems Research; J. Klasmeier, University of Osnabrueck / Institute of Environmental Systems Research

Plastic, especially microplastic contaminate the environment all over the world. To avoid further entry, sources have to be identified. For this, methods for the extraction of microplastics from different matrices, in this case from sediments, have to be developed. Here, a newly developed flotation method for fast extraction and screening of microplastic particles (> 100 µm) in large sediment samples is described. Recovery experiments were made with different polymer particles (PE, PP, PS, EPS, PET, PU, PA and PVC). The method is based on the principle of flotation and allowed even separating microplastic particles with densities in the range of the separation fluid (PET, PVC) with excellent recovery rates (> 93%). A reverse airflow is included to support separation of the lighter microplastic particles from the denser matrix components. To minimize the amount of fine sand particles which clogged the filter and aggravated visual detection of coloured polymer particles in the suspension, pre-treatment of the samples proved necessary. Fine sand particles were removed by sieving through a 63 µm standard stainless-steel sieve for soil samples which also removes small microplastic particles (< 63 µm) from the sample. Recovery rates of particles in the size range 400 µm – 1000 µm increased to 95% with dry sieving and more than 97% with wet sieving. All in all, this method allows fast and efficient screening of microplastic particles (> 63 µm) in large beach sediment samples.

MO274

Developing new methodologies for microplastic extraction from lake sediments to understand the extent of contamination in UK lakes.

C.E. Bancone, University College London / Geography; N. Rose, University College London / Department of Geography; R. Francis, KCL / Department of Geography

Microplastics (< 5 mm) are persistent environmental pollutants characterised by heterogeneous physico-chemical properties and a broad range of shapes, sizes, colours and composition. Microplastics may be directly released into the environment at this size (i.e. pellets and cosmetic microbeads) when they are known as primary microplastics. However, the majority of microplastics are secondary, i.e. they originate from the degradation of larger plastic items. An important source of secondary microplastics is represented by fibres released during washing of synthetic garments. Although microplastic contamination is thought to be ubiquitous in aquatic ecosystems, very little is known about the scale and extent of contamination in rivers and lakes. In particular lake sediments, may represent an important sink for microplastics as well as providing a means to assess historical trends. To assess microplastic abundance and distribution in the sediments of UK urban and rural lakes, reliable methodologies for microplastic sampling and extraction from sediments are still needed. To develop such a methodology to separate microplastics from sediment particles, extraction experiments with reference materials have been conducted. Natural sediment has been spiked with known concentrations of fibres and microbeads, encompassing plastic polymers commonly identified in environmental samples. Plastic-spiked sediment samples have been added to a range of high-density solutions (NaCl,

$ZnCl_2$, NaI and sodium polytungstate) to evaluate the separation efficiency of different floatation methods. ---- The results from these experiments have helped develop a reliable method for microplastic extraction from lake sediments which can then be applied to determine spatial and temporal distributions of microplastics in UK urban and rural lakes. This study presents the results from the extraction experiments and the preliminary results about temporal and spatial distribution of microplastics in sediments from Hampstead Heath ponds in London (urban sites) and from the Norfolk Broads National Park (rural sites).
Keywords: *Microplastics, lake sediments, microplastic extraction, density separation*

MO275

Identification and Quantification of Microfibers and Microparticles via FTIR imaging and Automated Analysis

S. Primpke, Alfred Wegener Institute / Shelf Sea System Ecology; P.A. Dias, Marquette University; G. Gerdts, Alfred Wegener Institute Helmholtz Centre for Polar and Marine Research / Shelf Sea System Ecology

The ubiquitous presence of small plastic particles and fibers (< 5 mm) with in the aquatic environment is of growing concern for sciences and societies. Nowadays these types of litter have already been found in the remotes areas of the world including the Arctic and Anarctic regions. Still, the analysis of these materials is a challenging topic as several steps are necessary like sampling, work up, and finally chemical identification. As most of these particles are barely visible by the naked eye, each of these steps has its own challenges. By FTIR imaging a rapid identification is possible and it was further improved via the automated analysis of complete filters. While the overall process is a powerful tool to characterize microplastic particles, the identification of microfibers was not possible within previous studies. To overcome this limitation we present a novel approach to measure, characterize and quantify microfibers and -particles concentrated onto membrane filters within one measurement. FTIR imaging was extended to fibers via a specialized sample handling to fix the fibers in the focal plane of the instrument. Further, after the automated analysis, an analytical procedure via Image Analysis was developed. Potential fibers were preselected from the dataset and further investigated. Different parameters allowed a detailed investigation with regard to object shape to differentiate small particles from short fibers. Afterwards, the fibers are investigated for each individual polymer type, their length and abundances. Via a filament closing process small gaps within larger fibers are closed to exclude an overestimation by overlaying objects. Subsequently the procedure was applied on datasets from studies of treated waste water to investigated type and number of micro-fibers and –particles within the effluent of the treatment plans. As first result in all of the investigated samples cellulose fibers were found. Moreover, synthetic fibers of different polymer types were successfully identified and consisted mainly of polyethylene, polypropylene, polyacrylates and polyamide. With this dataset we could show that we developed a versatile and easily applicable tool for the investigation of micro litter. The automated analysis of microfibers and –particles within one measurement further improved the necessary harmonization of microplastic research to lead to the implementation of standardized operational protocols (SOP) in the future.

Microplastic content in wastewater - a new thermoanalytical method

S. Spacek, TU Wien; O. Mallow, T. Schwarzböck, TU Wien / Institute for Water Quality and Resource Management AT; H. Rechberger, TU Wien, Institute for Water Quality and Resource Management; J. Fellner, TU Wien / Institute for Water Quality and Resource Management AT

The underlying Balance Method was originally developed for the determination of the fossil content in refuse-derived fuel. Recent activities at the TU Wien lead to an extension of the method to the field of (large) microplastics analytics. The concept is based on the distinctly different macro elemental composition of moisture and ash-free biogenic and fossil organic matter. Determining the content of the elements C, H, N, S and O in the dried sample and in the ignition residue is sufficient for calculating the corresponding plastic content (= fossil content): *Xb * mb + Xf * mf = (TXsample -TXi * mi)/(1-mi)* (Eq. 1) The mathematical fundament of the Balance Method is a system of equations, formulated according to the balance written above (Eq. 1). Whereby each element (= C, H, N, S, O) represents one equation in the system. The elemental composition of the sample and corresponding ash *(*TXsample, TXi) together with the ash content of the sample (mi) are measurable values. The material data constants of biogenic and fossil matter are defined as the elemental composition of the pure biogenic (Xb) and pure fossil (Xf) fraction of a certain sample type. A data reconciliation algorithm is applied to calculate the quantity of the unknown mass fractions (biogenic mb, fossil mf) including associated uncertainties. Several test series with different types of wastewater as well as environmental samples have already been analyzed. Complementary recovery tests emphasized the applicability of the Balance Method for microplastics quantification. However, specifying the material constants Xb and Xf demands a profound understanding of the material composition of a certain sample type. Preliminary sample information is crucial and can be provided by complementary methods, capable of polymer identification like Py/TED GC-MS or FTIR/ATR IR or Raman spectroscopy. Once the constants are fixed, the effort in the laboratory is reduced to a three-step analyzation procedure. Step 1 is sample preparation and homogenization including chemical oxidation (if necessary). Step 2 is the determination of the ash content by a simple loss on ignition test. The last step is strictly machine dependent and comprises the elemental analysis of the sample and the corresponding ash. This straight forward procedure represents a cost-efficient option in the field of microplastics quantification, especially for monitoring approaches.

Combining sampling of liquid matrices and an automated sample preparation for microplastic analysis using FPA µFTIR Imaging

J. Vollertsen, Aalborg University / Department of Civil Engineering, Section of Water and Environment; A. Vianello, Aalborg University / Civil Engineering Department - Section of Water and Environment; L.L. Iordachescu, Aalborg University / Department of Civil Engineering; I. Kirstein, University Aalborg / Civil Engineering; L.A. Rasmussen, Aalborg University / Department of Civil Engineering

Microplastic (MP) pollution is a global issue affecting almost all types of matrices such as marine waters, freshwaters, wastewaters, etc. In order to quantify the amount of microplastic in a sample, unwanted organic matter has to be removed. This is done by procedures including wet peroxide oxidation and enzymatic digestion. Typically the sample preparation is done in open laboratory vessels, involving the transfer of samples between vessels and filtering between steps. This procedure does though leave the sample open to the surrounding atmosphere, which increases the risk of contaminating it by airborne microplastics. Another issue is that the procedure is labor-intensive and prone to human mistakes. This study proposes a methodology to minimize sample contamination by performing sampling and sample preparation in the same closed device, first opening it when the microplastics concentrate is ready for final analysis. It does so in an automated way, thereby reducing the labor needed to conduct the sample preparation. The study furthermore present data on microplastics contamination rates and recovery rates applying this approach. The device is a custom-made filter holder that can hold a steel filter with a diameter of 150 mm and a mesh of for example 10 μm. All parts are made of stainless steel and can be muffled. The cleaned and closed filter unit is taken to the field and a sample collected by a vacuum pump sucking the sample through the filter or by using a pressure pump without plastic parts in contact with the water. Back in the laboratory, the device is placed in a rag and slowly flushed with a sequence of filtered (2 μm) treatment solutions: SDS, cellulase, protease, hydrogen peroxide. Between the steps, the filter is flushed with Milli-Q water to ensure proper separation of the chemicals. The process is automatized by a PLC-controller in order to minimize the amount of labor put into the sample preparation. Upon treatment, the filters are extracted inside a laminar flow cabinet and the particles concentrated. Finally, a sub-sample of the concentrate is analyzed by FPA μFTIR imaging.

Application of novel large area ATR (LAATR) for use with µFTIR Imaging technology: expanding analytical options for measuring <10 µm microplastic particles, fibres and surfaces.

N. van Alst, Aalborg University; M. Kansiz, Photothermal Spectroscopy Corp.; J. Vollertsen, Aalborg University / Department of Civil Engineering, Section of Water and Environment

With research on microplastics increasing every year, a consensus is forming on appropriate analytical methods. With light microscopy no longer being considered as a truly acceptable standalone analytical method for identification of smaller size ranges of microplastic, vibrational spectroscopy methods have become a staple holder in methods considered for standardisation of analytical methods. With the rise in interest for measuring microplastic particles smaller than 100 μm or even less than 10 μm, expansion of analytical methods using Focal Plane Array (FPA) based μFTIR imaging are becoming increasingly of interest. A novel ATR method has been made available called the large area ATR (LAATR), which consists of a diamond covered zinc selenide ATR unit. It is theorised to be especially good for analysis of particles and fibres under 10 μm in size. Furthermore, it has large potential for analysing surface characteristics of particles with spatial accuracy of only few microns. This study aims to provide clear proof of concept considering its function and performance, showing why it should be considered for a standardised mode of analysis when identifying and quantifying microplastics in the 1-10 μm size range.

Non-target analysis to measure microplastics and emerging debris by automatic microFTIR with Multivariate Curve Resolution analysis and Correlation analysis

Y. Kameda, Chiba Institute of Technology / Creative Engineering

General analysis method to measure microplastics are FTIR analysis after picking potential MPs on a membrane, followed by H2O2 digestion and density separation processes. But fine MPs whose sizes are less than 100 µm can not be picked up. Transparent small particles are also picked up. The picking process and FTIR analysis need much time and hard work. FTIR analysis is also difficult to classify MPs to polymer groups because there is difference between standard polymer spectra in libraries and those from environmental samples. New standard analysis methods are needed to reveal the fine MPs contamination and to compare research results qualitatively and quantitatively in the world. This present proposes a new analysis method with automatic microFTIR with Multivariate Curve Resolution analysis and Correlation analysis. The microFTIR can measure IR spectra of all debris including MPs on the membrane automatically. The main spectra can be extracted from the IR spectra data by Multivariate Curve Resolution analysis (MCR). These results can reveal quality of major debris. MPs sometimes are classified to minor debris. Therefore, correlation analysis can be identify MPs by comparison the spectra to library data which is composed of spectra of environmental samples. After these analysis procedures, image mapping data for each polymer can be performed. Sizes and numbers of all polymers and other debris can be also counted automatically. This novel analysis method was applied to domestic wastewater, oyster and river water. By this method, new polymers and new emerging debris which the general analysis can not detect were found. This method can also detect more fine MPs very easily than we expected.

Misidentification of PVC microplastics in environmentally weathered samples

S. Muniategui, Universidade da Coruña / Analytical Chemistry; V. Fernández-González, C. Moscoso-Pérez, J.M. Andrade-Garda, P. López-Mahía, Universidade da Coruña

Contamination of the marine environment is of increasing concern. Microplastics (MPs) can be present in the environment as manufactured microplastics (known as primary microplastics) or as a result of the continuous weathering of plastic litter, which yields progressively smaller plastic fragments (known as secondary microplastics). Once released, plastics and microplastics (MPs) may be subjected to degradation by several agents or routes, such as solar radiation, mechanical forces, and microbial action. Weathered plastics collected from the marine environment show considerable physical and chemical differences to pristine plastics [1]. Therefore, the assessment of the changes and processes that MPs suffer during weathering is essential to understand their effects in the environment and to their correct identification. PVC is the least stable of the high tonnage polymers as it has the highest sensitivity towards UV radiation and, therefore, photo-degradation is of highest importance. When PVC is exposed to sunlight, dechlorination is the first step, which leads to the formation of conjugated double bonds in a polyene polymer and hydrochloric acid [2]. Although thermal and UV stabilizers are added to extend the lifetime and stability of PVC products that are exposed to sunlight, MPs that remained for a long time in marine environments will be highly degraded. Moreover, existing methods for the assay of microplastic fragments typically involve either a flotation or density separation step using dense salt solutions. A saturated sodium chloride (density: 1.2 g cm^{-3}) is a common choice to density separation of MPs, but it could be insufficient to extract PVC microplastics, which have higher density (1.38 – 1.41 g cm^{-3}) [3]. The combination of all these factors, could make PVC MPs to be underestimated when analysed in environmental samples, making the direct identification of PVC an analytical challenge. In this work, chemical and physical changes on a standard PVC MP are characterized by ATR-FTIR, SEM and X-Ray Fluorescence analysis. [1] Silva, A.B. *et al.* 2018. 3-dimensional imaging of nanoplastic transport through a sand column using magnetic resonance imaging

J. Koestel, Swedish University of Agricultural Sciences / Department of Soil and Environment; E. Bäckström, Swedish University of Agricultural Sciences / Department of Aquatic Sciences and Assessment; A. Lehoux, Uppsala University / Department of Earth Sciences; A. Missong, Forschungszentrum Jülich / Institute of Bio- and Geosciences; N. Gottselig, Bonn University / Institute of Crop Science and Resource Conservation; S. Haber-Pohlmeier, RWTH Aachen University / Institute of Technical and Macromolecular Chemistry; M. Futter, Swedish University of Agricultural Science / Aquatic Sciences and Assessment

Comparatively little is known about the fate and impact of micro and nanoplastics in soils. Research in this field is complicated by the opaque nature of soil and the abundance of organic matter which is difficult to distinguish from plastics. Testing and establishing suitable methods for measuring micro- and nanoplastic presence and mobility in intact soils is at the forefront of ongoing research. In this pilot study we were explored the potential of quantitative 3-dimensional magnetic resonance imaging (MRI) of nano-plastic transport through soil like material, using nano-particles with superparamagnetic properties. The applied nano-particles were 40 nm diameter dextran spheres, coating an 8 nm diameter iron oxide core (Fe_3O_4). Particles were terminated with carboxyl groups and were doped with a fluorescent material (rhodamine b). A pulse of a nano-plastics suspension containing 0.5 mmol l^{-1} iron was applied onto a packed sand column (3 cm diameter, 6.3 cm height) under near-saturated steady state water flow (1.2 ml min^{-1}) while the sand column was placed inside the high-field MRI scanner at the IBG-3 in Jülich. Eleven consecutive 3-dimensional MRI images were obtained with a resolution of approximately 0.39 x 2.2 x 0.79 mm in x, y and z directions using a stop-flow approach (the water flow was stopped during MRI image acquisition to suppress nano-particle transport). The MRI experiment was preceded by consecutive additional leaching experiments on the same column at the same flow rate but without flow interruption. Here we used i) chloride ions as a conservative tracer; ii) fluorescent polystyrene nano-particles of the same diameter and similar surface termination as the dextran particles; iii) the superparamagnetic dextran particles to investigate possible transport differences caused by the flow interruptions during MRI scanning. The corresponding three breakthrough curves were analyzed in the effluent, exploiting electric conductivity contrasts or fluorescent properties. First results show that MRI images provided excellent means to separate the dextran particle plume inside the column from the background MRI signals. Preliminary evaluations of the effluent breakthrough curves indicate very similar transport properties for all investigated substances. We infer that the dextran particles with the iron cores may be suited as an MRI detectable proxy for polystyrene plastic transport and mobility in intact soils.

MO282

Fingerprinting of chemicals released from plastic polymers by UV-light

M.M. Plassmann, Stockholm University / Department of Environmental Science and Analytical Chemistry ACES; O. Sandblom, Stockholm University / Department of Environmental Science and Analytical Chemistry; M. MacLeod, Stockholm University / Department of Environmental Science and Analytical Chemistry ACES

Plastic production has been increasing over the last decades and has led to pollution of both the marine and terrestrial environment by (micro)plastic. The need for good analytical methods to determine the composition and concentrations of plastic in environmental samples is growing. Currently detection of plastics is done mostly by FTIR or Raman spectroscopy, and sometimes by pyrolysis GC-MS. These methods depend on an extensive sample preparation and may be specific for certain size fractions of plastic. Here we propose a new detection strategy which theoretically does not depend on any sample preparation and could potentially be applied to macro-, micro- and nanoplastic detection. The goal of this study was to establish fingerprints of the mixture of chemicals released by different plastic polymers under UV-light to identify plastics in unknown samples. We developed a "weathering wheel" in which plastic particles in the presence of water and sand were exposed to UV-light. We exposed cryo-milled PE, PP, PS, PET, PU and PVC particles (0.4 μm – 1 mm) for four days. The chemicals released into the water were subsequently concentrated using solid phase extraction (Oasis HLB Plus, Waters) and analysed by liquid chromatography coupled to high resolution mass spectrometry (LC-Orbitrap Q Exactive HF, Thermo). By using non-target screening the full spectrum of detected peaks was used to establish a chemical "fingerprint" for each polymer. At least 100 characteristic peaks for each polymer were detected. We then examine the hypothesis that these fingerprints can be used to identify the presence and composition of mixtures of plastic polymers in unknown samples.

MO283

How circular are plastic flows today, and how circular can they be tomorrow? - A material flow analysis for selected plastics in Switzerland

M. Klotz, M. Haupt, ETH Zurich / Institute of Environmental Engineering; A. Binkert, ETH Zurich; H. Wiesinger, ETH Zurich / Civil, Environmental and Geomatic Engineering - Ecological Systems Design; Z. Wang, ETH Zurich; S. Hellweg, ETH Zurich / Institute of Environmental Engineering

Recycling of plastics can reduce the need for natural resources and energy. Currently, no good overview about the flows of secondary plastics into new products in Switzerland exists. To fill that gap, and with the further aim to propose suitable plastic recycling strategies, a static material flow analysis (MFA) for selected plastic types in Switzerland has been conducted. The focus was on the connection of the end-of-life treatment with product manufacturing. Therefore, the flows to and from different processes of the recycling chain, starting from the waste collection, have been investigated in detail. The plastic products have been grouped into categories with similar characteristics and requirements. The amount of secondary material produced and used within different product categories has been determined. It has been found that Polyethylene Terephthalate (PET), High-Density Polyethylene (HDPE) and Low-Density Polyethylene (LDPE) constituted the largest share of the secondary plastics produced in mechanical recycling in 2017. The recyclate originated mainly from PET and HDPE consumer bottles and from LDPE non-consumer packaging films. Typical applications for the secondary polymers are consumer bottles, tubes and pipes. Currently, the use of secondary polymers is often limited by (unknown) material quality. Contaminants from previous applications as well as additives from polymer manufacturing may hamper closed material cycles. In order to investigate possible future scenarios, the static MFA will be transformed into a dynamic MFA considering individual product lifetimes. The results of the analyzes can serve as a basis for further investigations, including life cycle and risk assessments. This finally allows to determine an optimum degree of recycling and provide a basis for regulatory decisions.

MO284

Chemical transfer from food contact material - A statistical model with limited data requirement and increased predictive power

M. Douziech, Radboud University Nijmegen; A. Benítez López, Radboud University Nijmegen / Environmental Science; C.A. Askham, Ostfold Research AS; J.A. Hendriks, Radboud University Nijmegen / Department of Environmental Science; A. Ernstoff, Quantis / Quantitative Sustainability Assessment; H. King, Unilever; M.A. Huijbregts, Radboud University Nijmegen / Department of Environmental Science

Plastic packaging is used to improve the shelf life, and to help ensure quality and safety of food products. Plastic packaging materials, called food contact materials (FCM), can be a potential source of chemical contaminants in food products. The amount of chemical (hereafter migrant) transferred from the packaging material to food can be determined experimentally or using migration models. Process-based migration models have a limited applicability domain and their predictive performance is low if only estimated chemical-specific diffusion coefficients are available. To overcome these two limitations, we aimed to develop a statistical model with higher accuracy and predictive performance. We used linear mixed effect models (LMM) and the database of the US Environmental Protection Agency (N=10,235 migration results, for 70 migrants, 16 packaging types, and 117 food/food simulants) to predict the fraction of migrant transferred from the FCM into the food. The model statistically relates the fraction transferred to factors related to the migrant, food product composition, FCM, and experimental design. The predictive performance of the LMM for transfer fractions of new migrants for FCM and foods that were part of the database was clearly higher than the process-based model when only estimated diffusion coefficients were available (Coefficient of Efficiency (CoE) of 0.46 for the LMM vs. -0.002 for the process-based model). The predictive performance of the LMM was also higher for new FCM with migrant and food combinations present in the database (CoE = 0.50). Our statistical model confirmed the negative relationship between the fraction transferred and the molecular weight (MW) of a migrant and the positive relationship between the fat content of the food and the fraction transferred. The relationship between the MW and fraction transferred was also influenced by the FCM's crystallinity: large chemicals (MW>400 g/mol) migrated more from FCM with low crystallinity than from FCM with high crystallinity. Our results indicate that statistical modelling approaches can help improve the accuracy of migration predictions, while keeping the complexity and input data requirements to a minimum. This method could make assessing chemical exposure from FCM easier in high-throughput risk screening exercises or life cycle assessment-based approaches as long as the starting concentration of the migrant in the FCM is known.

Mechanical stress causes microplastic release from PET mineral water bottles

A.S. Winkler, State University of Milano / Department for Environmental Science and Policy; N. Santo, University of Milan / Unitech NOLIMITS; E. Bolzoni, P. Tremolada, University of Milan / Department of Environmental Science and Policy; R. Bacchetta, University of Milan

Plastic particle ingestion has become of concern as a possible threat to human health. Previous works have already explored the presence of microplastic (MP) in the bottled drinking water as a source of MP intake. Here, we consider the release of MP particles from single-use PET mineral water bottles upon exposure to mechanical stress utilizing scanning electron microscopy (SEM), which allows the implementation of morphological and elemental analysis of the plastic material surface and quantification of MP concentrations in sample water. The aim of this study is to better evaluate the sources of MP intake from plastic bottles, especially considering the effect of daily use on these bottles such as the abrasion of the PET and PE material. For that, we analysed MP release of PET-bottlenecks and PE-caps on their surfaces after a series of bottle openings/closings (one time, ten times, 100 times). Furthermore, we will investigate the occurrence of MP particles on the inner wall surface of the PET bottles and measure MP concentrations of the water after exposing the bottles to mechanical stress (squeezing treatment; none, one minute, ten minutes). All investigated bottles were purchased in Italian supermarkets and included different brands and water types. An in-house manufactured filtration apparatus was used to filter the sample water. To assess sample contamination or particle loss during the procedure in the lab, blank and positive control samples were included. The first results show a considerable increase of MP particles occurrence on the surface of PET and PE material (bottleneck and caps) after opening and closing the bottles 100 times. Considering these findings, MP concentrations in the bottled mineral water are expected to increase after exposure to mechanical stress (squeezing treatment). More information about MP concentration in mineral water - possibly increased through release of particles from the bottle inner wall - will be presented in the conference. In addition to the implications of the results, also the applicability of the used filtration and analysis technique will be discussed.

MO286

On the pathway towards the standardization for exposure assessment throughout life cycle of nanocomposites

M. BLAZQUEZ, INKOA SISTEMAS / RTD; V. Marchante, L. Gendre, Cranfield Univeristy; K. Starost, J. Njuguna, Robert Gordon University; J. Schutz, CSIRO; A. Egizabal, C. Elizetxea, Tecnalia Research Innovation; M.P. Cajaraville, University of the Basque Country UPV/EHU / Dept. Zoology and Animal Cell Biology Faculty of Science and Technology and Research Centre for Experimental Marine Biology and Biotechnology PIE

Both researchers and legislators have claimed the necessity to standardize the exposure assessment throughout the life cycle of polymer nanocomposites. In the present study we have developed and compared three different operational protocols to investigate changes in particle emission behavior of mechanically degraded polypropylene (PP) samples with different fillers including talc and not reinforced PP (as reference samples) and two types of nanoclays: wollastonite and montmorillonite. The presence or absence of engineered nanomaterials (ENMs) in the nanocomposite formulation has been investigated as the main factor causing differences in the particle emission profile. The three protocols, despite the fact of being carried out using the same samples and operating conditions, have yielded different figures for particles generation. Here we propose an integrative approach providing released particles as a function of the quantity of removed material in a certain time. The proposed option would allow comparing variations in the number of emitted particles by means of different mechanical processes. Finally, we have also concluded that no universal conclusions can be derived on how nanofillers modify particle size distribution and particle concentration of released particles during mechanical degradation of solid nanocomposites as it is a multidimensional phenomenon. MO287

Fate of Particulate Plastic in Sewage Sludge Treatment and Transport Behaviour in Unsaturated Porous Media

A. Keller, Eawag Swiss federal Institute of Aquatic Science and Technology / Process Engineering; J. Jimenez Martinez, Eawag Swiss federal Institute of Aquatic Science and Technology; D.M. Mitrano, Eawag - Swiss federal Institute of Aquatic Science and Technology / Process Engineering

While the occurrence of particulate plastic in the environment is widely discussed, mechanistic understanding of particle fate and transport is limited as few process oriented studies exist. Research on this topic is particularly limited due difficulties to detect plastic in complex matrices. To overcome these challenges, we synthesized metal-doped microplastic fibers and nanoplastic particles and successfully used them to trace particulate plastic in complex systems by measuring the metal as a proxy for plastic. In particular, in a pilot-scale wastewater treatment plant (WWTP), we found that >95% of the plastic spiked into the system was removed from the water column via the sewage sludge. Since 50% of sewage sludge is used as agricultural fertiliser in Europe, this may play an important role for plastic accumulation on agricultural fields. Still, a detailed assessment of mass flows, especially leaching from the sludge and further transport within the soil column, is missing. To help close this knowledge gap, we continued to investigate the transport of metal doped plastic particles from the sludge by-product of our previous experiments. A lifelike association of the plastic with the sludge matrix can be assumed, since the plastic underwent a realistic waste water treatment process. Sludge treatment consisted of anaerobic digestion followed by effluent dewatering by a decanter centrifuge. The mass balance over the dewatering process showed that the largest share of the plastic stayed associated with the solid fraction and only a small portion was recycled to the WWTP influent via the supernatant. From this, it was concluded that the major share of plastic particles are spread on agricultural fields in sludge application as fertiliser. Transport and leaching experiments were subsequently conducted with the processed sewage sludge. To reproduce different sludge application practices, samples with different water contents were tested. Transport studies in unsaturated glass bead columns were conducted both with pristine plastic particles as well as with plastic containing sludge. To decouple the process of plastic detachment from the sludge matrix and the migration through the column, leaching tests in the similar setting were also conducted. By combining the results from both experiments, first insights into the transport behaviour of microplastic fibres and nanoplastic particles were gained that can help to better understand the fate of plastic in soils.

MO288

Optical roughness - A suitable parameter to describe the fragmentation of plastics?

S. Meinecke, Umweltbundesamt; F. König, German Environment Agency UBA; T. Hüffer, University of Vienna / Department of Environmental Geosciences

Plastics are important products with a wide range of applications in industry and the household sector because they are inexpensive and durable. Unfortunately, these advantages lead to miss use and mismanagement and large quantities of plastic end up uncontrolled in the environment. Littering is hereby an important path of entry. After their introduction into the environmental, a number of factors (e.g., UV radiation, mechanical stress, and biodegradation) lead to the fragmentation of larger plastics parts into smaller plastic pieces and finally into secondary microplastics (pieces < 5mm). Within the scope of the BMBF (Federal Ministry of Education and Research) project ENSURE (Development of new plastics for a clean environment by determining relevant entry paths), the fragmentation process in semi terrestrial environments will be investigated. For this purpose, several shore zones with wave impact are set up in mesocosms of the stream and pond simulation system (FSA) of the Federal Environment Agency (UBA). Various plastic test specimens of different shapes are added in the artificial shore zones. The fragmentation processes of macroplastics and rates of microplastic formation in the environment is crucial and not sufficient investigated by now. In order to investigate these processes, suitable methods and parameters have to be found first. One suitable parameter could be the change of the surface roughness of the test specimens. This contribution presents the investigation to use optical roughness measurements for the fragmentation process of plastics and compares the results of the initial roughness measurements with gravimetric measurements of macroplastics in mesocosm.

MO289

Drinking plastics?

I. Kirstein, University Aalborg / Civil Engineering; L.A. Rasmussen, L. Iordachescu, Aalborg University / Department of Civil Engineering; H.B. Wittgren, Svenskt Vatten; J. Vollertsen, Aalborg University / Department of Civil Engineering, Section of Water and Environment

The presence of microplastics has been previously reported in numerous natural habitats as well as in the digestive tracts and cell tissues of a number of species. Recently, microplastics were also detected in food and drinking water designated for human consumption. Consequently, researchers all over the globe remark concerns about the potential implications for human health. Beside incomplete removal during water purification, the deterioration of plastic equipment and pipes used during water purification or transport in waterworks is likely a source for microplastics in drinking water. Up to date, limited data is available on microplastics concentrations in drinking water. The few studies conducted so far reported about generally low numbers of microplastics in drinking water but also about contamination possibly due to handling and the use of plastic equipment during sampling and processing. Therefore, it is essential that quality assurance is in place and demonstrated, but also that an adequate volume of drinking water is assessed, in order to reliably analyse microplastics in drinking water distribution systems.We designed a drinking water sampling workflow to reduce and control the contamination risk during sampling and processing. Following, up to 1 m^3 of drinking water were sampled per site directly from the distribution pipes through 3 μm stainless steel filters in a closed steel filter system. Using μFT-IR imaging enabled us to assess the presence, identity and quantity of small microplastics (>10 µm).

MO290

Development of a standard addition method for the preparation of water samples for microplastic analysis

G. Bordos, D. Nagy, Z. Palotai, WESSLING Hungary Ltd; B. Kriszt, Szent István University / Department of Environmental Safety and Ecotoxicology; S. Szoboszlay, Szent István University / Institute of Aquaculture and Environmental Safety

It is well known, that huge amount of plastic waste enters the environment. Despite of their resistance for microbiological degradation, different physical-chemical processes (e.g. photooxidation) causes chain cleavages in the polymer structure and result in smaller and smaller fragments. This is the main reason for one of the most important problems of the ecosystem: the presence of microplastics in the environment. Microplastics (plastic prticles < 5mm) have been detected globally in a wide range of environmental elements, but the methods of sampling, sample preparation and analysis are not harmonised yet. Different methods apply different steps to clean up the microplastics as much as possible from the matrix of the sample (e.g. plankton in water or sand particles in sediment). For this, usually density separation, oxidation and filtration are applied. The number of particles may be decreased after the preparation if the equipment or solutions for these steps are not chosen well enough. Also, sample transfer from one step to another during the preparation may cause losses of particles. The efficiency of the extraction processes is barely monitored, the lack of these measurements causes uncertainty in the observed environmental concentration. To improve the knowledge on sample preparation efficiency, we developed a standard addition method, where recovery rates can be analysed fast and precisely. For the first tests three different equipment – the widely applied separation funnel and two specially designed glassware – have been used with three saturated salt solutions ($NaCl$; $CaCl_2$; $ZnCl_2$) that are also common in the literature. Commercial fluorescent microspheres with different densities and diameters have been added to the samples, tests have been conducted in three replicates. Results show that the glass flotation prototype with conical fittings provided the best results when it was applied with $ZnCl_2$. The prototype with the associated standard operating procedure has been also validated using field collected water samples, recovery rates have been detected over 90%. This work has been supported by project no. KFI_16-1-2017-0477, that has been implemented with the support provided by the National Research, Development and Innovation Fund of Hungary, financed under the "Vállalati KFI_16" funding scheme.

Can amino acid-specific stable carbon and nitrogen analysis improve quantifying arctic food web dynamics of persistent organic pollutants and mercury: a case study on the Greenland Sea food web

I. Eulaers, Aarhus University AU Arctic Research Centre / Department of Bioscience; A. Mosbech, Aarhus University AU Arctic Research Centre / Department of Bioscience Arctic Environment; R. Bossi, Aarhus University Department of Environmental Science; C. Bouchard, Greenland Institute of Natural Resources / Greenland Climate Research Centre; E.F. Møller, Aarhus University AU Arctic Research Centre / Department of Bioscience Marine Diversity and Experimental Ecology; R. Schulz, University of Koblenz-Landau / Institute for Environmental Sciences; J. Sun, University of Antwerp / Department of Biology; J. Søndergaard, Aarhus University AU Arctic Research Centre; K. Vorkamp, Aarhus University Department of Environmental Science / Department of Environmental Science; J.P. Zubrod, University of Koblenz-Landau / Institute for Environmental Sciences

Evaluating *in situ* biomagnification is a valuable posterior approach to further assess the chemical bioaccumulative potential of a substance identified a potential contaminant by its physicochemical characteristics, such as the octanol-water partitioning coefficient. The investigation of trophic magnification factors (TMFs) has consequently become the quantitative backbone of assessing real-world food web dynamics of contaminants. The reliability of TMFs rests however upon the accuracy with which the relative trophic level of the individuals investigated for their contaminant load is determined. In this respect, the advent of measuring stable carbon and nitrogen isotopes of individual amino acids, rather than of bulk tissue, seems particularly promising in eliminating uncertainty in food web baseline stable isotope values necessary to reliably determine relative trophic levels. The isotopic signature of essential amino acids remains in fact relatively unaltered throughout the food chain and therefore provides the food web baseline value for which previously only approximations could be employed. The Greenland Sea is a pristine Arctic marine ecosystem though its food web has up to now never been investigated for exposure to contaminants, such as mercury, persistent organic pollutants and per- and polyfluoroalkyl substances, typically found in the Arctic despite its remoteness from primary sources and ongoing mitigation under the Stockholm and Minamata Conventions. Being particularly interested in evaluating the performance of the amino acid-specific analysis based TMFs we investigate the food web dynamics of the above substances using both bulk tissue and compound-specific analysis for stable carbon and nitrogen isotopes. The food web investigated here composes particulate organic matter (POM), two copepod species, four amphipod species, three euphasiid species, twelve fish species, and four seabird species. The availability of POM and different primary consumers allows us to uniquely present on their bulk tissue and compound-specific stable isotope values, most often not available in food web assessments, and as such compare the performance of the TMFs resulting from both methods. Moreover, POM and copepods were collected at several locations allowing us to evaluate the spatial variation in food web baseline isotopic values, and how adequately amino acid-specific analysis can resolve this frequently stumbled upon issue when employing bulk tissue analysis.

MO292

Can elevated radiocaesium in benthic fish off Fukushima be explained by trophic transfer through benthic food webs?

C. Bradshaw, I. Holmerin, Stockholm University / Department of Ecology, Environment and Plant Sciences; F. Svensson, SLU Aquatic Sciences and Assessment; F. Nascimento, Stockholm University / Department of Ecology, Environment and Plant Sciences; J. Kanda, T. Ishimaru, Tokyo University of Marine Science and Technology

Seven years after the accident at the Fukushima Dai-ichi Nuclear Power Plant (FDNPP), activity concentrations of radiocaesium (^{137}Cs and ^{134}Cs) still remain elevated in some bottom sediments, benthic invertebrates and benthic fish in the surrounding marine environment. The long ecological half-life of Cs isotopes in these organisms is thought to be partly due to delayed accumulation through the benthic food web, but the exact mechanisms are not fully understood. This study analysed in more detail the benthic food web structure at a number of sites at varying distances from the FDNPP and related this to the activity concentrations of Cs measured in the sediment, benthic invertebrates and benthic fish at each site. Food web structure was elucidated by visual analysis of fish stomach contents and stable isotope (SI) analysis (δC, δN) of benthic invertebrates and fish. Visual gut content analyses indicated that the fish ate predominantly small shrimps, gammarid crustaceans and a range of polychaete worms, with bivalve and gastropod molluscs also being taken. The stable isotope distribution in the fish and invertebrates, as analysed by fitting of mixing models, further strengthened the food web structure theorised by the results from the visual gut content. Concentrations of Cs in the sampled invertebrates varied by two orders of magnitude, with the highest values in infaunal benthic deposit feeders such as sea cucumbers, heart urchins and some polychaetes, sampled in soft sediments at 120m water depth. Cs concentrations were more strongly related to the functional group of the organisms than, for example, proximity to or direction from the

FNDPP. Fish Cs concentrations were also highest at offshore sites. Invertebrate SI signatures varied widely (δC: -7.8 to -22.6; δN: 6.3 to 13.3), but those of benthic fish did not (δC: -16.1 to -20.0; δN: 10.1 to 14.0). There was no obvious relationship between δC or δN and Cs concentrations. Benthic fish in this area are generalist feeders and their prey items contain varying amounts of radiocaesium. Sediments in the area near FDNPP still seem to be a source of radiocaesium to the food web, with the highest concentrations in the sediments also reflected in concentrations in benthic invertebrates and fish. However, there is considerable spatial variability in Cs concentrations in all compartments, as well as in food web structures, leading to unpredictability in Cs accumulation, which is a challenge for risk assessment.

MO293

Does pesticide contamination affect assemblages of algae, macroinvertebrates, and biofilm meiofauna in Swedish agricultural streams?

W. Goedkoop, Swedish University of Agri Sciences / Department of Aquatic Sciences and Assessment; W. Traunspurger, Bielefeld University / Animal Ecology; S. Höss, Ecossa / Animal Ecology; M. Kahlert, SLU Swedish University of Agricultural Sciences / Department of Aquatic Sciences and Assessment; M. Bighiu, Swedish University of Agricultural Sciences / Department of Aquatic Sciences and Assessment

We studied the effects of agricultural pesticides on assemblages of benthic macroinvertebrates, epibenthic algae, and biofilm meiofauna in 32 streams in landscapes with intensive agriculture in Southern Sweden. We used data from a pesticide screening study (montly of biweekly grab samples) and data from 4 national monitoring sites (time-integrated samples) that had been collected during the spraying season (i.e. April–October). We used acute EC50-values to calculate ∑TU as a measure of exposure to observed pesticide mixtures. These calculations showed that some 5% of the collected water samples had ∑TU that exceeded EU's uniform principles (i.e. ∑TU > 0.01 for *Daphnia*and fish). The vast majority (>88%) of ∑TU for algae was lower than 0.01. Only for 12 of 438 samples (or less than 3%) did ∑TU for algae exceed 0.02, of which 6 in the time-integrated samples collected in the monitoring sites. Benthic algal assemblages showed a large variability in species composition and biomass, but mostly resembled assemblages typical for nutrient-rich streams. The share of diatom frustule deformations exceeded 1% in 10 of 32 streams, suggesting that these sites could be impacted by pollution. Benthic macroinvertebrate fauna showed relatively high ASPT-scores in all but three streams, indicating high or good ecological status according to legal Swedish assessment criteria. However, when the SPEAR-pesticides metric and assessment criteria by Beketov et al. (2009, Environ. Poll. 157: 1841–) were applied, only four of the streams were judged at good status. Interestingly, ASPT and SPEAR-pesticides show a strong correlation (r=0.79), suggesting that both metrics largely quantify similar stressors, but that there is a mismatch for the assessment scale. Obviously, pesticide mixtures are one of several stressors in a complex stressor scenario that act on these streams. Analyses of biofilm nematodes using the Nema-SPEAR index showed that all but three streams were at high or good status. RDA showed that only meiofauna assemblages correlated significantly to ∑TU for *Daphnia*. This may be due to the fact that meiofauna assemblages in epilithic biofilms are more exposed and that pesticides may accumulate in biofilms.

MO294

Does the discharge of chemicals to the environment harm wildlife populations? Introducing the ChemPop Project

A.C. Johnson, CEH Wallingford / Wallingford; R. Shore, Centre for Ecology & Hydrology; F. Edwards, Centre for Ecology Hydrology Maclean Building; M.D. Juergens, Centre for Ecology and Hydrology / Wallingford; R. Williams, Centre for Ecology & Hydrology Maclean Building; N. Isaac, NERC Centre for Ecology & Hydrology; B. Woodcock, Centre for Ecology Hydrology Maclean Building / Wallingford; A. Nunn, I. Cowx, University of Hull / Hull International Fisheries Institute; P.D. Jepson, Zoological Society of London; J.P. Sumpter, Brunel University / Institute of Environment Health and Societies

We introduce a new project funded by NERC in the UK, which will address the research questions I: What are the impacts of hazardous chemicals on populations, ecosystems and ecosystem services and II: their relation to other pressures in the environment. We will address these by mining Britain's extensive wildlife monitoring databases which were instigated up to 40 years ago. Traditional chemical risk assessment relies on laboratory ecotoxicity studies, and then to model (in effect speculate) what the population or ecosystem functioning consequences might be. We aim to move beyond these current limitations by interrogating wildlife population data in the terrestrial, freshwater and marine spheres in the context of chemical exposure to help move the subject further forward. Our high-level aim is to identify which populations and environments are doing well under the current chemical regime and which are not. This will allow the UK to focus its research where the greatest wildlife declines are occurring. This should bring clarity to the issue of chemicals in the environment that continues to provoke great anxiety and uncertainty. Chemical exposures we will examine include pesticides in the terrestrial and freshwater environments, the de facto mixture in wastewater effluent, metals and persistent organic pollutants. We will be looking at macroinvertebrates and fishes in our rivers, invertebrates and sparrowhawks on land and cetaceans (dolphins and killer whales) off our coasts. These environments and species represent current concerns across the natural environment for both diffuse and point source pollution. We will focus on species and taxa that are either core providers of ecosystem services or represent aspects of native biodiversity identified by the public as important. There are many stressors and compensating factors other than chemicals that can influence wildlife populations. We will ask how important are chemical stressors in relation to other pressures in the environment? By comparing long-term and spatially explicit trends in natural populations, with the response predicted by classical ecotoxicity as reported in the literature, we will evaluate whether such tests are indicative of impacts in the wild. This is essential to assess to what extent traditional risk assessments, typical of those used in the Water Framework and similar Directives, are predictive of outcomes for wildlife populations in terrestrial, freshwater or marine environments.

MO296

Environmental behavior and bioaccumulation of contaminants of emerging concern in northern freshwater ecosystems

A. Arriola, A. Evenset, Akvaplan-niva AS; I. Krogseth, NILU - Norwegian Institute for Air Research; D. Herzke, NILU - Norwegian Institute for Air Research / FRAM Centre Tromso; N.A. Warner, NILU - Norwegian Institute for Air Research / Environmental Chemistry; C. Möckel, K. Breivik, NILU - Norwegian Institute for Air Research

Remote northern ecosystems are often viewed as net receptors of persistent organic pollutants (POPs). These contaminants are transported to Arctic regions via long-range atmospheric transport, but can also have local sources within the Arctic. While concentrations of some legacy POPs have declined in Arctic ecosystems, there is increasing concern about emerging organic contaminants that may have similar properties: toxicity, bioaccumulative, persistent and capable of long-range transport. However, our understanding of their environmental behavior and bioaccumulation in the Arctic environment and ecosystems is still limited. Hence, our objective is to investigate their concentrations, trophic transfer and bioaccumulation in Arctic freshwater ecosystems. We selected two lakes located in Northern Norway, Takvatnet (69 °N 19 °E) and Storvannet (70 °N 23 °E). Their ecosystems are well-studied, and they have similar food webs with Arctic Char (*Salvelinus Alpinus*) and Brown Trout (*Salmo Trutta*) as top predators. Takvatnet is a remote lake, with no known local sources of contaminants. Storvannet is situated in a populated area, with several local sources of organic contaminants. Sediments, zooplankton, benthos, three-spined sticklebacks (*Gasterosteus aculeatus*), char and trout were sampled from Takvatnet (2017, 2018) and Storvannet (2018). Passive air and water samplers were also deployed. Morphometric data, otoliths and samples for stable isotope analysis ($\delta^{15}N$, $\delta^{13}C$) and lipid content were collected from all organisms. Initial samples of muscle and liver from char and trout in Takvatnet were analyzed for selected chlorinated paraffins (CPs), Dechlorane Plus and analogues, new brominated flame retardants (NBFRs) and some legacy POPs including polychlorinated biphenyls (PCBs), polybrominated diphenyl ethers (PBDEs) and dichlorodiphenyltrichloroethane (DDT). Preliminary results show higher PCB concentrations in trout (muscle: 355 ng/g lw, liver: 187 ng/g lw) than in char (muscle: 101 ng/g lw, liver: 111 ng/g lw), consistent with trout occupying a higher trophic level. Dechlorane 603 and short- and medium chained CPs were detected near detection limits, while no NBFRs were detected. Contaminant levels throughout the trophic levels in both lakes will be used in combination with a mechanistic model to improve our understanding and predictive capability of environmental drivers, trophic transfer and bioaccumulation of these compounds in freshwater ecosystems.

MO297

Feeding composition, trophic level and location affects the Persistent Organic Pollutants and Emergent compounds levels in Andean Condor

M. Duclós, Universidad Andrés Bello / Doctorado en Medicina de la Conservación; V. Quirici, Universidad Andrés Bello / Centro de Investigación para la Sustentabilidad; E. Pavez, Unión de Ornitólogos de Chile; P. Sabat, Universidad de Chile / Instituto de Ecología y Biodiversidad; F.M. Jaksic, Pontificia Universidad Catolica de Chile / Centro de Ecologia Aplicada y Sustentabilidad; J. Roscales, Institute of Organic Chemistry of the Spanish National Research Council (IQOG-CSIC) / Department of Instrumental Analysis and Environmental Chemistry; B. Jimenez, IQOG-CSIC / Department of Instrumental Analysis and Environmental Chemistry; C. Galbán-Malagón, Universidad Andrés Bello / Department of Ecology and Biodiversity

Persistent organic pollutants (POPs) are now known to pose a potential risk to human, wildlife and ecosystems health. Due to their persistence and volatility, they can travel long distances and settle in places far away from their origin. In Chile pollutants are distributed in an altitudinal, latitudinal and anthropogenic gradient, presenting higher concentrations in central Chile. Otherwise, due to their toxicity, they may generate varied health effects, having consequences in reproduction, early development and behavior in individuals and populations. The bioaccumulation and biomagnification capacity of POPs affects mainly the species located at the top of the food chain. The main entry route, at least in terrestrial organisms, is through ingestion. Therefore, feeding behaviour can influence the

exposure to pollutants and consequently their health status. The Andean condor (*Vultur gryphus*) is especially vulnerable to POPs because it is scavenger and very long-lived. According to our knowledge, studies on this subject in the Andean condor are gap to be filled until now. Therefore, the objective of this study is to evaluate the relationship between food sources and contaminant levels in two high density Andean condor nuclei in Chile. Identify the composition and trophic level of food resources through analysis of pellets and stable isotopes of Carbon (C) and Nitrogen (N) and finally relate the levels of POPs to food sources. The study area comprises three zones that coincide with these two high-density nuclei. Pellets and feathers were collected. Pellets were used to determine the composition of the diet. Feathers were used to determine levels of stable isotopes and POPs. We analyzed 18 PCB congeners, 6 DDTs isomers, 27 PBDE congeners and 2 DP isomers. Diet analysis, showed that cattle was the main source of food and significant differences between the isotopic signals of C and N in central Chile and the southern areas, where the central population presented enriched values of C and less than N. Regarding the compounds analyzed, only 32 were found above the limit of quantification. The families of contaminants best represented were PCBS, DDTS and PBDES, being the 91% of the compounds found. Our results pointed that C signal provides a good proxy of latitudinal feeding zones/ranges in Andean Condor, an influential factor in terms of pollutant emissions; while the differences in the N signals evidence dietary differences in terms of trophic position.

MO298

Food web dynamics of per- and polyfluoroalkyl substances and mercury in the Greenland Sea, Northeast Greenland

H. Sakpal, University of Koblenz- Landau / Institute of Environmental Sciences; J.P. Zubrod, University of Koblenz-Landau / Institute for Environmental Sciences; R. Bossi, Aarhus University / Department of Environmental Science; C. Bouchard, Greenland Institute of Natural Resources / Greenland Climate Research Centre; E.F. Møller, Aarhus University / Arctic Research Centre, Department of Bioscience; R. Schulz, University of Koblenz-Landau / Institute for Environmental Sciences; J. Sun, University of Antwerp / Department of Biology; J. Søndergaard, A. Mosbech, I. Eulaers, Aarhus University / Arctic Research Centre, Department of Bioscience

The Arctic has turned into a sink for various anthropogenic compounds such as persistent organic pollutants (POPs) and mercury (Hg) that tend to biomagnify and consequently cause toxicity in a wide range of higher trophic species. Nonetheless, new chemicals with POP-like chemical properties remain unregulated and continuously enter into the environment. Among these, several per- and polyfluoroalkyl substances (PFASs) are of special interest as they have been found widely in Arctic species. Among the PFASs, only the production and consumption of perfluorooctane sulfonate (PFOS) is currently restricted under the Stockholm Convention for POPs. Similarly, Hg, also being widely documented in Arctic biota and considered of major toxicological concern, has recently been restricted globally, under the Minamata Convention. The objective of the present study is to provide the first assessment of food web biomagnification of PFASs and Hg in the Greenland Sea off Northeast Greenland, a pristine region currently facing rapid environmental change. The food web investigated spans from primary consumers, i.e. *Calanus* spp., over benthic and pelagic invertebrates and fish, up to seabirds. The relative trophic position was determined using bulk tissue stable nitrogen isotopes (δ^{15}N), and we will present several biomagnification proxies to quantify and characterize the food web dynamics of the targeted compounds. Preliminary results show increasing Hg concentrations along the food web from *Calanus* spp. (median=0.03 μg g^{-1} dw; range=0.03–0.07 μg g^{-1}dw), being assigned trophic level 2.0, over other invertebrates (median=0.04 μg g^{-1} dw; range=0.01–0.25 μg g^{-1}dw), feeding at trophic levels ranging from 1.8–2.8, over several benthic and pelagic fish (median=0.12 μg g^{-1} dw; range=0.10–0.15 μg g^{-1}dw), feeding at trophic levels ranging from 2.7–3.3, up to the highest concentrations in the seabird species (median=0.31 μg g^{-1} dw; range=0.11–0.50 μg g^{-1} dw), feeding at trophic levels ranging from 3.3–4.0. We will present a more detailed assessment of Hg and PFAS dynamics in the Greenland Sea food web, thus providing the first comprehensive and quantitative baseline study for this pristine though rapidly changing Greenlandic food web.

MO299

From population level effects to community functioning: a network approach

M. Hagen-Kissling, Eurofins-MITOX B.V.; F. Bakker, Eurofins-Mitox

Assessment of the ecological recovery of populations after exposure to environmental stressors (e.g. plant protection products) is, so far, abundance-based only: if after a certain interval, untreated and treated study sites don't show differences with respect to the inhabiting populations, recovery is assumed. Studying abundances of species populations in isolation does not enable the behaviour of the ecosystem to be predicted, as often emergent or counterintuitive effects can arise from the myriad of pathways of interactions. A shift in focus from species to interaction networks is necessary to achieve sustainable pest management, to conserve ecosystem processes and ultimately landscape-scale delivery of ecosystem services. Network approaches provide a powerful presentation of the pattern of interactions among species, highlight their interdependence and help to make inferences about effects of observed disturbances on species composition, functionality, resilience and ecological recovery of communities. We populated a network model with abundance data of a natural non-target arthropod community obtained from a hay meadow. Using a machine learning approach, we constructed a co-occurrence network. After validation, we evaluated network metrics, like the percentage of taxa that were trophically top (taxa with "no" consumers = top-predators), intermediate (taxa that both consume and are consumed), and basal (taxa that do not consume other arthropod taxa, but are e.g. herbivores), connectance (the proportion of possible links between species that are realized) and modularity (subsets of species (= modules) that are internally highly connected). Furthermore, we investigated the importance of the interacting taxa for the robustness of the overall network. In a subsequent step, we disturbed the network (reduced abundance of certain taxa) and evaluated the network metrics in comparison to the results of the undisturbed network. This yielded indexed measures of functionality, resilience and ecological recovery of the manipulated network. Several important network features, like connectance, modularity and robustness changed due to the disturbance. With this method, we achieved a ranking or categorization of effects on single populations with regard to their impact on the overall ecosystem robustness and functioning. We conclude that network approaches are an important tool to interpret the results of higher tier field studies for environmental risk assessments.

MO300

Mercury accumulation in the trophic webs in a tropical estuary: Cartagena Bay, Colombian Caribbean

P. Cogua, Universidad Santiago de Cali; G. Duque, Universidad Nacional de Colombia / Facultad de Ingeniería y Administración, Departamento de Ingeniería

The metil-mercury bioaccumulation process is determined by throphic position and the feeding habits of species. At Cartagena Bay there are trophic webs based on detritus and phytoplankton that may show different mercury bioaccumulation patterns, which were tested at different climatic seasons and bay areas at the present study. Five field trips at different rain levels and at five bay areas each time were carried out in order to collect fishes of different trophic levels, phytoplankton samples and detritus. A positive correlation between the total mercury concentration (HgT) and the metil-mercury (MeHg) concentration in the phytoplankton was found ($r=0,77$; $p< 0,0001$). All the fish species collected accumulated total mercury, from which, 10 species had levels of this metal higher than those permitted by the WHO for vulnerable communities. Not only the carnivorous had higher levels of mercury than planktivorous and detritivorous fishes but also the bigger the fish the higher the total mercury level as expected. The metil- mercury level in phytoplankton was 22%, whereas in zooplankton was 23% and in fishes more than 50% of the total mercury. The metil mercury is accumulated more efficiently by the planktivorous pathway than the detritivorous pathway.

MO301

Riparian Spiders in Ecotoxicological Studies

G. Beaubien, Middle Tennessee State University / Biology; C. Olson, Middle Tennessee State University / Department of Civil and Environmental Engineering; R.R. Otter, Middle Tennessee State University / Biology; D. Walters, U.S. Geological Survey / Columbia Environmental Research Center; M. Mills, U.S. Environmental Protection Agency / National Risk Management Research Laboratory; M.M. Chumchal, Texas Christian University / http//www.aquaticecologylab.tcu.edu/

A major first level inquiry for many environmental contaminant studies is to determine whether exposure is occurring in the aquatic or terrestrial ecosystem. More complex scenarios, however, can occur when contaminants and organisms are exchanged between linked aquatic-terrestrial systems. Historically, ecotoxicological studies operated under the assumption that once a contaminant enters the aquatic ecosystem, it is primarily an aquatic concern only and that export to the terrestrial ecosystem is insignificant (i.e., aquatic systems are sinks for contaminants). Early interchange studies highlighted the importance of contaminant transport in the form of cross-system biotic subsidies, for example emerging aquatic insects or salmon carcasses. More recently, riparian spiders have gained traction as a valuable tool in this field of study. These abundant and widespread predators feed on aquatic emergent insects and can act as a bridge to the terrestrial food-chain. Their life history characteristics (e.g., ubiquitous distribution, small home ranges, short life spans) make them attractive as potential model organisms. Progressively, more studies are using riparian spiders to investigate a variety of topics related to contaminant fate and exposure, including food-chain dynamics and contaminant monitoring and export. Here we overview key studies utilizing riparian spiders as environmental indicators, current research foci, and future research directions.

MO302

SYSTEMLINK - a new project on the effects of stressors across ecosystem barriers.

R. Schulz, M. Bundschuh, M.H. Entling, H. Jungkunst, E. Kroener, A. Lorke, University of Koblenz-Landau / Institute for Environmental Sciences; R. Schaefer, G.E. Schaumann, University Koblenz-Landau / Institute for Environmental Sciences; K. Schwenk, University of Koblenz-Landau / Institute for

Environmental Sciences
The impact of matter input from terrestrial sources on aquatic systems is well known. The reverse process, i.e. the transport from water (source) to land (sink) in aquatic-terrestrial meta-ecosystems, has received less attention. In SYSTEMLINK, we focuson the bottom-up and top-down mediated interactions in terrestrial ecosystems, which propagate from aquatic environments as a result of their exposure to anthropogenic stress. We consider micropollutants (fungicides and insecticides) and invasive species (riparian plants and invertebrates) as important manifestations of multiple stressors in disturbed aquatic ecosystems. We hypothesise that 1) invasive invertebrates and insecticide exposure and 2) invasive riparian plants and fungicide exposure cause top-down and bottom-up mediated responses in terrestrial ecosystems, respectively. We test these general and several more specific hypotheses through collaborative experiments in replicated outdoor aquatic-terrestrial mesocosms (*site-scale*) amended by joint pot experiments (*batch-scale*), field studies (*landscape-scale*), and modelling. All experimental setups will be derived from the landscape scale representing a multi-stress environment. Several scales will regularly be combined to overcome scale-specific restrictions and to ensure both cause-effect quantification as well as environmental relevance of the results. Ultimately, SYSTEMLINK thrives to increase our knowledge on effect translation across ecosystem boundaries. By integrating biogeochemical fluxes and biological subsidies we will be able to quantify their relative importance. Furthermore, we will closely combine the often-separated aquatic and terrestrial research areas.

MO303
The pollution driven bacteria and ciliate community structure in a highly impacted microbial loop-based freshwater river ecosystem
J. Li, Y. Zhou, T. Michelena, Wenzhou-Kean University
The Wen-Rui Tang River is an important river system in Wenzhou, Zhejiang Province, China and is considered the mother river of the city. Historical use and modern industrial activities have resulted in the river becoming severely polluted. It has become one of Wenzhou's largest pollution sources and one of the main pollution distribution centers, directly affecting the day-to-day life of Wenzhou citizens. To understand the ecological impacts of the pollutants, this projected assessed the water quality and ecosystem structure of the Wen-Rui Tang River as a function of time and land use over an 18 km reach of the river as it transits Wenzhou from the agricultural areas at the boundaries of the city, through the Sanyang Wetland and the urban core. Based upon current and previous work, the primary pollutants for the river have been shown to be organics such as total phosphorus and total suspended solids. These pollutants have had serious deleterious effects on the aquatic ecosystem. The reduced light penetration due to excessive suspended solids and the high organic loading has created a microbial loop trophic system. This project assessed the temporal and spatial distribution of bacteria and ciliate populations in the Wen-Rui Tang River system in order to develop an understanding of the microbial community of the ecosystem. The data detail the distribution of microbes as a function of water quality and provide a basis for understanding the structure of the microbial loop trophic system. Correlation of the bacterial and ciliate populations with pollutant levels and land use provide a means to develop ecosystem models to be used as a tool to guide remediation of the Wen-Rui Tang. The data presented here forms the basis to develop a model of a freshwater microbial loop ecosystem. The model developed with this data will enable more accurate targeting of remediation strategies to rehabilitate the Wen-Rui Tang, which is at the heart of Wenzhou history and culture.

MO304
Tracer or poison: is labelling with stable isotopes safe for aquatic food webs?
J.P. Zubrod, University of Koblenz-Landau / Institute for Environmental Sciences; M. Konschak, University Koblenz-Landau / Institute for Environmental Sciences; S. Lüderwald, Universität Koblenz-Landau / Institute for Environmental Sciences; R. Schulz, University of Koblenz-Landau / Institute for Environmental Sciences; M. Bundschuh, Institute for Environmental Sciences University of Koblenz-Landau / Department of Aquatic Sciences and Assessment
Heavy stable isotopes (such as ^{15}N) are commonly used to trace the flow of energy, nutrients, and matter in food webs based on the assumption that their enrichment does not affect the physiology of consumers. However, a recent study (Andriukonis & Gorokhova, 2017, Scientific Reports) implies that growth of algae was negatively correlated with ^{15}N concentration in medium, while at an intermediate level of labelling (3.5 at%) growth lag phase was shortest (effect size [ES] ~10%). To test if this is a universal phenomenon in aquatic food webs that would rule out the use of ^{15}N as tracer, we performed two experiments. In the first one, we tested if consumption of a labelled photoautotrophic resource does affect the survival and fitness of an aquatic primary consumer. We cultured algae (*Desmodesmus subspicatus*) at differing ^{15}N concentrations (0.37-50 at%) before they were fed to *Daphnia magna* during a 21-day lasting reproduction test. The experiment followed in general OECD 211 but with 6 animals cultured in 150 mL medium with a replication of five. In the second experiment, we tested if heterotrophic microorganisms show similar effects as observed for algae. Therefore, black alder leaf material was subjected to colonization and decomposition by a natural microbial community (particularly fungi and bacteria) for 12 days with medium containing increasing ^{15}N concentrations (n=15). During the first experiment, reproduction was not affected (ES < 5%). However and contrary to literature, mortality data indicate the ^{15}N labelling at 3.5 at% to be rather unfavorable with survival being reduced by 10% compared to the control. This observation is supported by the leaf decomposition being lowest for this treatment during the second experiment (ES >10%), although differing non-significantly to the control (i.e., 0.37 at%). Currently, we are analyzing preserved samples of both experiments (e.g., physiological condition of daphnids and microorganisms) to verify the identified trends (i.e., detrimental implications in the survival of a primary consumer and the functioning of microbial decomposers at 3.5 at%). As the present and literature data indicate, nonetheless, that relevant heavy stable isotope concentrations (i.e., up to 35 at%) do not affect biological and ecological responses considerably, labelling with ^{15}N still seems well-suited to trace the flow of energy, nutrients, and matter in aquatic food webs.

MO305
Tracing indirect effects: stable isotope and elemental analysis as state-of-the-art tools
J.P. Zubrod, D. Englert, University of Koblenz-Landau / Institute for Environmental Sciences; S. Lüderwald, Universität Koblenz-Landau / Institute for Environmental Sciences; B. Fuß, A. Pollitt, R. Schulz, University of Koblenz-Landau; M. Bundschuh, Institute for Environmental Sciences University of Koblenz-Landau / Department of Aquatic Sciences and Assessment
Changes in trophic interactions or food web structure are hard to detect using traditional approaches. Stable isotope signatures and elemental composition, which both provide information on the assimilated resource, appear as promising tools. To test for their suitability in an ecotoxicological context, in a first experiment, the omnivorous amphipod *Gammarus fossarum* was given the choice to feed either on black alder leaves or prey on mayfly larvae (*Baetis* sp.). This trophic interaction was assessed under exposure towards the neonicotinoid thiacloprid (0.75 μg/L). The study followed a multi-factorial design (thiacloprid x *Baetis* x leaves) to assess the effect of all factors – individually and in combination. Consumption of *Baetis* and leaves were monitored for two weeks and stable isotope signatures and elemental composition were determined for both resources as well as the predator (i.e., *G. fossarum*) at the termination of the experiment. In a second experiment, we tested if chemical stress could affect stable isotope signatures by exposing gammarids towards thiacloprid (0, 0.75, or 6 μg/L) for up to six weeks and providing them with a single food source (i.e., leaves or *Baetis*). In the first experiment, thiacloprid exposure affected the food choice of *G. fossarum*: a higher consumption of *Baetis* was observed, while this was not reflected by gammarids' elemental composition. However, the N-content of *Gammarus* was increased by thiacloprid when only fed *Baetis*. While providing valuable physiological information, elemental analysis thus seems unsuitable to trace changes in dietary interactions due to chemical stress. In contrast, mixing models based on stable isotope signatures well reflected the increased predation success and no differences in signatures were observed between exposed and unexposed animals when only leaves or only *Baetis* were offered. Moreover, the second experiment revealed that even after six weeks of exposure towards 6 μg/L, a concentration significantly reducing physiological fitness of gammarids and increasing their mortality rates, final stable isotope signatures differed only minimally (< 0.5 ‰) when compared to the control. Although further experiments with different test systems (i.e., combinations of consumers and resources as well as chemical stressors) seem necessary to draw reliable conclusions, our data suggest that stable isotope analysis is indeed a promising tool to trace indirect effects of chemical stressors in exposed food webs.

MO306
Transfer of mercury within a sediment-nettle-insect food web at a chlor-alkali landfill
L. Yung, C. Bertheau, Université de Bourgogne FrancheComté; N. Regier, University of Geneva / Department Forel Earth and Environmental Sciences; V. Slaveykova, University of Geneva / Département F.-A. Forel des sciences de lenvironnement et de leau; D. Cazaux, INOVYN France; M. Chalot, Université de Bourgogne Franche-Comté
Mercury (Hg) commonly enters ecosystems through anthropogenic sources such as atmospheric emissions or wastewater from industries. Sediment landfills from chlor-alkali industries require Hg stabilization to prevent air pollution by evaporated Hg. We recently demonstrated the relevance of phytomanagement process based on poplar plantations to revegetate and confine the Hg released from the soil in an experimental plantation located at a sediment landfill. Five years after the plantation, biotic and abiotic conditions have promoted the appearance of a spontaneous herbaceous cover highly dominated by the stinging nettle (*Urtica dioïca L.*). In natural conditions, this plant species hosts an important diversity of insects playing a key role in trophic interactions within the ecosystem. As demonstrated for aquatic ecosystems, Hg is readily biomagnified through food webs, from plants to insects, birds and mammals. The present study aimed at evaluating the trophic interactions at the nettle scale in a phytomanagement field trial and their implications for the Hg flux through a sediment-nettle-insect food web system. Insects were collected every month using a sweep net, from April to September 2017 and 2018. Once taxonomically and

ecologically characterized, the total Hg (THg) concentrations of the 18 most abundant taxa were analysed using an AMA-254 analyser. Several trophic links were identified with a ratio of herbivorous /predatory of 23 %. The mean concentrations of THg for insects collected from the experimental plantation were significantly higher than those from the control site. Within the nettle-related food web, the THg concentration followed the order of nettles (21.2 ± 1.0 μg/kg) < herbivorous (27.5 ± 4.3) < predator specialists (43.0 ± 14.1) < predator generalists (617.3 ± 47.2) showing a significant bioaccumulation. Moreover, we observed that insects that spent part of their life cycle directly on Hg sources had a higher THg concentration average (918.4 ± 80.5 μg/kg) than generalist predators of the nettle food web. Hence, our study showed a complex network of trophic interactions from the studied nettle-insect food web. Overall, taxa that contributed the most to the Hg transfer to the highest trophic links were generalist predators and those in direct contact with Hg sources. Moreover, in revegetated sediment landfills, plants did not seem to be the primary source of Hg exposure for wildlife.

MO307

Trophic transfer and insect metamorphosis decouple contaminant exposure in linked aquatic-terrestrial food webs

J.M. Kraus, U.S. Geological Survey / Fort Collins Science Center; R. Wanty, USGS; T.S. Schmidt, USGS / Colorado Water Science Center; D. Walters, U.S. Geological Survey / Columbia Environmental Research Center; R. Wolf, Perkin Elmer

Aquatic insects link food web dynamics across freshwater-terrestrial boundaries and subsidize riparian consumer populations. Contaminants can accumulate in organic matter and organisms affecting contaminant exposure and resource quality for consumers, yet the factors regulating these patterns at the land-water interface are not well understood. To test how exposure concentrations in aquatic food webs are related to those on land, we conducted a large-scale field study of the accumulation patterns of trace metals through linked stream-forest food webs in the Colorado Rocky Mountains (USA). Metals were transferred across trophic and metamorphic steps less efficiently from high metal streams, resulting in a decoupling of exposure risk between food webs in aquatic and terrestrial ecosystems. Although the relationships between consumer and resource tissue concentrations weakened with each trophic transfer, they were not lost until metamorphosis from larvae to adult. On average, metal concentrations increased with each trophic step then decreased sharply across metamorphosis from larval to adult insects. Our results indicate that insect metamorphosis and trophic processes combine to limit trace metal transfer from contaminated freshwaters. These findings have implications for managing exposure and developing riparian organisms as indicators of aquatic contamination. Furthermore, our findings bolster our working hypothesis that metamorphosis is a critical process regulating the cross-ecosystem effects of contaminants and that, being an act of self-consumption and tissue building, metamorphosis may have similar effects on insect chemistry as trophic transfer.

MO308

Trophic Transfer of Radioisotopes of the Micronutrients Manganese, Cobalt and Zinc in the Baltic Sea: A Cosm Study of a Shallow Benthic Food Web

I. Holmerin, J. Holmberg, Stockholm University / Department of Ecology, Environment and Plant Sciences; L. Kiel Jensen, T.H. Hevrøy, NRPA; C. Bradshaw, Stockholm University / Department of Ecology Environment and Plant Sciences

The Baltic Sea is regarded as one of the seas with the highest levels of radioactive pollution from anthropogenic sources. Despite this, little is known of radionuclides' ecological fate in brackish environments. In this study, a multi-species cosm trial was used to investigate the fate of three radioactive isotopes of micronutrients, Mn-54, Co-57 and Zn-65, which are regularly released into the Baltic Sea from nuclear power plants (NPPs). A parallel trial was done with C-14 to verify the carbon flow and the trophic structure of the cosms. The cosm trial consisted of exposing a benthic Baltic Sea community, consisting of the macroalgae *Fucus vesiculosus* (bladder wrack) and two grazers, the gastropod *Theodoxus fluviatilis* and the isopod *Idotea baltica*, to trace amounts of these radionuclides. With this setup several relevant factors could be studied. Primarily, adding the radionuclides to the cosms allowed for the investigation of the direct uptake from water to both algae and grazers. Secondly, the potential effects of eutrophication on the uptake of radionuclides could be investigated by exposing the cosms to different nutrient levels before the radionuclide addition. Thirdly, by having different combinations of grazers and macroalgae in the cosms before the radionuclide exposure allowed the effects of grazer-macroalgae interactions on the uptake to be studied. Finally, the difference in uptake depending on indirect exposure could be distinguished by using exposed macroalgae to feed non-exposed grazers. Overall, these factors are all relevant by themselves and the combination of them through this study provides a way to detect any synergistic effects on radionuclide uptake in the benthic community between these factors. These approaches also allow this study to identify and verify trophic links and consequently the ecological fate of the three radionuclides. Results from the cosm trials showed that uptake from water of all radionuclides occurred in *F. vesiculosus*. Furthermore, radionuclide uptake was observed in *T. fluviatilis* and the isopod *I. baltica* both when exposed to water and when feeding on exposed *F. vesiculosus*. These results will be of importance for further risk assessments of NPP-derived radionuclides and could indicate priority targets in NPP waste water treatment.

From Hazard Assessment to Regulatory Risk Management Action - Approach Development for UVCBs (P)

MO309

The Safety Assessment of Natural Complex Substances: Program Development

D.T. Salvito, Research Institute for Fragrance Materials (RIFM) / Dept of Environmental Science

Natural Complex Substances (NCSs) are plant extracts prepared by a variety of processing methods (e.g., steam distillation) and used in perfumery. In a regulatory context, these would be considered multiconstituent substances (MCSs) or unknown, variable composition, or biological substances (UVCBs). The Research Institute for Fragrance Materials has established an ongoing safety assessment program addressing human health and environmental risk of ingredients utilized in the preparation of fragrance compounds used in a variety of consumer and personal care products. The next phase in this program is the assessment of NCSs. A framework has been developed addressing the applicability of endpoint evaluation based on whole substance, blocks, or individual components. These endpoints include environmental hazard (i.e., PBT evaluation) and risk, skin sensitization, phototoxicity, genotoxicity, respiratory, repeat dose, and reproduction. Additionally a library of terpene blocks and methodology for grouping related NCSs to facilitate this assessment process has been proposed. NCSs should be able to be grouped based on the plant type, the part the NCS is extracted from (e.g., fruit, branches), how the part is processed, and the chemical composition of the extract. As these safety assessments are developed and published they will be publicly available at the Food and Chemical Toxicology Fragrance Material Assessment Center (http://fragrancematerialsafetyresource.elsevier.com/).

From mapping to identification: Paving the way to UVCB risk assessment

S.E. Deglin, ILSI Health and Environmental Sciences Institute (HESI); M.R. Embry, Health and Environmental Sciences Institute (HESI); R. Hoke, E. I. du Pont de Nemours and Company / Electronics & Imaging; K. Jenner, Givaudan / Global Regulatory Affairs & Product Safety; E. Leinala, OECD; D. Lyon, Shell Oil Company / Shell Health Risk Science Team; J. Parnis, Trent University / Cemistry; D.T. Salvito, Research Institute for Fragrance Materials, Inc. / Department of Environmental Science

Risk assessment of complex substances such as multi-constituent substances (MCs), and substances of Unknown or Variable Composition, Complex Reaction Products, and Biological Materials (UVCBs), presents numerous challenges. International regulatory programs (specifically REACH, Canada's Chemicals Management Plan, and USEPA's PMN process) have highlighted the complexities of characterizing fate and exposure, risk assessment, and registration of these types of substances. This is why HESI's UVCB Committee is working on developing approaches for assessing ecological risks of UVCBs to meet regulatory needs. A grouping framework was created to map the vast and complex universe of UVCB substances according to chemical and/or functional classes, exposure and use patterns, production volume, potential toxicity and other criteria. This framework is the foundation of all work performed on this project. It provides a better understanding of the nature of these substances and their sector of use, as well as some insight on which substances present the most significant regulatory challenges. In a second step, the Committee will develop identification and characterization strategies for the mapped substance groups. For each group, the overall goal is to determine the minimum level of information required to perform a robust and fit-for-purpose ecological risk assessment. To do so, the Committee has been exploring various issues including definitions of acceptable levels of uncertainty and variability when assessing risk and strategies to characterize substances with limited or no structural information; and development of criteria that could be used in a weight of evidence approach to substance identification and characterization. Characterization approaches have included discussions around how knowledge of source material and production processes can help inform substance identification. This two-pronged approach is expected to ensure that the efforts and resources deployed for UVCBs risk assessment match actual needs, and help streamline the risk assessment process. Examples of UVCB mapping will be presented and some of the most common categories of UVCBs will be highlighted along with the associated assessment challenges. Substance identification and characterization methods will be illustrated, as well as how they provide the necessary information for a reliable risk assessment. [The views of the authors of this presentation are those of the authors and do not represent the views of their respective organizations]

Modelling and Monitoring of Pesticides Fate and Exposure in a Regulatory Context (P)

TU001
COMPARISON OF SOIL PHOTOLYSIS IN DRY AND MOIST SOIL LAYERS
T. Cooper, Smithers Viscient (ESG) Limited / Envirnomental Fate and Metabolism; S. Swales, Smithers Viscient ESG Ltd / Environmental Fate and Metabolism
The OECD guidelines for the testing of phototransformation of chemicals on soil surfaces are a draft document from January 2002. The guideline suggests two types of soil layers may be used for investigation, one maintained at soil moisture of approximately 75% of field capacity and one allowed to dry out completely. When a test substance is applied to soil for investigation into phototransformation, the results obtained can vary significantly depending on whether it is applied to moist or dry soil layers. Though the rate and method of phototransformation is dependent on the nature and structure of the test substance, there may be trends observed between test substances for the different types of soil layers. Whilst the OECD guideline remains draft, there is opportunity to consider and potentially adapt, the methodology used in soil photolysis investigations. Whilst SETAC 1995 is still the recommended guideline for PPP's, it is increasingly common for studies to be conducted using both moist and dry soil layers. In addition to the obvious cost and timeline implications, the different designs could lead to more extensive issues e.g. different degradation rates and pathways. This poster examines the similarities and differences in phototransformation routes and rates when the same compound is applied under moist and dry soil conditions.

TU002
Field Soil Degradation under Exclusion of Surface Processes, Comparing Sand Cover against Incorporation of the Test Substance
J. Hassink, J. Hassink, B. Jene, T. Richter, BASF SE / Environmental Fate; B. Gottesbueren, BASF SE / Crop Protection, Environmental Fate Modelling; M. Roos-Majewsky, BASF SE / Environmental Fate
The degradation of a potential volatile plant protection product (vapour pressure > 1 x 10^{-4} Pa at 25°C) under field conditions was investigated at four sites in Europe. Two trials were performed in Germany, one trial was performed in France and one in the UK. Applications were conducted on bare soil in August or September. Following application of the substance, two of the following procedures were compared to eliminate the impact of surface loss processes (e.g. photolysis, volatilization) on the $DegT_{50matrix}$ value as recommended in the OECD Guidance document for Conducting Pesticide Terrestrial Field Dissipation Studies:[(1)] Even application of a layer of commercial fine sand to the soil surface, achieving a depth of at least 3 mm, although not recommended by the OECD Guidance if the substance has a vapour pressure > 1 x 10^{-4} Pa, unless other experimental evidence is available that volatilization is not a route of dissipation. Incorporation of the substance in the soil immediately after spraying to the soil surface and mixing over a target depth of 7 cm. A plot power harrow was used for the application and after harrowing, the plots were rolled. The first soil sampling was done directly after the applied procedure. No tillage or fertilization was performed in the course of the study and no crops were grown throughout any of the trials. The plots were kept free of vegetation. Soil specimens were taken down to a soil depth of max. 50 cm, cut into sections of 10 cm, extracted with appropriate organic solvents followed by LC-MS/MS analysis with a limit of detection (LOD) of 0.01 mg/kg for the test substance. The results show no significant differences of the employed procedures on the soil degradation/dissipation of the test substance. The application of a layer of fine sand to the soil surface is already sufficient to prevent dissipation of the applied test substance with a vapour pressure of > 1 x 10^{-4} Pa. [(1)] OECD Guidance Document for Conducting Pesticide Terrestrial Field Dissipation Studies, Series on Testing & Assessment No. 232, Series on Pesticides No. 82, March 04, 2016, ENV/JM/MONO(2016)6

TU003
Benefits of the new EFSA guidance on soil exposure compared to current regulatory procedure
M. Egsmose, EFSA; A. Tiktak, PBL Netherlands Environmental Assessment Agency / Water Agriculture and Food
1. Introduction Following MS consultations EFSA initiated a revision of the guidance for the soil exposure assessment and soil persistence. The EFSA soil exposure guidance (GD) covers applications of plant protection products to annual- and permanent crops [1]. The exposure assessment targets obtain a 90^{th} percentile of the PEC in space and time in the selected regulatory zones North, Centre and South. The calculated exposure concentrations will be used for risk assessment of soil organisms living in the soil. 2. Comparison of EFSA GD with current regulatory procedure The EFSA guidance introduces a tiered approach with increasing realism from lower to higher tiers for exposure refinement when needed. Pre-defined scenarios have been provided for the first tier for each regulatory zone; these can be used for both EU- and zonal assessments. For Member State (MS) assessments, an EU MS can be selected as well. The new approach also takes into account realistic description of foliar wash-off from the crop canopy. Further the soil density, average annual temperature and rainfall are taken into account allowing natural variability to be considered. The new approach introduces options for considering the type of application, e.g. spray applications or incorporation into the soil. Non-homogeneous treatments such as in-row and between-row applications can be included as well. As a higher tier, the guidance allows users to generate own data on plant protection products for improving the canopy wash-off processes. The EFSA GD is supported by user-friendly software tools where PERSAM provides quick solutions to Tier-1 and Tier-2 while the numerical models PELMO and PEARL can be used for refinement of the exposure assessment at Tier-3. The models also provide options for the user to perform the complete soil risk assessment and can produce complete output reports for regulatory submissions. 3. Conclusions The EFSA GD on soil exposure and the supporting software tools take EU wide environmental variability into account and provide a substantial scientific improvement compared to the current regulatory procedure. The new guidance is expected to be implemented for regulatory use during 2019. 4. References [1] EFSA. 2017. EFSA Guidance Document for predicting environmental concentrations of active substances of plant protection products and transformation products of these active substances in soil. Exposure Assessment of Residual Organochlorine Pesticides (OCPs) in Upland and Pasture land Soils in Korea
B. Park, RDA / Chemical Safety; S. Lim, National Institute of Agricultural Sciences,RDA; S. Ryu, International Institute Science, RDA; G. Choi, NAAS RDA
Residual organochlorine pesticides (OCPs) are chemical substances that are resistant to environmental degradation chemical, biological and photolytic process, and are bioaccumulated with potential significant impacts on human health and the environment. The majority of OCPs were designated as persistent organic pollutants (POPs) by the international community at the Stockholm Convention on Persistent Organic Pollutant. This study was conducted to investigate the OCPs residue in paddy and upland soils. Extraction and clean-up method for the quantitative analysis of OCPs was developed and validated by gas chromatography (GC). Recovery and limit of detection (LOD) of OCPs in soil were 74.4-115.6 and 0.02-0.08 g/kg, respectively. The precision was reliable since RSD percentage (0.5-3.5) was below 20, which was the normal percent value. The residue of OCPs in pasture land and upland soils was analyzed by the developed method, and α-endosulfan, -endosulfan, and endosulfan sulfate were detected at 0.36-87.16, 0.06-179.46, and 2.44-287.16 g/kg, respectively. The detection frequency of three compounds were 7.8%, 16.9% and 29.9 among 109 samples, respectively. But OCPs in onion, carrot and radish, which are cultivated crops in OCPs detection soil, were not detected. These results showed that the residue in paddy and upland soils were lower level than bioaccumulation occurring.

TU005
Comparison of the measured and predicted pesticide concentrations in soils of Russia
A. Astaykina, Moscow State University / Soil Science; V. Kolupaeva, V. Gorbatov, All-Russian Research Institute of Phytopathology, 5, Institute street, Bolshie Vyazemy, Odintsovo district, Moscow region, 143050, Russia
Mathematical modeling is an efficient technique to predict pesticides behavior in soil, air, water and groundwater. The main advantages of mathematical modeling include efficiency, time saving and ability to cover a large variety of pesticides application in natural conditions. Mathematical models as an instrument to assess the pesticides concentrations in environment are widely used in European Union. Currently, the pesticides behavior predicting based on the PEARL model designed in the EU as well as the standard Russian scenarios are a part of a multilevel risk assessment of the pesticides, being registered in Russia. The simulated pesticides concentrations are used for the environmental risk assessment of pesticides to non-target organisms. The environmental risk assessment is calculated as the ratio between the acute toxicity or chronic toxicity LC_{50}(NOEC) and pesticide concentrations in soil, surface and ground water. This paper attempts to answer the question: may the predicted concentration be compared with the measured concentration and be applied for environmental risk assessment? The aims of this study were to 1) *determine* the pesticides residues in 3 types of soils under field

conditions; 2) compare measured and simulated pesticides concentrations in soils; 3) evaluate the *quality of mathematical modelling to predict pesticides concentrations; 4) illustrate the application PEC in soil for environmental risk assessment of 6 pesticides to the earthworms.* The concentrations of lenacil, metsulfuron-methyl, triallate, pyrimethanil, fenpropimorph and chlorantraniliprole were determined during the period from 1999 to 2011 in the soils of Moscow, Kursk and Saratov regions. The predicted concentrations of these pesticides were calculated by model PEARL with the standard scenarios for the mentioned regions. The comparison of the measured and predicted data showed that the model results generally agree with the pesticide concentrations under field conditions. The model PEARL may be recommended as the efficient tool to predict pesticides behavior in soil. The risk evaluation of pesticides to earthworms are commonly based on the ratio of the acute toxicity or chronic toxicity LC_{50}(NOEC) and the pesticide concentrations in soil. The acute effects of the studied pesticides to earthworms were negligible. But the application of pyrimethanil and fenpropimorph could have the negative implications for the growth and reproduction of earthworms.

TU006
Identification of groundwater monitoring web for the investigation of the presence of residues of 1,3-dichloropropene and related compounds in Italy
A. Finizio, University Milano - Bicocca / Department of Earth and Environmental Sciences; C. Vaj, Dow AgroSciences Italia s.r.l. / Regulatory and Stewardship; R. Verro, University Milano - Bicocca - Lybra ambiente e territorio S.r.l. / Department of Earth and Environmental Sciences; A. Alix, Corteva Agrisciences / Risk Management; R. Bradascio, Corteva agriscience / Regulatory and Stewardship; S. Knowles, Retired; I. van Wesenbeeck, Corteva agriscience
In Italy, the use fumigants in on bare soil, pre-planting/sowing of the crop, is widely consolidated in agricultural practices, particularly in horticulture. 1,3-dichloropropene (1,3-D) has been used to control nematodes in agriculture since the 1960's, it is therefore a very well-known compound and a number of studies describing its environmental fate and effects are available in literature. The prevention of groundwater contamination from 1,3-D has often been a subject of interest including from a regulatory point of view. In a previous work, areas vulnerable to the leaching of 1,3-D were identified in Italy. The percent of sand content was selected as the key parameter to classify the soils, the area being considered as vulnerable where sand content in soil was >80%. This choice was based on the label recommendations for the commercial products containing 1,3-D, i.e. risk mitigation measure *Do not apply in soil with a percentage of sand >80%*. In this work, we proceeded with the identification of a suitable set of groundwater wells to be included in a monitoring program, starting from the areas previously identified. The attention was focused on two provinces, one in Sicily (Ragusa) and one in Veneto (Verona), located in South and North Italy respectively, and representing different crops and agronomic practices (e.g. greenhouse and open field). Suitable wells were identified using information about geolocalization, structure and availability, and an onsite survey to check the local conditions at wells location. The final identification of the groundwater wells was based on the following criteria: location of wells in areas where 1,3-D is utilized, hydrogeological conditions; accessibility to selected areas; operating conditions of wells; and depth of water. During the sampling phase, wells were characterized by determining their precise location on a map, recording generic information on wells, as well as measuring a set of parameters such as pH, redox potential, conductivity, dissolved oxygen, and turbidity. Water samples were analyzed for the presence of 1,3-D and process impurities. Preliminary results show no to very low residue of the measured compounds. Final results will be presented and discussed. All the critical issues encountered during the wells identification and sampling phases will also be discussed.

TU007
Developing a MACRO meta-model for Swedish drinking water abstraction zones
S. Reichenberger, DR. KNOELL CONSULT GmbH / Environmental Fate / Modelling / GIS; M. Gönczi, SLU / Centre for Chemical Pesticides; N. Kehrein, knoell Germany GmbH / Environmental Fate / Modelling / GIS; S. Multsch, DR. KNOELL CONSULT GmbH / Environmental Fate / Modelling / GIS; N. Jarvis, SLU / Soil and environment; J. Kreuger, Swedish University of Agricultural Science / Centre for Chemical Pesticides
In Sweden farmers are legally obliged to apply to local authorities for permits for pesticide use if their land lies within a designated water abstraction zone. To facilitate risk assessment and decision-making for water abstraction zones, a web-based decision support tool is being developed by SLU. The tool, which is to be used both by local authorities (who make the decisions) and farmers/landowners and consultants, will comprise a meta-model of the well-established leaching model MACRO. In a first step, ca. 19000 leaching simulations were performed with MACRO 5.2 for a pilot region in Sweden (SW Skåne). The simulations constitute 39 soil scenarios (defined by substrate type, soil texture and organic matter content), 1 climate, 1 crop, 3 application seasons and 160 dummy compounds (cominbations of Koc, DegT50 and Freundlich exponent). The aggregated output variables to be used for meta-model development were total leaching flux and total percolation over 20 years at 2 m depth, as well as overall mean flux concentrations. In a second step, a tool for meta-model development using CART (Classification and Regression Trees) was implemented in R. Subsequently, the meta-model was calibrated and evaluated using a cross-validation analysis. The poster will discuss the results of the calibration and validation exercise. Future plans include the extension of the analysis to other climatic regions in Sweden as well as the development of a spatially distributed version of the decision support tool to support water authorities working with the EU Water Framework Directive.

TU008
GeoPEARL UK - a fully spatially-distributed, higher-tier modelling approach for refining UK groundwater exposure estimates
J. Carnall, G. Hughes, Cambridge Environmental Assessments
Limited options are currently available within the UK regulatory process for higher-tier refinement of groundwater exposure estimates for plant protection products (PPPs). Hughes (2015) previously reported a higher-tier modelling approach for assessing the exposure of groundwater in the UK to PPPs at Tier 3b of the FOCUS assessment scheme (FOCUS, 2009). This approach incorporated elements of both the UK higher tier drainflow and NL GeoPEARL assessment frameworks, pairing 15 UK soil classes with 4 representative weather stations (dry, moderate, wet and very wet climates) in a series of 30-year simulations using the FOCUS-PEARL and FOCUS-MACRO models. The results of these simulations were weighted according to the extent of crop production on each soil/climate combination, and a cumulative frequency distribution was produced, from which the 80th spatial percentile PECgw value was derived. In this poster we present a fully spatially-distributed, higher-tier modelling approach for the UK, to assess the risk posed by PPPs to groundwater at Tier 3b of the FOCUS assessment scheme. Climate files suitable for use with the FOCUS-PEARL model have been derived from MARS weather data (provided by the Joint Research Centre at 25 km resolution), and typical crop rotations for each soil type and region have also been included. The cumulative frequency distribution resulting from the spatially-distributed modelling approach is compared with corresponding results from the standard FOCUS groundwater scenarios relevant to the UK, and the refinement provided by the spatially-distributed approach is assessed. **References:** Hughes (2015). Development of a UK higher tier groundwater environmental risk assessment for pesticides. Poster presentation at SETAC conference, 2015. FOCUS (2009). Assessing Potential for Movement of Active Substances and their Metabolites to Ground Water in the EU. Report of the FOCUS Ground Water Work Group, EC Document Reference Sanco/13144/2010 version 1, 604 pp.\n

TU009
Using modelling approaches to transfer results of groundwater monitoring studies to other regions of interest
N. Kehrein, knoell Germany; S. Mayer, Bayer AG / Crop Science Division; R. Sur, Bayer AG - Crop Science Division / Environmental Safety
Groundwater monitoring is part of the European risk assessment scheme for the (re-)authorisation of plant protection products (PPP). Its main objective is to preclude negative effects on humans, animals, and the environment by confirming compliance of active substances and their metabolites with appropriate protection goals in groundwater. Conducting groundwater monitoring is complex, labour intensive, and usually requires several years of sample collection. The number of monitoring sites within a study is limited by the associated costs and required effort to ensure high study quality. It is therefore often necessary to focus monitoring on the main regions of product use. Spatial modelling approaches can be employed to set results of monitoring studies into context and to compare them with other regions which are not covered by monitoring. By using in-silico methods, the vulnerability of occurring environmental conditions to PPP leaching to groundwater is estimated and compared. Vulnerabilities are based on spatially explicit exposure estimates calculated by process-based models such as FOCUS PEARL. Monitoring results can then be transferred and mapped to other regions if it can be shown that existing monitoring sites are representative for their respective environmental conditions. The presented approach is cost-efficient and creates a mechanistic link between pedoclimatic conditions and groundwater vulnerability. It reduces uncertainty by considering the natural variability of environmental parameters. It provides the means for the transfer of monitoring results from one region or country to another without the need to conduct new groundwater surveillance. The estimated groundwater vulnerability can also be used to support the selection of suitable monitoring locations.

TU010
Modelling options to assess hydraulic connectivity of agricultural fields with monitoring wells for edge-of-field groundwater surveillance
N. Kehrein, W. He, knoell Germany; F. Hegler, DR. KNOELL CONSULT GmbH; R. Sur, Bayer AG - Crop Science Division / Environmental Safety
Groundwater monitoring for residues of active substances and their metabolites is an important part of the European risk assessment scheme for the (re-)authorisation of plant protection products (PPP). In case of edge-of-field studies, monitoring wells for sample collection can be placed at various distances to test fields treated with PPP depending on the purpose and corresponding design of a groundwater monitoring study. A common challenge for the design of monitoring

studies and the interpretation of monitoring data is the need to demonstrate that well and filter screen are appropriately placed in order to detect potential residues. This is mainly determined by the hydraulic connectivity which depends on the well's location, filter placement in the saturated zone, and other environmental factors and properties. We evaluated two options to assess the hydraulic connectivity with the help of computer models. The first option uses Darcy's law and piston flow dynamics to estimate a catchment that has a hydraulic connection to the filter screen. It generally requires only few parameters which might be available as part of the monitoring study or which can be estimated with sufficient accuracy. The second option employs a two dimensional representation of the aquifer using the dynamic OpenGeoSys model. Its scenarios can be set up with a varying degree of complexity in order to accommodate different levels of data availability. The influx of leachate and PPP residues crossing the aquifer's upper boundary are simulated with FOCUS PEARL, a one dimensional process-based model for the unsaturated zone. Two dimensional aquifer simulations provide additional insight into dispersion behaviour and influence of time-dependent groundwater recharge on substance transport. The described modelling options could be used in a tiered or combined approach to assess hydraulic connectivity and support the interpretation of groundwater monitoring studies.

TU011

Work of a SETAC Group to Develop the Scientific Basis for Guidance for Regulatory Groundwater Monitoring of Crop Protection Products and their Metabolites in Europe

A. Boivin, ANSES / U3EIV; A. Gimsing, Ministry of Environment and Food of Denmark

Groundwater monitoring is considered a higher tier assessment in the regulatory groundwater assessment of crop protection products in Europe, but little guidance has been provided to date on study designs. The SETAC EMAG-Pest GW group (a mixture of regulatory, academic, and industry scientists) in 2015 began developing the scientific basis for guidance for use by regulators and industry scientists. The work of SETAC EMAG-Pest GW is now being considered for publication and should be published ASAP. In this work, it was considered that rigid study designs are not appropriate since the study design needs to be tailored to the specific protection goal being addressed as well as study objectives, which may also vary. Study designs should consider environmental conditions, the properties affecting environmental behaviour of the substance being studied, and site and use conditions. To illustrate how study design can vary, the group has proposed general study designs for seven hypothetical exposure assessment options, ranging from protecting all zones of saturation below the soil surface to only groundwater used to supply drinking water. Designs include recommendations on in-field and edge of field studies, as well as studies focused on catchments and aquifers. Examples of potential designs and recommendations on the use of publically available monitoring data has also been included. Also general recommendations on well installation and sampling procedures have been provided. Methodology has also been developed for assessing the relative vulnerability of agricultural regions and the vulnerability of specific sites for use in study design and site selection. This work aims to facilitate the assessment of groundwater monitoring as higher tier and/or its design, mainly by presenting different exposure assessment options.

TU012

Development of a Harmonized Protocol for Measurement of Foliar Wash-off Coefficients: First Results

E. Hellpointner, Bayer AG, Crop Science Division / Environmental Safety; L. Hand, Syngenta Limited / Product Metabolism; P. Volz, BASF SE, 67117 Limburgerhof / Crop Protection - Environmental Fate; A. Perry, Eurofins Agroscience Services Ltd, Melbourne, Derbyshire, DE73 8AG; S. Prost, Eurofins Agroscience Services EcoChem GmbH, 75223 Niefern-Öschelbronn; V. Gourlay, RLP AgroScience, IfA; D. Hennecke, Fraunhofer IME - Institute for Molecular Biology and Applied Ecology / Ecological chemistry; M. Popescu, Agrochemex, Manningtree, Essex, CO11 2NF

The foliar wash-off coefficient is a parameter in FOCUS ground and surface water modelling which can refine the soil loading after a sprayed application of pesticides. EFSA accepts that the modelling default can be superseded by experimental data with plants under a range of relevant conditions. Previous attempts to generate such data have suffered from the lack of a harmonised protocol for the study conduct. Specifically, the selection of crop types and growth stages was not deemed suitable to cover the submitted GAP. Furthermore, the analytical methods were not always validated appropriately. An ECPA workshop in 2015 proposed that the most suitable first step in development of a harmonised protocol would be to agree the design of a "single test" (i.e. a single crop/growth stage/AI/formulation) and conduct a ring test on this design. The purpose of the ring-test would be to establish the robustness of the design in several laboratories and, importantly, to understand the impact of the specific rainfall delivery system used; i.e., whether a highly sophisticated system is necessary or whether a simpler system could be adequate. The concept of the proposed design is that whole plants are used (rather than individual leaves) to retain as much realism as possible. The wash-off coefficient is then determined by comparison of compound residues in two sets of plants (with and without a defined rainfall event) measured using a GLP validated crop residue method. Appropriate control sets will be employed to determine the extent of other dissipation processes. This initial ring test is under way using tebuconazole (Folicur EW 250) sprayed at 100 g ai/ha onto tomato plants at BBCH25. Each participant will measure the residues before and after a rainfall event of 20 mm/hour for 1 hour and will calculate the wash-off coefficient from these data. Rainfall droplet size distribution and intensity will also be measured using a Laser Precipitation Monitor (LPM) to aid understanding in the case that significant differences are observed. This poster will summarise the results obtained from the initial ring test. Keywords: *foliar, wash-off coefficient, ring test \n \n \n \n*

TU013

Understanding plant root uptake of pesticides from hydroponic solution

B.M. Jones, A. Verhoef, University of Reading / Department of Geography and Environmental Science; S. Webb, Syngenta; P. Sweeney, Syngenta / Environment Product Safety; C.D. Collins, University of Reading / Soil Research Centre

Plant uptake has been suggested to influence the mobility of Plant Protection Products (PPPs). High uptake can aid with the retention of PPPs within the profile and reduce their potential to leach into potable water supplies. The suggestion of a relationship between the physio-chemical properties of a compound and the ability of a plant to take up a compound was first reported as a Gaussian-shape curve of Transpiration Stream Concentration Factor (TSCF) against the octanol-water partition coefficient (log K_{ow}). Plant Uptake Factor (PUF) was suggested as an alternative to TSCF and was based on the description of plant uptake by environmental fate models. PUF is derived from changes in the solution and therefore considers the change in concentration surrounding the plant roots from uptake over time, whereas TSCF only considers the translocation into the shoots and omits the storage within the roots. Another assumption commonly made within laboratory experiments is that crop uptake of plant protection products is passive i.e. compounds are taken up as solutes during transpiration. It also means that as the concentration increases within the plant roots and decreases in solution, the diffusion of the compound across the cell membranes should become slower. To the author's knowledge, this has not yet been tested and all previous studies have only reported a PUF/TSCF value after one time period. This experiment was set up to test whether TSCF and PUF value remain constant over a longer period, with destructive harvesting at each sampling point. This will also test the current assumption of environmental fate models where only one PUF value is required per compound. Wheat was grown in hydroponic solution and exposed to [^{14}C] 1,2,4-Triazole. They were destructively harvested at time-points of 1,2,6,12,16 and 21 days. Results from this experiment will show whether PUF and TSCF remain stable, as expected, or whether the plant uptake changes over time. This will help to determine whether the uptake of pesticides is constant with respect to transpiration for extended periods in the life cycle of a plant and therefore using a single PUF value across the crop growth cycle is correct. *Acknowledgements* – BBSRC for funding this project and Syngenta for supplying the radiolabelled compound, for the use of their laboratory and facilities and for being a CASE partner to this project.

TU014

Computational Fluid Dynamics modelling for plant canopy interception of pesticide spray droplets

L. Padilla, STONE EnvironmentalEngineering & Science,Inc.; S. Grant, Syngenta Crop Protection LLC; J. Dunne, Stone Environmental Inc; J.W. Perine, Syngenta; M.F. Winchell, STONE EnvironmentalEngineering & Science,Inc. / Environmental Systems Modeling; M. Ledson, Syngenta

Accurately quantifying the magnitude and implications of off-target transport of plant protection products (PPPs) via spray drift is critical to evaluating ecological and bystander exposure and inferring potential spray drift impact to adjacent crops. Past work with this aim has included field, wind tunnel, and laboratory studies examining the contribution of environmental conditions, spray equipment, and spray mix (active ingredient and/or formulation) on the potential extent of off-target transport. However, there is limited research focused on better understanding factors affecting deposition on a more finite spatial scale such as the physical properties of intercepting objects that may affect directly adjacent airflow and the trajectory of the spray particles entrained. Exposure assessments for regulatory purposes typically assume 100% of drift in the vicinity of plants are captured by the canopy and do not account for the unique physical properties of individual plant species/types. Improved modelling of plant canopy interaction with PPP particles entrained in airflow has the potential to improve understanding of the relative capture efficiency of off-target plant species and to inform the PPP authorisation process. The aim of this work is to improve the understanding of pesticide spray drift particle interactions with plant canopies and the relative capture efficiency of different canopies. This presentation demonstrates an application of ANSYS FLUENT (a computational fluid dynamics (CFD) modelling tool) to estimate the capture efficiency of various plants and plant clusters receiving pesticide spray drift from applications made in a wind tunnel. Model-predicted canopy capture from two different CFD approaches are compared to measured canopy capture. The first approach includes realistic, high-resolution, 3D plant geometry generated using photogrammetry freeware. The second approach uses simplified plant geometry to greatly reduce the number of grid cells in the model domain. This approximation makes the number and extent of plants included in simulations scalable to plant clusters and potentially up to field scale. The trade-off between accuracy and complexity is also assessed.

Impact of aged sorption on drainflow and run-off losses from treated fields using the FOCUS surface water Step 3 scenarios

K. Hammel, Bayer AG, Crop Science Division / Environmental Safety; B. Jene, BASF SE / Environmental Fate; C. Fang, P. Sharma, Corteva agriscience; M. Huang, FMC Agricultural Solutions; L. Oger, ECPA

The EFSA (2018) opinion on the CRD aged sorption guidance paves the way to include a relevant process for transport of plant protection products (PPP) in soil into the EU regulatory framework. Thus it can be considered a milestone to better informed regulatory decisions on exposure assessment of PPP. Both, EFSA opinion and CRD guidance are focussed on the relevance of aged sorption for leaching to groundwater where travel and residence time in soil are typically in the order of years which allows the aged sorption processes to fully evolve. In the EFSA (2018) opinion the statement is found that for entries of PPP into surface waters travel times are short so that aged soption is not relevant and should therefore not be used for PECsw. While it is reasonable to assume that the travel time to surface water is in general shorter than to groundwater, it is questionable to exclude the aged sorption process *a priori* from surface water exposure assessment. Firstly, because the aged sorption model employed accounts automatically for the effect of time (for short times the aged sorption effect will be correspondingly low). So there is no necessity to exclude its use. Secondly, residence time in soils especially for drainflow entries is typically in the order of weeks and months up to years, a time scale where aged sorption is expected to be relevant. In order to explore potential effects of aged sorption on surface water exposure FOCUS Step 3 calculations were performed with substance parameters of a test substance (ECPA07) which was used for a detailled case study in EFSA (2018). The results indicate that PECsw for drainflow entries are substantially lower when including aged sorption. Because aged sorption is generally relevant for transport processes in soils, these findings suggest the necessity to revise the proposed exclusion of aged sorption for PECsw assessments. EFSA (2018). Scientific Opinion about the Guidance of the Chemical Regulation Directorate (UK) on how aged sorption studies for pesticides should be conducted, analysed and used in regulatory assessments. EFSA Journal 2018;16(8):5382, 86 pp. https://doi.org/10.2903/

TU016

Off-field deposition of pesticides via run-off/erosion entries coming from treated fields using FOCUS surface water Step 3

K. Hammel, Bayer AG, Crop Science Division / Environmental Safety

The EFSA (2017) soil risk assessment opinion requires to include run-off/erosion entries from treated fields into off-field areas. There, it is discussed to use the 90th percentile retention efficacy of vegetated filter strips (VFS) (from FOCUS, 2007) as used in FOCUS surface water to derive the deposition of run-off/erosion entries in off-field areas. As the conservativeness of this approach is unclear EFSA (2017) recommends to re-evaluate the existing information with regard to worst case situations for off-field areas. In this work it is aimed to derive a concept for the deposition of run-off/erosion entries in off-field areas for edge-of-field situations. It is proposed to consider FOCUS surface water Step 3 for this purpose which was designed to generate realistic worst case pesticide losses from agricultural fields. As mitigation in-field VFS of low, mean and high retention efficacy are considered. The specific filter function of these VFS was derived form empirical data underlying the FOCUS (2007) retention efficacy recommendations. The mass deposited on the edge of the VFS by a run-off/erosion event was used to calculate a maximum local off-field PECsoil. Multiyear calculations allow to derive a local realistic worst case PECsoil which was here set to the 80th percentile of annual maxima. An exemplary assessment using Step 3 scenario R3, and dummy substance E showed that 80th percentile off-field PECsoil are substantially lower than the corresponding value using lower tier (Step 2) run-off/erosion losses. Conservative assessment of mitigation by VFS would consider high retention efficay for short VFS 1 m long, medium retention efficay for a VFS 4 m long and low retention for a VFS 10 m long. The approach demonstrates the feasibility to use FOCUS surface water Step 3 to define potential local off-field exposure and allows to define suitable mitigations. However, these exposure values represent a local worst-case situation which hardly affects the total population of an off-field organism under real-world conditions. Therefore, these local exposure values have to be set into context to the exposure relevant for effects at the population level as defined by specific Protection Goals. EFSA (2017). Scientific Opinion addressing the state of the science on risk assessment of plant protection products for in-soil organisms FOCUS (2007). Landscape And Mitigation Factors In Aquatic Risk Assessment. Volume 1. Extended Summary and Recommendations

TU017

Landscape level simulation of off field exposure by runoff - Development of realistic worst-case scenarios and effectiveness of mitigation measures

J. Kleinmann, WSC Scientific GmbH; M. Wang, WSC Scientific GmbH / Dept Efate Modelling; K. Hammel, Bayer AG, Crop Science Division / Environmental Safety; S. Bub, Tier3 Solutions; F. Krebs, Dr Knoell Consult GmbH; G. Ernst, Bayer Ag / Ecotoxicology; T. Schad, Bayer AG Crop Science Division / Environmental Modelling

In EFSAs (2017) scientific opinion on risk assessment for in-soil organisms a preliminary approach for off-field soil exposure was proposed. Runoff is mentioned in this proposal as a major exposure route for off-field habitats. Since no suitable off-field exposure scenarios were available, generic worst-case assumptions have been proposed by EFSA (2017). Therefore, in the present study a previously initiated framework for the development of such scenarios was extended and applied to identified scenarios. In this modelling framework, the runoff from each field in a given landscape can be simulated using FOCUS PRZM. By using different deposition models, off field exposure from runoff can be simulated on the landscape level. This modelling framework combined with spatially explicit modelling, has been used to simulate off-crop exposure from runoff in generic and real-world landscapes. Additionally, the effectiveness of mitigation measures, such as in-crop buffers and in-field margins has been evaluated.

TU018

Pesticide exposure scenario for aquatic organisms in Korea - Conceptual model for protection goals

J. Oh, NAS, RDA / agro-food safety; W. Beltman, Wageningen Environmental Research / Environmental Risk Assessment; M. ter Horst, Wageningen Environmental Research, WUR / Environmental Risk Assessment Team; S. Kim, NAS RDA

The pesticide registration system for environmental risk assessment in Republic of Korea is currently in the process of improvement. The current scenarios for surface water are too simple to reflect reality; not take into account the spatio-temporal distribution of environmental factors in Korea and the physic-chemical properties, repeated application and various exposure routes of pesticides. This study is being phased in to improve the exposure scenarios for aquatic organisms in a more realistic way. First, one scenario for the worst case (90th percentile) was confirmed instead of scenario zones, because Korea is quite homogeneous considering agro-environmental conditions. Second, three protection goals were selected for water bodies and aquatic organisms; mudfish in paddy rice fields, aquatic ecosystem in small stream in paddy rice area and aquatic ecosystem in small stream adjacent fruit orchards. Third, ERCs (Ecotoxicological Relevant Concentration) are established for each protection goal. Lastly, the conceptual models were assumed for exposure situation of pesticides. For the next step, this study will be proceeded with data-based model development process.

TU019

Relevance of the Pesticide Application Timer (PAT) in multi-year FOCUS surface water modelling

B. Kind, J. Kleinmann, K. Billau, WSC Scientific GmbH

For the registration of plant protection products in the EU, a safe use with regard to surface water and sediment organisms? needs to be demonstrated. The FOCUS work group developed a stepwise approach. At step 3 different models for drainage, runoff and spray drift entry into different surface water bodies were combined. Due to limitations of these models, the modellin period was limited to 12 - 16 months. Currently, the possibility to run multi-year simulations at step 3 is discussed and an approach was presented by EFSA. In the present study multi-year runs were performed using AutoPEC SW to evaluate the possible consequences of an extension of the modelling period for the final risk assessment in surface water and sediment. In the draft scientific report on multi-year simulations EFSA (2018) proposed to implement a number of changes to the exposure calculation for surface water and sediment independently of the extension of the modelling period. In the present work the final concentrations in surface water and sediment (PEC) considering the same application date in each year were compared to PECs resulting from application dates selected by the Pesticide Application Timer. Therefore, final maximum PEC values as well as various temporal percentiles for the exposure assessment were evaluated using exposure profile analysis conducted with the software PEC Robot. The resulting PEC values and the consequences for the aquatic risk assessment are discussed. It turned out that weather conditions do have an impact on the amount of substances reaching surface water and sediment via drainage and runoff and hence on the final PEC_{SW} and PEC_{SED}. This is in line with previous research on application timing in PEC_{GW} modelling. Here, the difference between worst-case (rain on day of application) and realistic case (applying SW PAT rules for PEC_{GW}) was up to 20-fold. Hence, the selection of the application dates based on a Pesticide Application Timer seems to be reasonable and should be used also for the multi-year assessment.

TU020

Combining the pesticide usage in an agricultural catchment to pesticide occurrence in river waters

P. Högmander, K.S. Siimes, Finnish Environment Institute SYKE / KTK / Contaminants; V.A. Junttila, Finnish Environment Institute SYKE / Centre for Sustainable Consumption and Production

The amount of pesticides used in the catchment area of river Savijoki in Southern Finland is compared to the concentration of pesticides found in stream water during years 2016-2018. The pesticide usage in the area was assessed through an inquiry targeted annually on about 80 farmers in the Savijoki area in the years 2016-2018 as a part of the SAVE project. The water samples were collected at two sampling sites from Spring to late Autumn. The results of this comparison are reported. Such results form a basis for, e.g., the evaluation of current risk reduction requirements of the used pesticides.

TU021

Towards the derivation of generic dilution factors for drinking water abstraction using landscape level assessment

S. Gebler, BASF SE / Agricultural Solutions - Global Environmental Fate Modelling; B. Gottesbueren, BASF SE / Crop Protection, Environmental Fate Modelling; T. Schröder, BASF SE / Agricultural Solutions - Global Environmental Fate Modelling

Surface water is an important source for drinking water supply in many European countries. The exposure assessment of plant protection products (PPP) at drinking water abstraction points is hence of specific interest and also a particular point in the EU regulatory framework (regulation 1107/2009). There is no generic guidance available on the derivation of a drinking water abstraction concentration. The only EU-known approach is the national approach of the Netherlands which is an integral part of their regulatory framework. This Dutch exposure assessment is simplistic but a very solid first Tier approach. It dilutes the edge-of-field PEC_{sw} considering the use intensity (most important is the cropping area within a drinking water catchment) and other dilution factors like application practice and dissipation in the water system. However, the calculation of the dilution factor so far mainly considers highly simplified worst-case assumptions. The Dutch approach assumes e.g. that all agricultural land is connected and releases water to a water body. Our work explores the dilution factors at landscape level to get a better insight into more realistic scenarios. Specifically, our goals are: (i) the derivation of a generic dilution factor on landscape level; (ii) identification of representative vulnerable drinking water catchments in the EU for generic and regulatory use. On this account we analyzed different catchments in Europe for specific crops using a GIS based approach. The focus was on catchment characteristics (crop area, soil hydraulic properties) which have a strong impact on runoff generation and therefore on the dilution of PPPs in surface water. In a first step, the potential dilution variation by crop area was investigated taking into account the stream course from headwater catchment to a larger main river. In the second step, other impacting factors (e.g. soil hydraulic conductivity) are included with the aim to explore the most vulnerable combinations of catchment characteristics for the different test catchments. The data can then be used to derive vulnerable scenarios regarding the dilution on EU level for a specific crop. It is expected that our approach leads to crop-dependent dilution factors for typical catchments in the EU that potentially can be used as a first Tier exposure assessment to derive a drinking water abstraction concentration.

TU022

A modular catchment model to support regulatory landscape-scale aquatic risk assessment

S. Multsch, DR. KNOELL CONSULT GmbH / Environmental Fate / Modelling / GIS; F. Krebs, S. Reichenberger, knoell Germany GmbH; P. Kraft, L. Breuer, Justus Liebig University Giessen / Institute for Landscape Ecology and Resources Management; L. Wipfler, Wageningen Environmental Research / Environmental Risk Assessment Team; W. Beltman, Wageningen Environmental Research / Environmental Risk Assessment; T. Schad, Bayer AG / Environmental Modelling

Landscape modelling is key for future environmental risk assessment (ERA) of aquatic ecosystems related to plant protection products (PPP). Currently, local field scale models are used at lower tiers to simulate transport and fate of PPP in edge-of-field surface waters due to runoff, drainage and spray drift deposition. These local models predict the exposure concentration in predefined water bodies, i.e. streams, ditches and ponds, while neglecting the real dimension of catchments, and hence, of natural habitats of non-target species. In a higher tier approach a new generation of tools can provide more realistically relevant concentration patterns for effect and risk assessment for various biological entities, e.g. populations, communities or entire habitats. A framework for the risk assessment at landscape scale is discussed in a separate conference paper. The new approach under development operates at the catchment scale. The basis for the newly implemented tool is the hydrological programming library 'Catchment Modelling Framework (CMF)'. To allow for water and solute fluxes across entire landscapes single fields are connected to each other and to river segments by flux connections. This approach allows predicting exposure at any location in the landscape at a flexible time step. Water and solute fluxes from single fields can be either simulated by the tool or by using predefined time series. This allows the tool to use simulated outcomes from e.g. FOCUS models (e.g. MACRO, PRZM) and align with the EU risk assessment approach. The catchment tool has been connected to a TOXSWA module to simulate PPP fate for the entire catchment. A case study will be presented in which the new tool is used to simulate PPP concentrations in surface water across an entire landscape. The spatial domain is represented by the Rummen catchment in Belgium which is dominated by the cultivation of orchards. Growing pome fruit requires in that region pest management including the use of insecticides which may impact aquatic communities by spray drift input into water bodies. All minor and major river reaches are being simulated, corresponding to a total length of 150km river. Concentration patterns are provided for river reaches with a length of 50-100m, resulting from different scenarios regarding climate (wet, medium and dry) and application pattern. Uncertainties of the hydrological model affecting the assessment are identified related to structural and input data uncertainty.

TU023

Applicability of environmental emission and fate model PeCHREM/G-CIEMS for monitoring plan of paddy pesticides in water quality management

Y. Imaizumi, National Institute for Environmental Studies / Center for Health and Environmental Risk Research; R. Kitsutaka, K. Yoshizawa, Bureau of Waterworks Tokyo Metropolitan Government; N. Suzuki, National Institute for Environmental Studies / Center for Health and Environmental Risk Research

Residual pesticide levels in river water are regularly monitored by water suppliers for water quality management of drinking water in Japan. The residual pesticides are controlled as a complementary item for water quality management with an index which is a total value of ratios of each measured concentration to each target concentration. This index should be not more than 1. Target pesticides are listed in the Waterworks Law in Japan (118 items are listed as of April 1, 2018). Water suppliers don't have an obligation, but need to determine monitoring plan which contains frequency, sampling periods, and target pesticides of the monitoring based on each area's situation, including not to monitor any pesticides. For effective and efficient management, information about temporal-spatial distributions of multiple pesticides in river water is important. We have been developing the emission estimation method (PeCHREM) for pesticides used typically in paddy fields, and the multimedia environmental fate model (G-CIEMS). The combined PeCHREM/G-CIEMS model could predict environmental concentrations of many pesticides with high temporal-spatial resolution (5km × 5km grid in atmosphere, average 9.7 km^2 of catchments, and average 5.6 km of river segments) in areas all over Japan. We have been evaluating reliability of this model from comparison of simulated concentrations with observed ones in river waters for several dozens of pesticides. This study focused on applicability of this model for water quality management, especially for prioritization of the listed pesticides for the regular monitoring. We performed constant monitoring of tap water sources at four points and river water at upper 12 points of water intake points. Finally 23 pesticides (halosulfuron methyl, simetryn, azoxystrobin, (E)-metominostrobin, fentrazamide, pyraclonil, EPN, molinate, dimethametryn, butachlor, orysastrobin, bentazon, iprobenfos (IBP), fenobucarb (BPMC), daimuron, isoprothiolane (IPT), pretilachlor, fenthion (MPP), pyroquilon, mefenacet, bromobutide, bensulfuron methyl, and MCPA) were selected as target pesticides which were detected in least one sample and were suitable for model simulation. The maximum concentrations were compared between predictions and observations for the quantified 122 combinations from total 368 combinations of 16 sampling points and 23 pesticides. The 87 combinations had a prediction error of less than one order of magnitude.

TU024

Connecting pesticide use data and environmental exposure and risk assessment

A. Bolekhan, Bayer AG, Crop Science Division; K. Szegedi, BASF SE, Agrarzentrum Limburgerhof / APD/EF; M.A. Thomas, Bayer U.S., Crop Science Division

Environmental risk assessment for plant protection products (PPPs) in Europe is performed for individual products based on the worst-case label recommended use patterns with respect to application rate, frequency and intervals between treatments, which might not necessarily reflect realistic pesticide usage. The current risk assessment frame does not take into consideration that farmers may reduce number of applications as well as application rates compared to the recommended on the label depending on the actual pest or disease pressure, but on the other hand apply simultaneously or sequentially different products during the growing season. The latter is considered a major point of uncertainty. Several guidance documents mention the need to take this aspect into account in the future and question the appropriateness of higher tier and recovery refinement options in the risk assessment of single products at present. To address concerns regarding sequential treatments, available information on realistic application practices of PPPs beyond the individual product level were analysed. The investigated data sets were collected by market research companies and are publicly (commercially) available. As a first step, we investigated generic patterns and trends with respect to the number of applications, and cumulative application rates within a season for several crops, countries, and indications. As a second step, typical spray sequences were analysed for several crop-country combinations. Typical use rates were compared to application rates on the label. The results show that actual application patterns may differ from the registered label recommendations. In many cases farmers indeed use the PPPs at rates lower than recommended and/or apply fewer treatments than maximum registered number of applications resulting in a significantly lower seasonal load of individual products and actives. These findings suggest that an additional safety factor is already introduced by assessing the worst-case label use patterns. The protectiveness of the single product risk assessment for the realistic situation with multiple products treatment needs to be further investigated considering these conclusions.

TU025
efam: automated modeling software for environmental risk assessment
R. Juraske, DR. KNOELL CONSULT GmbH; M. Burns, Knoell France SAS; P.P. Lenhardt, W. Reiher, T. Hauck, knoell Germany
For the registration of plant protection products the agrochemical industry needs to provide environmental risk assessments for active substances and related products. To conduct these risk assessments, obligatory and officially provided third-party computer models are used in many countries worldwide. The computer models are used to obtain an estimate of the amount of substance that will enter the environment (Predicted Environmental Concentrations, PEC). PECs are calculated for different environmental compartments by different simulation models. Hence, in an environmental risk assessment several different models need to be set-up, parametrized, or run separately. This decentralized working procedure unfortunately implies significant drawbacks. The main issues are: replicated entry of identical input data, great extent of manual work, high quality assurance effort, challenging data management due to scattered information of the input/output files, and time-consuming workflow documentation. To make the whole procedure more efficient, knoell developed the modular built and extendible software package efam (environmental fate automated modeling) to facilitate automated modeling and reporting. The aim was to create a software application that can drive regulatory necessary computer models and evaluate the results from one single platform in an automated manner. The software is developed in a modular structure allowing for integration of individual modeling tools. This structure enables flexible adaptation at the modular-level, e.g. when new models are released, or new model versions are made available and need to be applied. Using efam, model calculations do no longer need to be carried out on desktop computers, but can be performed on a more powerful and remote server located in a secured data center. The software can help automating and optimizing the workflow for individuals or groups of people dealing with environmental fate and exposure assessment. It is developed to automate model parameterization and model simulations, extract the results and transfer the output to formatted tables suitable for dossier/report incorporation. The development is of interest, not only in terms of speeding up modeling and report generation, but also it will optimize the organization of data, reduce the occurrence of manual input errors and reduce the effort required for quality control. Simplified data exchange with relevant stakeholders is currently under discussion as further field of application.

TU026
Ecological relevance of the Biota Quality Standards
L. Teunen, University of Antwerp; C. Belpaire, Research Institute for Nature and Forest INBO; R. Blust, L. Bervoets, University of Antwerp / Department of Biology (SPHERE Research Group)
Biota Quality Standards were set by the European Commission with the goal to protect top predators and humans from secondary poisoning by chemical accumulation in the food chain. In reality, a vast exceedance of these standards for a number of components is observed, without an eminent decrease in the ecological water quality. In the present study, the relationship between accumulated concentrations in muscle tissue of European eel (*Anguilla anguilla*) and European perch (*Perca fluviatilis*) and the ecological water quality was investigated. Fishwere collected from 33 different sampling locations throughout Flanders (Belgium). Accumulated concentrations of HCB, Hg, PBDEs, HBCD, PFOS, heptachlorepoxide, dioxins and PCBs were measured. Additionally, 2 PAHs were measured in translocated quagga mussels (*Dreissena bugensis*). Ecological water quality was assessed using the Index of Biological Integrity (IBI), applying fish community, and the Multimetric Macroinvertebrate index Flanders (MMIF). The main goal of the study was to define a threshold value for which accumulated concentrations reflect a decrease in ecological water quality. These results could have an important impact on the revision and fine-tuning of current Biota Quality Standards.

TU027
Freundlich sorption-desorption isotherms of hexazinone in the bonechar-amended soil using a bath equilibrium method
K. Mendes, University of São Paulo / Ecotoxicology lab; L.V. JUNQUEIRA, CENA Center for Nuclear Energy in Agriculture / Ecotoxicology; F.G. ALONSO, CENA/USP; C.S. Almeida, University of São Paulo USP / Ecotoxicology Laboratory; V. Takeshita, Mato Grosso State University / Agronomy; V.L. Tornisielo, CENA Center for Nuclear Energy in Agriculture / Ecotoxicology Laboratory
Hexazinone [3-cyclohexyl-6-dimethylamino-1-methyl-1,3,5-triazine-2,4(1H,3H)-dione] belong to the chemical group of the triazinone, and is selective herbicides inhibitors of photosystem II, used in pre- and post-emergence of annual grasses and broadleaf weeds, and can be easily leached to groundwater sources. Bonechar (BC), as well as biochar have been shown to strongly sorb organic compounds and could be used as an adsorbent to increase herbicides sorption and decrease leaching, although its application form is still little known. The aim of this research was to assess the absorbent effect of a cow BC on the sorption-desorption of hexazinone in Ultisol-Typic Hapludalf (sandy loam texture) using a bath equilibrium method. The BC was added to soil at 0 (control – unamended) and 5% (w w-1) ratio, corresponding 60 t ha-1. Five solutions (0.63, 1.25, 1.88, 2.50, and 3.13 mg L-1) were prepared of [triazine-6-14C] hexazinone (radiochemical purity 99.7%, specific activity 3.14 MBq mg−1). Sorption-desorption isotherms were calculated from the Freundlich model. The Kf values calculated for the hexazinone sorption on the unamended and BC-amended soil were 0.12 and 20.76 μmol (1-1/n) L1/n kg-1, respectively. Desorption on the unamended and BC-amended soil was 6.58 and 0.55%, respectively. The 1/n(desorption) are greater than 1/n(sorption), suggesting that the hexazinone sorption by all treatments was reversible. H values ranged from 1.08 to 1.59 for hexazinone on all treatments. The results indicate that addition of BC promotes the high sorption and low desorption of hexazinone in the surface soil. We assume it is possible to minimize the pollution of soil-applied herbicide simultaneously as the BC, and then hexazinone can remain in the soil for a long time. However, this carbonaceous material may influence negatively the herbicide efficacy on weed control, which is worthy of further investigations, especially in field conditions.

Can Regulatory Risk Assessment Protect Wildlife? (P)

TU028
Birds risk assessment scheme vs real life; Polish experience
A. Muszyńska, M. Bielasik - Rosińska, MERIT MARK
According to EFSA guidance *Risk Assessment for Birds and Mammals* (2009), several species of birds are included. Step by step evaluation traverses from ‘indicator’ to ‘focal’ species, where latter one must be representative of real species occurring in particular crop and its growth stage. In this approach, a positive outcome of evaluation indicates low risk for the bird’s population. But is it safe for them in reality? From year 2000, population of bird’s species in Poland is estimated as a part of national multiannual state environmental monitoring programme. The latest Chief Inspectorate of Environmental Protection report: *Monitoring of Birds of Poland (2015-2018)* investigated state changes in common birds population in the agricultural landscape over the course of last 18 years. All collected data served to establish the Farmland Bird Index (FBI). Based on robust information provided by the national programme *Monitoring of Birds of Poland* and harmonized standard risk assessment scheme (including focal species) compilation and comparison is presented.

TU029
Accuracy of GPS-tag tracking for wildlife risk assessment relevant field scenarios - the current situation
I. Katzschner, O. Mayer, T. Grimm, Rifcon GmbH; J. Ludwigs, Rifcon GmbH / Business Development; M. Münderle, Rifcon GmbH
The automatic acquisition of detailed animal movement data with GPS-tags is now a common scientific method and is still evolving. However, the improvement of data accuracy is not as much in focus as the drive to increase tag lifespan or decrease tag weight in order to monitor smaller species. Moreover, the main scientific focus is on the acquisition of long-term movement data (e.g. daily or monthly) to put animal movement behaviour in context, for example with respect to biotic and abiotic parameters. However, the main requirements of data intended to support risk assessments conducted for the purpose of pesticide registration are the continuous minute-by-minute recording of the exact position and movements of tagged individuals. GPS-tags are currently available for medium-sized species such as hares and these tags are able to record highly detailed spatio-temporal movement data over several days without any undue disturbance to the tagged animal. However, detailed data require short intervals between recording events effectively limiting the life of the tag’s battery. The GPS-tag method for recording animal movements can also be used in pesticide risk assessment field studies, for example to determine so-called PT values (i.e. estimations of the time tagged animals spend in different crops) or verify exposure in treated crop fields. However, one of the main concerns associated with this method is its accuracy and this can be a crucial requirement when tracking species such as lagomorphs moving along field margins and borders. Depending on the risk scenario to be covered, the behaviour of the species under investigation and the distribution of the crop of concern within an agricultural landscape, the issue of accuracy can be of greater or lesser importance. In order to assess the reliability of GPS-tag data sets for use in regulatory processes, GPS-tags need to be evaluated and their advantages/disadvantages discussed and compared to more commonly applied methods. We therefore present GPS-tag data for medium-sized mammals showing the accuracy of recorded locations under different field scenarios (including measurements of activity). Our results indicate that species ecology, landscape structure and other factors need to be considered when deciding whether currently available GPS tracking systems can provide reliable PT estimates for pesticide risk assessment as required by the current EFSA wildlife guideline.

TU030
Bats, birds & shrews in environmental risk assessment
T. Grimm, R. Blöcher, F. von Blanckenhagen, Rifcon GmbH; J. Ludwigs, Rifcon GmbH / Business Development

Bats are not specifically considered in the current pesticide risk assessment guidance for birds and mammals in the European Union, which evaluates the risk to birds and to mammals such as rodents, shrews and lagomorphs based on dietary exposure. The implicit assumption seems to have been that all mammals, including rather unique groups such as bats, are protected by the current avian or mammalian risk assessment scheme. However, the biology of bats differs in various aspects to these groups. It is therefore reasonable to question whether bats should potentially be considered as an additional species group in terrestrial vertebrate risk assessments performed in the EU. Therefore, we have conducted a review of the publically available literature and have compiled a list of relevant European bat species that potentially are present in the agricultural landscape. The major and minor crops of importance as foraging habitats have also been established, whilst considering foraging techniques for added context. As food intake is considered the main route of bat exposure to pesticides, information on daily energy expenditure and subsequent food intake has also been gathered from the literature to determine appropriate food intake rates. These data have been compared to the current insectivorous food intake rates for birds and mammals given in the current EFSA Bird and Mammal Guidance Document (2009). Toxicological endpoints for bats gathered from publications on the impact of pesticides were identified regarding their suitability to be used in risk assessments. Comparisons are made between endpoints for bats and commonly agreed toxicological endpoints of pesticides from laboratory studies with rats and mice, and the results are discussed. With this information, environmental risk assessments based on the same prerequisites following main concepts of the EFSA Bird and Mammal Guidance Document were conducted for insectivorous birds and shrews and for representative bat species. A comparison of these scenarios will be made and the outcome will be discussed, in order to evaluate whether the risk of pesticides to bats is sufficiently assessed and covered by the currently performed risk assessment scheme for birds and ground-dwelling mammals.

TU031

Can regulatory pesticide risk assessment scheme protect insectivorous bats?

R.R. Sabo, THE UNIVERSITY OF VETERINARY MEDICINE AND PHARMACY IN KOŠICE / Department of pharmacology and toxicology; . Korytăr, THE UNIVERSITY OF VETERINARY MEDICINE AND PHARMACY IN KOEICE / DEPARTMENT OF EPIZOOTIOLOGY AND PARASITOLOGY; L. Sabov_, J. LegCth, THE UNIVERSITY OF VETERINARY MEDICINE AND PHARMACY IN KOEICE / Department of pharmacology and toxicology

The chiropterofauna is an important component of the ecosystem in various types of landscape. It has been proven that 28 species of insectivorous bats of two main families (*Rhinolophidae* and *Vespertilionidae*) mostly occur in the Slovakia. In our literature review we had identified two critical periods, when bats may be under certain scenario exposed to residues of applied pesticides. First one is reproduction season of bats which lasts in Slovakia from May to July. This is very sensitive period for the bats, because there must be abundant prey available near the roost of summer colony. Pesticides should be applied to crops with little or no hazard to honeybees. That is why insecticides with_longer term toxic effects or tank mixes (synergistic toxic effects to insects, e.g. pyrethroids with fungicides) require special protective measures. One of the most commonly used restrictions in such cases is late evening/night application. If insecticide with prolonged residual toxicity is applied in the evening/night, it can not only harm insects but secondary also the insectivorous bats. The time before hibernation may be considered as second critical period for bats. During autumn bats must build up energy reserves for hibernation, it's a period of intense hunting. Because pesticides are not applied in such quantity in comparison with late spring and summer applications, we do not expect acute effects. Based on Guidance of EFSA (2009) proposals for selection of bird and mammal species as focal species we identified total of five bat species which at least partly fulfil set criteria. The Lesser Mouse-eared Bat (*Myotis blythii*) and the Greater Mouse-eared Bat (*Myotis myotis*) are specialized in hunting insects crawling on the ground. The Noctule Bat (*Nyctalus noctula*) and the Serotine (*Eptesicus serotinus*) are quite commonly observed in Central Europe, hunting insects by rapid flights along vegetation edges or in open areas; they also pick prey directly from the ground or from the canopy of trees. The last one selected bat is the Common Pipistrelle Bat (*Pipistrellus pipistrellus*) weighing only 3.8 to 7.0g, i. e. rapid energy exchange makes it ideal focal bat species with numerous small flying insects found in its diet. Potential harmful effect to bats needs to be reflected more detailed in future research and maybe the result will be that some pesticide with extended residual toxicity can require additional application restrictions to those indicated on the label.

Understanding the Complexity of the Natural Aquatic Environment Facing Global Changes (P)

Biomarker approach to assess the toxicity of S-metolachlor and Terbuthylazine in the benthic clam Scrobicularia plana

I.B. Gutiérrez, MARE Marine and Environmental Sciences Centre / Life Science Department; A.d. Mesquita, Department of Biology & CESAM - University of Aveiro / Department of Biology and CESAM; F.J. Gonçalves, University of Aveiro / department of Biology & CESAM; J.C. Marques, MARE - Marine and Environmental Sciences Centre, Dep. of Life Sciences, Faculty of Sciences and Technology, University of Coimbra / MARE, Dep. of Life Sciences, Coimbra University; A. Gonçalves, MARE - Marine and Environmental Sciences Centre, Department of Life Sciences, Faculty of Sciences and Technology, University of Coimbra & Dep. of Biology and CESAM, University of Aveiro / MARE (Marine and Environmental Sciences Centre), Department of Life Sciences, Faculty of Sciences and Technology / Dep. of Biology and CESAM

The overexploitation of the farmlands in the Mediterranean region contributes to an overuse of herbicides that have the potential to pollute adjacent aquatic systems. The Mondego estuary, located near the city of Figueira da Foz (Portugal), is surrounded by farmland, namely rice and corn crops. Primextra® Gold TZ is the most-used herbicide in this area, being constituted by two main active ingredients, S-metolachlor (SMOC) and terbuthylazine (TBA) that are toxic for aquatic environments. *Scrobicularia plana* was selected to carry out bioassays because of its ability to filter pollutants and its key role in estuarine functioning. Organisms were exposed to a range of concentrations of each chemical, individually. *S. plana* showed higher sensitivity to SMOC (big - LC_{50}=40.702 mg/L; small - LC_{50}=41.517mg/L) than to TBA (big - LC_{50}=118.590mg/L; small - LC_{50} =108.418 mg/L),being big size class, generally, the most tolerant. The sensitiveness of organisms to pollutants' exposure is associated to its ability to cope with oxidative stress. Thus, antioxidant enzymes (glutathione peroxidase (tGPx), glutathione reductase (GRed) and glutathione-S-transferase (GST)), besides the quantification of TBARS were analysed through spectrophotometry-based methods.To both size classes, GST activated under SMOC exposure, surpassing the levels of activity from controls and from the field. GRed showed a quite specific response to TBA, being activated progressively through growing concentrations of chemical, especially the activities of big size organisms that surpass the levels from the field.The present work highlights GRed and GST are suitable biomarkers of the toxicity to the studied substances in *S. plana*. GST demonstrated to be more accurate biomarker for SMOC toxicity as it rises its activity under lower concentrations than of TBA. Thus, the search for biomarkers is crucial to the implementation of measures to rehabilitate polluted aquatic environments before the damages turn irreversible. This study was supported by Fundação para a Ciência e a Tecnologia (FCT) through the strategic projects UID/AMB/50017/2013 granted to CESAM and UID/MAR/04292/2013 granted to MARE. FCT funded A. F. Mesquita and A.M.M. Gonçalves, (SFRH/BD/139831/2018 and SFRH/BPD/97210/2013),co-funded by the Human Potential Operational Programme (National Strategic Reference Framework 2007–2013), European Social Fund (EU), and the program POPH/FSE.

Marques, MARE - Marine and Environmental Sciences Centre, Dep. of Life Sciences, Faculty of Sciences and Technology, University of Coimbra / MARE, Dep. of Life Sciences, Coimbra University; A.M. Gonçalves, MARE, Dep. of Life Sciences, Coimbra University/Biologia Department & CESAM, Aveiro University

The hazardous impacts of broadly used pesticides on non-target species has been widely documented. Aquatic systems are particularly endangered, as substances reach the systems by water run-off, endangering its community and structure. The effect of Copper Sulphate and Tebuconazole was assessed for *Lemna minor* and *Raphidocelis subcapitata* exposed to combined bioassays of a contaminant and a temperature (20ºC and 25ºC), regarding impacts in the species' fatty acid (FA) and carbohydrate (CHO) profiles. CuSO4 effects depended on the temperature for both FA and CHO profiles. At 20?C, species presented the lowest FA content at a contaminant concentration of 1.20mg/l for *R. subcapitata* and 0.40mg/l for *L. minor*; with the increase of contaminant concentration, CHO content of *L. minor* increased, but decreased in *R. subcapitata*. At 25?C, the lowest FA content occurred at a concentration of 1.55mg/l in *R. subcapitata* and 1.76mg/l in *L. minor*, while the lowest CHO content occurred at the highest contaminant concentration in both species (2.20mg/l for *R. subcapitata* and 1.93mg/l for *L. minor*). The effect of Tebuconazole differed among species: in *L. minor*, the lowest FA content occurred at a concentration of 0.10mg/l at 20ºC and 0.12 mg/l at 25ºC, while in *R. subcapitata* FA content decreased with the raise of contaminant concentration, regardless the temperature. Tebuconazole induced an increase in CHO content at 20?C in *L. minor*, while resulting in a decrease in CHO content at 25?C in *R. subcapitata*. Primary producers, such as the species referred, are major sources of energy and essential long-chain polyunsaturated fatty acids in trophic chains, with animals not capable to produce these compounds at relevant rates. This study highlights the harmful effects of pesticides on primary producers and thus, affecting the whole trophic web, stressing the need for preventing major impacts on ecosystems by chemicals' usage and adapting pest control to ecosystem-sound practices.This study was supported by FCT through the strategic projects UID/AMB/50017/2013 granted to CESAM and UID/MAR/04292/2013 granted to MARE. FCT funded C. P. Rocha, T. Vidal, A. P. Cuco, N. Abrantes, A. M. M. Gonçalves, C. Nunes (SFRH/BD/140922/2018; SFRH/BPD/94562/2013; DPA 17-781; IF/01198/2014; SFRH/BPD/97210/2013; SFRH/BPD/100627/2014). The research was partially supported through the project Ref. POCI-01-0145-FEDER-022127.

Do toxins offer a competitive advantage for cyanobacteria facing global changes?

S. KIM TIAM, MNHN/CNRS / Cyanobactéries, Cyanotoxines et Environnement

Aquatic ecosystems are complex and dynamic adaptive systems driven by multiple biotic and abiotic factors. Over the past three decades, the increasing anthropic pressures, which are exerted on natural aquatic environment have caused the multiplication of cyanobacterial blooms and enhanced the incidence of the proliferations within these ecosystems. Moreover, it was clearly demonstrated that global changes have a large influence not only on the multiplication of cyanobacterial blooms but also on the occurrence of blooms of toxin-producing cyanobacteria. In this context, it is important to understand cyanobacteria adaptation to global changes and in particular, the underlying mechanisms that could offer ecological advantages to toxin-producing genotypes, allowing them to dominate the cyanobacteria bloom. Hence, the influence of two abiotic factors (light and temperature) was evaluated on toxin producers and non-toxin producers. We hypothesized that cyanobacteria synthetizing toxins will be more resistant in light and temperature stress conditions thank to a possible role of toxins in photosynthesis and/or photoprotection. In order to test this hypothesis, four *Planktothrix* strains were selected: two microcystin (a potent cyanotoxin) and two non-microcystin producers. A 24-hour experiment composed with a 4-hour stress exposure followed by a recovery phase was performed. The cultures in triplicate exposed to high light intensity (150 μmol.m^{-2}.s^{-1}) or high temperature (33°C) were compared with controls (20°C, 6 μmol.m^{-2}.s^{-1}). The effects of stress were evaluated on the relative expression of genes involved in photosynthesis (*psaA, psbA, acpA, cpcA, fnr*), photoprotection (*ocp, frp, flv1, flv3, hlip*), temperature tolerance (*dnaK, groEL, groES, hslO, hspA, hspG*), oxidative stress regulation(*sodB, gor*), toxins synthesis (*mcy*) and other secondary metabolites synthesis (*mdn, aer, oci, apt, mic)*. Our results revealed that cyanobacteria have specific responses regarding the nature of the stress with impacts of genes involved in photosynthesis and photoprotection in light stress conditions, while the temperature stress impacted the heat shock proteins. Nevertheless, the data obtained do not confirm that microcystin plays a specific role in photoprotective mechanisms during the first hours of stress since photosynthetic capacities were more impacted for microcystin producers compared to non-microcystin producers.

TU035

How climate change enhances nanoparticle toxicity towards freshwater biofilms

B. Bonet, The University of Birmingham / The School of Geography, Earth and Environmental Sciences; I. Lynch, University of Birmingham / Geography Earth Environmental Science; S. Krause, University of Birmingham / The School of Geography Earth and Environmental Sciences

Aquatic ecosystems are threatened by multiple environmental stressors. Release of toxicants such as engineered nanoparticles (ENPs) into aquatic systems and their effects on these ecosystems remain poorly understood. This, combined with the acceleration of global climate warming (ENP + ΔTºC), could have significant consequences for aquatic life. This study focus on responses of fluvial biofilms, as key points of ENP entry into aquatic food webs, and examines the effects of combined stressors at community and ecosystem levels using an extended set of end-points as an integrated approach. To achieve this aim, an outdoor microcosm study using different temperatures (18ºC and 25ºC) was performed. After 4 weeks of biofilm colonization at both temperatures, ENP were added obtaining 4 treatments (x5 replicates each): (1) control , (2) 50 μg/L of PVP-coated AgNPs (50 nm), (3) 25 μg/L of Ag_2S NP (30 nm) aged from pristine AgNP as a stable form of silver, known to have lower dissolution potential, and (4) 50 μg/L of AgNO3 as a positive (Ag^+) control. Sampling was done at the beginning of ENP exposition (0h), and after 1, 3, 15 and 30 days. Functional and structural changes were assessed using a range of end-points: enzyme activities and related metabolites, quantification/identification of secreted biomolecules and resulting ENP-coronas, analysis of extracellular polymeric substances (EPS), metabolism, photosynthetic activity, algal biomass, ENP bioaccumulation, and confocal and taxonomic observations of biofilm community composition. Metabolism increased with increased temperature but reduced in the presence of AgNP and Ag^+. Surprisingly, under warm conditions Ag_2S decreased the photosynthetic activity and algal biomass like the Ag^+ control, while AgNP increased both. Increased water temperature also caused homogenisation of biofilm composition and structure, and combined with AgNP or Ag^+, an increase of dead cells and a decrease of biofilm EPS. These results point out that warmer water can enhance AgNP and Ag^+ potential toxicity as well as modifying the behaviour of "non-toxic" compound like Ag_2S. These biological changes contrast with the fact that chemical (metal) analyses could not detect Ag in the water (total dissolved Ag^+) as concentrations were below the limit of detection of ICP-MS. This reinforces the importance of biological assays as early warning indicators. Results from chemical analyses and the rest of biological assays will be presented in detail.

TU036

Damselfly larvae become more sensitive to the pesticide chlorpyrifos under a neglected aspect of global change: increased thermal variation

J. Verheyen, R. Stoks, KU Leuven / Biology

There is increasing concern that climate change may make organisms more sensitive to chemical pollution. Many pesticides are indeed more toxic at higher mean temperatures. Yet, we know next to nothing about the effect of another key component of climate change, the increase of daily temperature fluctuations (DTFs), on pesticide toxicity. Therefore, we tested the effect of the pesticide chlorpyrifos under different levels of DTF (constant = 0°C, low = 5°C (current maximum level) and high = 10°C (predicted maximum level under global warming)) around the same mean temperature on key life history and physiological variables of *Ischnura elegans* damselfly larvae in a common-garden experiment. Notably, chlorpyrifos did not cause mortality or reduced growth rate at the constant temperature (0°C DTF), yet increased mortality 6x and reduced growth rate with 122 % at low and 111 % at high DTF. This indicates that daily short-term exposures to higher temperatures are enough to considerably increase pesticide toxicity. Moreover, the here used CPF concentration would have been regarded a NOEC ('No Observed Effect Concentration') if we had only tested the species under the standard conditions of constant 20°C. These standard conditions are typically used in laboratory ecotoxicity testing, while at the current DTF (going up to 5°C in this region), this CPF concentration may cause considerable mortality. However, a further increase from 5° DTF to 10°C DTF may not result in a further increase of pesticide toxicity. Our study adds to the few others showing an increased toxicity of pesticides under DTF and our results highlight the biological importance of including daily temperature fluctuations in ecological risk assessment of pesticides and as an extra dimension in the climate-induced toxicant sensitivity concept.

Impact of agricultural run-off and climate warming on key organisms and ecosystem functions in shallow aquatic ecosystems

E.M. Gross, University of Lorraine / Laboratoire Interdisciplinaire des Ecosystemes Continentaux; J. Leflaive, ECOLAB UMR 5245 CNRS; B.H. Polst, Helmholtz centre for environmental research - UFZ / Department of Bioanalytical Ecotoxicology; J. Allen, Université de Toulouse / ECOLAB UMR CNRS 5245; N. Kipferler, Ludwig-Maximilians-University Munich / Department of Biology; V. Vijayaraj, Universite de Lorraine / Laboratoire Interdisciplinaire des Ecosystemes Continentaux LIEC UMR CNRS; S. Bouletreau, Université de Toulouse / ECOLAB UMR CNRS 5245; V. Jassey, Université de Toulouse / ECOLAB UMR CNRS 7360; M. Schmitt-Jansen, Helmholz Centre for Environmental Research-UFZ / Bioanalytical Ecotoxicology; H. Stibor, Ludwig-Maximilians-University Munich / Department of Biology; S. Hilt, Leibniz Institute of Freshwater Ecology and Inland Fisheries / Ecosystem Research Division

Aquatic ecosystems are exposed to a multitude of stressors such as climate warming and agricultural run-off (ARO). This might cause severe disturbances up to the loss of ecosystem functions and services. Within the project CLIMSHIFT, we study the impact of these stressors on shallow aquatic systems by using micro- and mesocosms combined with modelling. Our objectives are to understand and reveal individual and interactive mechanisms of climate warming and ARO by using a combination of response variables at the individual over the community level up to major ecosystem functions. In two microcosm experiments, we tested the effect on competing primary producers in shallow aquatic systems: submerged aquatic plants, benthic and phytoplankton algae. We used a factorial design with 2 temperatures and 6 ARO levels. Experiment I used a concentration-response curve for a fixed ARO mixture, comprised of nitrates, copper, a herbicide, an insecticide and a fungicide. Experiment II used a defined low concentration of the same ARO, applied as single, double and triple dose either at once or pulsed. Exp_II tested microbial respiration in the biofilm and sediment as well as the degradation of leaf litter. In Exp_I, phytoplankton biomass increased with ARO treatment, and more strongly at higher temperature. Periphyton biomass increased first with increasing ARO concentration and then declined. Photosynthetic yield declined in both phytoplankton and periphyton with increasing ARO concentration. ARO only affected plant length in in one of three submerged macrophytes, and temperature caused an increase in plant length in the other two species, while ARO had no effect. In Exp_II, a pulsed addition of the ARO cocktail had in general less effect than the same amount of pollutants added in a single dose. In general, comparable effects for phytoplankton and periphyton were observed at the same concentration of ARO tested. A lower photosynthetic activity was measured in two of the macrophytes. Microbial respiration was much stronger at 22°C than at 26°C in both biofilm and sediment. Leaf litter degradation was significantly affected by both ARO and temperature. Ultimately, shifts in primary producers might lead to a regime shift in shallow aquatic ecosystems and to the loss of submerged aquatic plants. This will cause a loss in ecosystem functions and services and thereby a shift towards an inferiour ecological status.

Effect of organic pollutants on Daphnia magna
A. Seyoum, Orebro University / School of Science and Technology, Life Science Centre; A. Pradhan, Orebro University / The Life Science Center-Biology; J. Jass, Orebro University / School of Science and Technology, Biology; P. Olsson, Orebro University / The Life Science Center-Biology
Effect of organic pollutants on *Daphnia magna* Asmerom Seyoum, Ajay Pradhan, Jana Jass, Per-Erik Olsson **Biology, the Life Science Center, School of Science and Technology, Örebro University, Örebro, Sweden**
<strong>Abstract Detection of organic contaminants in the aquatic environment at low concentrations, has raised concerns for animal and human health. Phthalates and perfluorinated alkylated substances (PFAS) are among the most frequently detected persistent organic pollutants in the environment. Phthalates are mainly used as plasticizers to increase durability, resistivity and flexibility of plastic material. However, they are not chemically bonded to PVC and they may leach out and enter into the environment. Similarly, PFAS have many industrial applications due to their unique surfactant properties as well as their remarkable stability that results from high energy carbon-fluorine bonds. The increased use of these persistent compounds has resulted in contamination of the aquatic ecosystem and may threaten the aquatic life. We used *Daphnia magna* as a model organism to study effects of the most commonly detected phthalates i.e. di (2-ethylhexyl) phthalate (DEHP), diethyl phthalate (DEP) and dibutyl phthalate (DBP) as well as the widely used PFAS, perfluorooctane sulfonate (PFOS) and perfluorooctanoic acid (PFOA). *D. magna* were exposed to 1 and 10 μM phthalate and 1, 10 and 25 μM PFAS to investigate the chronic effects on hatching, development, reproduction, fat metabolism and lifespan. Exposures to phthalate and PFAS didn't result in acute lethality. However, preliminary data indicate that PFOS at 10 and 25 μM results in hatching delay of *D. magna* ephippia. Analysis of fat metabolism indicates that DEHP, DEP and DBP increase fat accumulation in Daphnia, and gene expression analysis following phthalate exposure in *D. magna* suggest that fatty acid accumulation is due to inhibition of enzymes involved in fatty acid uptake and catabolism. DEP and DBP did not alter the reproduction output, but surprisingly DEHP increased the reproductive output. PFAS on the other hand, decreased the reproductive output. Phthalate and PFOS exposure of *D. magna* led to decreased body length and lifespan. The results suggests that chronic exposure of *D. magna* to phthalates and PFAS at sublethal concentrations result in toxic effects. *Keywords*: Plasticizer, PFAS, Toxicity, Gene expression \n

TU039
Biodiversity, water quality and environment contaminants of the Bay of Bengal
M. Shoeb, N. Nahar, University of Dhaka / Department of Chemistry
The Bay of Bengal is located at the northeastern end of the Indian Ocean and has an area of 2,172,000 km^2. Several major rivers run into the Bay of Bengal. The coastal areas of Bangladesh (along the Bay of Bengal) include 60% of the Sundarbans, the mangrove forest of the Ganges/Brahmaputra delta in the West and areas with coral reefs in the Cox's Bazar provinces in the East. These areas are economically important because of fishing and biodiversity due to rich source of flora and fauna. In order to determine biodiversity, water quality parameters and environmental contaminants, 110 water samples were collected from Mongla, Kuakata sea beach and Saint Martin area. pH of samples from Kuakata were ranged from 7.58 - 8.77 with an average of 8.83 ± 2 which indicates lower ion presence in the water samples. Total Organic Carbon (TOC) is an indirect is an indirect measure of organic molecules present in water bodies and measured as carbon which was analyzed for the collected samples by TOC analyzer and found in the range of 0.78- 1.78 mg/L with an average 1.24 mg/L. Concentration of NO_3^-, SO_4^{2-} and PO_4^{3-} were determined by ion chromatography and only SO_4^{2-} was in a very low concentration. Dissolved Oxygen (DO) and (BOD) of the water samples were determined by multi parameter analyzer. Average DO and BOD were 8.33 ± 1.82 and 0.31 ± 0.03 mg/L indicating that the water system were well oxygenated and good quality with low pollution. Water samples from seven different sources were analyzed for 5 metals such as Pb, Cd, Mn, Hg and As using Atomic Absorption Spectroscopy (AAS) and the contamination of metal elements were found in a very insignificant levels (Pb < 0.2 mg/L, Cd < 0.01 mg/L, Mn < 0.02 mg/L, Hg < 0.001 mg/L and As < 0.005 mg/L). Two seaweeds were collected from Saint Martin and were investigated for chemical diversity and will be reported in the presentation.

TU040
Ecotoxicity assessment of post-fire runoff on freshwater aquatic species
N. Abrantes, University of Aveiro-CESAM / CESAM/DAO; I. Campos, University of Aveiro / Department of Environment and CESAM; P. Pereira, University of Aveiro / Department of Biology and CESAM; F.J. Gonçalves, University of Aveiro / department of Biology & CESAM; J.J. Keizer, University of Aveiro / Department of Environment and CESAM
Wildfire is a major disturbance of forests worldwide, posing an important threat to life, human goods and natural resources, not only on burnt areas, but also on adjacent aquatic ecosystems. Indeed, the environmental impacts of wildfires promote significant effects to the structure and functioning of the different ecosystem compartments. Wildfires have an important role in contaminants production and mobilization, such as polycyclic aromatic hydrocarbons (PAHs) and metals. These elements, mostly bound to ashes, can reach downstream water bodies by post-fire runoff, which can be toxic to aquatic biota. These detrimental off-site effects are particularly notorious during the initial post-fire period, although not necessary limited to it. However, the potential toxic outcomes of the input of such contaminants across the aquatic biota have received, so far, little research attention. This knowledge gap was addressed here through laboratory assays in which three aquatic species from distinct trophic levels: the algae (*Raphidocelis subcapitata*), the macrophyte (*Lemna minor*) and the invertebrate (Daphnia magna), were exposed to different dilutions of post-fire runoff and surface downstream water. The runoff was collected in a burnt and unburnt eucalypt stand as well as surface water from the burnt catchment outlet. The samples were collected during the first rainfall events after the wildfire, twelve and eighteen months later. We assessed the chemical composition in terms of PAHs and metals and effects of those runoffs on: (1) growth inhibition of *R. subcapitata* and *L. minor*; and (2) immobilization of *D. magna*. The chemical assessment proved the existing concern of wildfires impacts on aquatic systems, as a diffuse source of PAHs and metals. The results allowed discriminate the off-site effects of wildfires on distinct aquatic species. In general, unburnt surface runoff revealed to be less toxic to the producers, while the primary consumer was not significantly affected in any of the tested water samples. Moreover, it allowed to determinate the threshold concentrations of PAHs and metals that can be considered at low/high risk for aquatic biota. It was also demonstrated that detrimental off-site effects of wildfires are not limited to the immediately post-fire situation. This study highlights the need to additional research to understand the complexity of the potentially deleterious ecological effects of wildfires on aquatic communities.

TU041
Forest fires as potential triggers for mobilisation of major and trace elements (metals) to the aquatic system
I. Campos, Universidade de Aveiro / Department of Environment Centre for Environmental and Marine Studies CESAM; J.J. Keizer, University of Aveiro / Department of Environment and CESAM; P. Pereira, University of Aveiro / Department of Biology and CESAM; N. Abrantes, University of Aveiro-CESAM / CESAM/DAO
The increasing occurrence of wildfires and their overall impacts on the environment highlight the need for an effective post-fire forest management, from ecological as well as socio-economic point of view. Wildfires and subsequent rainfall can play an important role in the environmental (re)mobilisation of major and trace elements (metals), which could be leached into the soil profile or transported downslope by surface runoff, impacting both ground water and surface water quality. In particular, fire-induced inputs of these elements into the environment are relevant due to their toxicity, environmental persistence and tendency to bioaccumulate and bioamplify along the trophic chain. However, the impacts of wildfires followed by rainfall on metals redistribution on water bodies are poorly documented. In this context, the present study evaluates the impacts of a wildfire on surface runoff and nearby water downstream the burnt area by metals (V, Mn, Co, Ni, Cu, As, Cd and Pb) in north-central Portugal. Surface runoff from burnt, unburnt and water downstream an eucalypt area were collected over five campaigns during 18 months, to evaluated the influence of precipitation and time-since-fire on the levels of metals loads as well as the impact attenuation. The chemical assessment revealed concerning levels of some metals in burnt runoff and stream water samples. In general, the burnt surface runoff presented the highest levels metals, while the concentrations in the stream water samples were higher than the unburnt surface runoff. The behavior of the major and trace elements studied with time-since-fire revealed differences among them. The research results have contributed to improve and clarify the role of wildfires and rainfall on the (re)mobilisation of metals, pointing out that wildfires can act as a potential source of environmental contamination of aquatic systems. Monitoring source water downstream of burned watersheds allow water managers to minimize adverse water-quality effects, such as by temporarily diverting compromised water or changing source water. Understanding the effects that wildfire have on water quality is essential for ecosystem management and risk assessment.

TU042
Linking individual fitness to population changes of the endobenthic worm Hediste disversicolor: A temporal case study in the multi-polluted Seine (France) estuary
S. Tlili, Catholic University of the West / Faculté des Sciences; M. Le Coz, Univ. Lille, CNRS, Univ. Littoral Côte dOpale / UMR 8187, LOG, Laboratoire dOcéanologie et de Géosciences, 62930 Wimereux, France; M. Mouloud, M.

Bruneau, A. Chatel, Catholic University of the West / UBL, Mer Molécules Santé; C. Mouneyrac, Université Catholique de lOuest / UBL, Mer Molécules Santé
The Seine estuary plays an important ecological and socio-economic role but is also the most stressed estuary in France. The northern mudflat of the Seine estuary is continuously subjected for long time to complex environmental stressors, such as chemical pollution and physical modifications such as harbor construction (*e.g.* the construction of "Port 2000" from 2001 to 2005). To assess the potential effect of those stressors (both natural and anthropogenic), in the last decade, monitoring programs focused on the integrative quality assessment of this vulnerable natural habitat using the endobenthic worm *Hediste diversicolor* as sentinel species (*e.g.* The National French Program of Ecotoxicology "PNETOX"). It seems now a necessity to collect and compare data from anterior programs in order to evaluate the environmental status of this site as well as the relevance of indigenous populations as an appropriate environmental quality tools. In this context, the aim of the present study was to compare potential links between individual fitness (growth, allometric relationships, energy reserves, reproduction status) and population changes (density, biomass and populations dynamics endpoints) in worms (*H. diversicolor*) seasonally collected during "the Port 2000" construction (2002-2004) and fourteen years after (2018). The modal decomposition of size distribution frequencies revealed that during the first period (2002-2004), *H. diversicolor* populations were characterized by a unique cohort and consequently, a single-modal recruitment of juvenile worms. In contrast during 2018, population analysis demonstrated the existence of two simultaneous cohorts and a bi-modal recruitment. Worms density was generally lower in 2003 and 2004 as compared to current (2018) density whereas an inverse pattern was observed for biomass. Individual growth parameters (L3 and weight) did not show any significant differences between sampling periods. Allometric relation-ships and energy reserves comparisons between the two studied periods are actually in progress. Preliminary results, issuing from linking individual fitness to populations changes could be indicate an amelioration of the environmental quality of the Seine estuary northern mudflat after the combined stress episode (2002-2004). The overall results demonstrate the relevance of using *H. diversicolor* population's endpoints for the environmental assessment of estuarine ecosystems in a combined stressors context.

TU043
Nutrient pollution determines membrane lipid profile of coral responded to ambient warming
C. Tang, National Museum of Marine Biology and Aquarium / Department of Biology; C. Lin, National Taiwan University / Institute of Environmental Health; W. Wang, National Sun Yat-Sen University / Department of Marine Biotechnology and Resources
Thermal stress causes mass coral bleaching and mortality. Nutrient pollution altering coral physiology increases the risk of health. Membrane lipids constitute the basic structural element to create cell a dynamic structure according to the circumstance. Characterizing the lipid profile of coral responded to environmental factors could give an insight into the mechanism of effect. Glycerophosphocholine profiling of the coral Seriatopora caliendrum responded to warming conditions (28–32?) under different nitrate loadings (0.05–0.5 mg/L as N) was performed using a lipidomic methodology. The symbiotic alga-related physiological factors of the coral were altered by increased nitrate, warming stimulation and the interaction. Warming-induced lipid variations in the coral were well modeled based on the incubated temperature according to the nitrate loading. Based on the physicochemical properties, the commonly changed lipids logically indicated a membrane accommodation relating to ambient warming and the induced photophysiological change in the coral. The changed lipids specific to the exposure loading of nitrate suggested a cause increasing the health risk of the coral. Although the increased nitrate alone did not induce a pronounced change in lipid metabolism of the coral, in conclusion, the effect was identified while acts with a warming condition.

By 2050, the world population will reach nine billion people and three quarters of the global population will live in cities. The development path to 2050 will be marked by shifts in land-use and weather patterns, and by changes in the way water and food resources are obtained and managed all over the world. These global changes (GCs) will affect the emissions, environmental transport pathways and fate of chemicals, and thus affect the exposure of the natural environment to chemicals. Future changes may also alter the sensitivity of ecosystems to chemical exposure. Therefore, the ECORISK2050 project brings together a world leading and interdisciplinary consortium of universities, research institutes, industry and regulatory and governmental authorities to deliver a cohort of Early Stage Researchers (ESRs). The coupled training goals and research objectives of the project are: (1) to assess how the inputs of chemicals from agriculture and urban environments and their fate and transport are affected by different environmental conditions, including those of specific EU regions, and how this will change under GC scenarios in order to assess the likely increase in chemical risks to human and ecosystem health; (2) to identify potential adaptation and mitigation strategies that can be implemented in the short and medium term, to abate unacceptable changes in risks, and use the GC scenarios to propose robust implementation pathways, and (3) to develop a set of tools for use by industry and policy makers, that allow the impacts of a range of GC-related drivers on chemicals risks to be assessed and managed. The project will deliver the next generation of scientists, consultants and industry and governmental decision-makers who have the knowledge and skill sets required to address the changing pressures that chemicals emitted by agricultural and urban activities pose to aquatic systems on the path to 2050 and beyond.

TU045
Anionic Herbicides: Using IAM chromatography to determine if acute effect concentrations to aquatic organisms are below baseline-toxicity
S. Droge, University of Amsterdam/IBED Institute / IBED
Many herbicides are acidic compounds, the most notorious one probably 2,4-D (pKa 2.7, logD7.4 -0.8, soil half life 34d). Several of these herbicides have relatively long aerobic half-lifes in soil, extending the PMT limit of >40 days. Due to the low pK_a, these herbicides are present predominantly in their anionic form in most environmental systems. This makes these compounds highly mobile. Of course, herbicides are meant to be specifically toxic to certain types of plants they are meant to control. As such, many anionic herbicides fit the criteria of PMT compounds. For the strict regulation dossiers of pesticides, these compounds are widely tested for toxicity to non-target species, particularly covering several taxa of aquatic organisms. It makes sense that many herbicides could be toxic to algae, but to what extent are they toxic to invertebrates and fish? All organic chemicals, including ionogenic compounds, have a baseline toxicity that is induced at a critical accumulate level in cell membranes, called the critical membrane burden (CMB). Ideally, a herbicide is specifically toxic to certain plant species, and exert no specific toxicity to any non-target organism other than the baseline toxicity any organic chemical presents (alone or in a mixture). In this study, we evaluated the affinity of 10 anionic herbicides to bind to cell membranes (K_{MW}) using a chromatographic column coated with immobilized phospholipids (IAM-HPLC). Using the obtained K_{MW}, the narcotic effect concentration ($LC_{50,narc}$) was predicted based on a critical narcotic cell membrane burden of 50-200 mmol/kg. The $logK_{MW,IAM}$ values were orders of magnitude higher than logD values. The predicted baseline $LC_{50,narc}$ values closely correspond for many herbicides to acute LC_{50} for daphnids and fish, while algae are effected by 1-4 orders of magnitude lower. This distinguishes the herbicide specificity. Exception is dinoseb, a known uncoupler of oxidative phosphorylation, which shows even higher toxicity to fish that to algae. This evaluation may inform regulators on the non-specificity of anionic herbicides to non-target organisms beyond a logD approach. It additionally relates to the potential pressure of the compound to the total toxicant stress of chemical mixtures in contaminated environments.

Clinica e Molecolare
In highly dynamic systems, such as transitional and coastal waters, establishing their chemical status is challenging. MONITOOL is an exciting European project consisting of 16 Partners covering the Atlantic region from the Canary Islands to the Scottish Highlands and Islands, which aims to address this complex analytical challenge, responding to European Directive [1] demands for the assessment of the chemical status of transitional and coastal waters. Diffusive Gradient in Thin Films (DGT), and passive samplers (PS), in general, are already widely used in investigative monitoring and there is an increasing interest in their use for the environmental assessment of water bodies, within European policies requirements. The main barrier hindering the regulatory acceptance of PS for compliance checking is the lack of appropriate Environmental Quality Standards (EQS). EQSs for metals are defined in the dissolved fraction, preventing the use of DGT-labile concentrations for the establishment of the chemical status of water bodies. The MONITOOL Project aims to define suitable EQS to allow for the use DGT devices [2] for the monitoring of these priority metals in a regulatory context. DGT design allows for the continuous accumulation of metals *in situ*, and subsequent quantitation via methods such as ICP-MS. While many of the chemical aspects of the devices have been well studied [3], effects of environmental physicochemical parameters on the functionality of the devices has not been examined in detail. Five-day deployments of DGT devices, alongside spot sampling and physicochemical parameter measurement, will be conducted in both wet and dry seasons in coastal and transitional waters of the North Atlantic coast. The first sampling campaigns were performed during winter 2017/2018 in 4 selected sites (transitional and coastal sites) in each consortium region (8 regions). All partners followed the same protocol for sampling and analysis to minimize the operational variability. Priority metals (Cd, Ni, Pb) and other specific metals (Al, Ag, Cu, Cr, Co, Fe, Mn, Zn) were analysed in waters and in the DGT resins. Statistical analysis is being applied to study relationships between metal concentrations in DGT and in spot water samples. Suitable EQS for DGTs will be calculated on basis the statistical relations obtained previously. This will permit a better implementation of the Water Framework Directive in variable systems like transitional and coastal waters.

The exposure of glyphosate and copper affect growth and reproduction on Daphnia exilis: a study transgenerational
A. Rodríguez Miguel, Instituto Politécnico Nacional. Escuela Nacional de Ciencias Biológicas; M. Hernández, Instituto Politcnico Nacional / Zoology; L. Martínez-Jerónimo, Instituto Politécnico Nacional. Escuela Nacional de Ciencias Biológicas; F. Martínez-Jerónimo, Escuela Nacional de Ciencias Biolgicas-I.P.N. / Laboratory of Experimental Hydrobiology
Currently, contamination of waters with glyphosate and copper is a worldwide problem; this is originated from agricultural, mining, and industrial activities. Although glyphosate is classified as an herbicide of reduced toxicity, several studies have demonstrated the occurrence of this pesticide at environmentally relevant concentrations, and toxic effects to aquatic biota have also been documented. Copper is an essential micronutrient at low concentrations; however, at high levels, it becomes toxic; this metal is also used as a biocide. Most chronic toxicological test guidelines only evaluate the toxic effects within one generation; however, negative effects could appear across generations, mainly when different toxics act jointly. We aimed to determine the transgenerational effects produced by mixtures of glyphosate and copper on the American cladoceran *Daphnia exilis*; measured endpoints were population growth, fecundity, metabolic biomarkers, and the size of the progeny. LC_{50}'s of both toxicants were determined. In the chronic toxicity studies *D. exilis* was exposed to the following mixtures of glyphosate (mg L^{-1}) and copper (mg L^{-1}): $LC_{0.05}$ (1.04 and 2.45); $LC_{0.5}$ (3.09 and 1.24); LC_5 (3.83 and 1.45) and LC_{10} (4.31 and 1.57), respectively. Experiments were performed during 21 d for each generation, at 25°C, 16:08 photoperiod, feeding with *Pseudokirchneriella subcapitata* ($8x10^5$ cells mL^{-1}). Survivorship, accumulated progeny and the number of clutches in the parental generation (F_0) were significantly higher than the values observed in F_1. Age of first reproduction was significantly different between F_0 and F_1 in the combinations $LC_{0.05}$ and $LC_{0.5}$. The concentration of lipids in *D. exilis* exposed to the mixture of glyphosate and copper in F_0 and F_1 was not significantly different in all the tested concentrations; nevertheless, carbohydrates content in F_1 was significantly increased respect to F_0 in $LC_{0.5}$ and LC_5. There was a reduction in the proteins content in F_1 compared to F_0, only in $LC_{0.5}$. The size of neonates varied among treatments and broods in F_0 and F_1; in F_0, some clutches were affected by the mixture of xenobiotics, especially in the $LC_{0.05}$ and LC_5 treatments. The mixture of glyphosate and copper significantly increased toxic effects on *D. exilis* in the F_1 generation, probably because in F_0 the cladocerans could develop resistance mechanism to tolerate toxicity, that influenced the response of progeny in the second generation.

TU048
Demographic transgenerational effects of glyphosate in the cladoceran Daphnia curvirostris
L.L. González-Trujillo, Escuela Nacional de Ciencias Biológicas. Instituto Politécnico Nacional / Department of Zoology; F. Martínez-Jerónimo, Escuela Nacional de Ciencias Biolgicas-I.P.N. / Laboratory of Experimental Hydrobiology
Glyphosate is an herbicide extensively used around the world. Although it is supposed to be biodegraded in some weeks, the active ingredient, as well as the adjuvants and other compounds in the commercial formulations, can produce toxic effects in the hydrobionts, temporally and in their future generations, modifying the structure and function in the aquatic ecosystems. Cladocerans are an important component of the freshwater zooplankton, as it is a fundamental link between primary producers and secondary consumers. The toxic response to pollutants in the progeny of exposed parents is not normally investigated in routine toxicity tests, notwithstanding negative, transgenerational damages could be expected. This study was aimed to determine the transgenerational effects produced by the herbicide glyphosate, as the commercial formulation FAENA®, and as active ingredient (AI) in *D. curvirostris*, evaluating demographic responses. We determined the 48-h acute toxicity of FAENA and AI, then five sublethal concentrations were chosen ($LC_{0.01}$, $LC_{0.1}$, LC_1, LC_5, and LC_{10}) for the exposure of *D. curvirostris*, from neonates to adults, in two generations (F_0 and F_1), during 21 days; to determine the modification in the response to the toxicants in the F_1 generation, simultaneous replicates with individuals of the same clutch were not exposed to glyphosate (recovery phase, F_{1R}). Assessed demographic parameters were survivorship, total progeny, the age of first reproduction, number of clutches, and inter-clutch time; the size of neonates in each clutch and that of adults at the end of experiments were also measured. The LC_{50} in *D. curvirostris* was 5.85 mg L^{-1}; however, the LC_{50} for AI was higher than 100 mg L^{-1} and was not experimentally determined. Demographic parameters were significantly affected in F_0 when cladocerans were exposed to FAENA, but with AI there were no differences between F_0 and F_1. In F_1 and F_{1R}, a reduced effect in the demographic parameters was observed, possibly because the organisms acquired mechanisms of resistance, despite in F_{1R} the individuals were grown in fresh culture medium without toxicants. The results demonstrated transgenerational effects in *D. curvirostris*. Also, we confirmed that the toxicity of glyphosate is caused by the ingredients in the commercial product FAENA, although it is not possible to identify the joint effect of the active ingredient with the assessed endpoints.

TU049
Examining American alligators as sentinels of toxic trace element exposure
F. Nilsen, US EPA / ORISE Fellow / National Exposure Research Lab; T.R. Rainwater, Clemson University; A. Brunell, Florida Fish and Wildlife Conservation Commission; B. Kassim, Merck Company Inc; J. Bowden, University of Florida; L. Guillette, Medical University of South Carolina; S.E. Long, T. Schock, National Institute of Standards and Technology / Analytical Chemistry Division
Toxic trace element exposure occurs through anthropogenic release of naturally occurring elements such as arsenic (As), cadmium (Cd), lead (Pb), and mercury (Hg), making them ubiquitous across the globe. Detrimental exposures can occur through ingestion of contaminated food sources; thus, many nations have consumption advisories in place; however, not all communities abide. As a result, populations that include a large proportion of marine species in their diet, including subsistence hunting communities, are routinely exposed to concentrations above advisory limits. To effectively monitor environmentally-driven trace element concentrations, and consequently the potential exposure in humans, sentinel species are needed that are more accessible than the marine mammals currently used as proxies. Due to the unique environmental conditions of the southeastern Atlantic coast of the United States, accumulation of Hg in this region is greater than most other locations in the country. There are also point sources of As, Cd, and Pb in this region. Upper trophic level predators in this region exhibit elevated concentrations of Hg and other contaminants. In this study, concentrations of As, Cd, Pb, Hg and six other trace elements (Al, Ni, Cu, Zn, Se, Mo) were examined in American alligators (*Alligator mississippiensis*) from seven sites along the southeastern Atlantic coast. The observed concentrations for the four toxic elements (As, Cd, Pb, and Hg) were comparable to those reported in humans, with Hg spanning the broadest range. The similarity in As, Cd, Pb, and Hg concentrations between alligators and humans observed in this study underscores how alligators can serve as a useful sentinel species for toxic element exposure.

TU050
Toxicity of the Antifouling Biocide Sea-Nine 211 (DCOIT) to Neotropical Marine Invertebrates
B. de Campos, UNIVERSIDADE ESTADUAL PAULISTA - UNESP; M.K. Fontes, UNESP Universidade Estadual Paulista Júlio de Mesquita Filho; D.M. Abessa, UNESP Universidade Estadual Paulista Júlio de Mesquita Filho / Department of Biosciences
The antifouling biocide 4,5-dichloro-2-n-octyl-4-isothiazolin-3-one (DCOIT), commercially known as Sea-Nine 211, came up to replace organotin based paints, which were banned in 2008. The toxicity of SeaNine has been recorded to various species of different trophic levels, but there are no studies evaluating its toxicity to neotropical species. The present study aims to evaluate the toxicity of SeaNine to the following neotropical species: *Perna perna* (Bivalvia), *Echinometra lucunter* (Echinodermata), and *Artemia salina* (Anostraca). The effects of DCOIT on the embryonic development of *E. lucunter* and *P. perna* were evaluated by exposing in vitro fertilized eggs to seriate dilutions of DCOIT (0.01 to 100 µg/L for *E.*

lucunter and 0.01 to 500μg/L for *P. perna).* For *A. salina* acute toxicity tests were conducted with nauplii, using concentrations between 10 and 1000μg/L. The respective $EC_{50\text{-}48h}$ obtained to *E. lucunter* and *P. perna* were 35.72 μg/L (17.71 – 71.02 μg/L) and 8.06 μg/L (6.96 – 9.36 μg/L), while the $EC_{10\text{-}48h}$ were 9.43 μg/L and 2.86 μg/L respectively. There was no statistically difference between the water and solvent control. In the test with *A. salina*, the $LC_{50\text{-}48h}$ and $LC_{10\text{-}48h}$ obtained were 173.9 μg/L (142 – 212.8 μg/L) and 94.96 μg/L respectively, both water and solvent control showed a survival of 100%. The LC and EC values obtained in this investigation are within the range of sensitivity found in literature for similar taxa representants. The DCOIT has been used as a substitute for TBT; however, the data presented in this work, supported by the literature, shows that both substances have a comparable toxicity (e.g. LC_{50} of TBT on the embryonic development of *P. lividus* = 37 μg/L). Thus, this study suggests that the environmentally friendly title labelled in the latter 1990's by the US.EPA may be not appropriate, and the SeaNine has the potential to cause ecological effects despite its rapid degradation in water.

TU051

Sub-lethal toxicity of chlorpyrifos to fresh water indicator mussel species Unio crassus Philipsson, 1788 (Bivalvia, Unionidae)

A.C. Gunal, Gazi University / Biology Education; B. Erkmen, Aksaray University / Department of Biology; P. Arslan, Ankara University / Biology; F. Erkoc, Gazi University / Biology Education

Chlorpyrifos is a non-systemic organophosphorus insecticide, used in agriculture to control pests, and indoors to control mosquitoes and fire ants. The World Health Organization (WHO) classifies chlorpyrifos as a category 2 (moderately hazardous) pesticide. Chlorpyrifos is highly toxic to fish and aquatic invertebrates. The objective of this study was to determine the acute sub-lethal (24-h and 96-h) toxicity of chlorpyrifos to the fresh water mussel *Unio crassus* (Bivalvia). The mussels were hand collected from Karaçay, Sinop, Turkey and acclimatized for one month before the experiments. Stock chlorpyrifos solution was prepared in DMSO and diluted to provide exposure concentrations of 10 and 100 μg/L. Controls received only aerated municipal tap water. At termination of exposure times hemolymph was collected by diluting with 4% formaldehyde (1:1) and counted in Thoma counting chambers under a light microscope to calculate total hemocyte counts (THC/ml). After hemolymph sampling mussels were sacrificied under ice anestesia for histopathologic examination. Tissues were fixed in Davidson's solution and routine histologic procedures were performed. Mean values of the control group were 682667 and 534706 THC/ml for 24 and 96-h, respectively. The cell counts decreased with respect to controls during 24-h; but increased in 96-h. No differences were found between 10 and 100 μg/L exposure concentrations; neither between 24 and 96-h control and 100 μg/L THC/ml results ($P > 0.05$). However 24-h control and 10 μg/L groups were significantly different ($P < 0.01$). The 96-h experimental group data did not show normal distribution. Non-parametric Kruskal Wallis H test results showed significant differences ($P < 0.01$) between all groups for 24-h experimental duration. Degenerations were observed in the digestive gland tissues after 96 h exposure to 100 μg/L chlorpyrifos. Further research is needed to elucidate the molecular mechanisms of chlorpyrifos toxicity, comparison of in vitro and vivo studies in other marine or fresh water mussel species, together with non-target indicator organisms.

TU052

Sulfate losses from gypsum amended agricultural fields do not pose a threat to riverine species in the catchment of the Baltic Sea

K. Rantamo, University of Jyvaskyla; H.E. Arola, University of Jyvaskyla / Department of Biological and Environmental Science; J. Aroviita, Finnish Environment Institute; M. Hannula, H. Hämäläinen, University of Jyvaskyla; R. Laaksonen, Regional Centre of Economic, Development, Transport and the Environment of Southwest Finland; T. Laamanen, M.T. Leppanen, Finnish Environment Institute; J. Salmelin, University of Jyvaskyla / The Department of Biological and Environmental Science; J. Syrjänen, University of Jyvaskyla; J. Turunen, P. Ekholm, Finnish Environment Institute

Eutrophication due to nutrient load from agriculture is a major problem in the Baltic Sea. Applying gypsum ($CaSO_4$? $2H_2O$) onto agricultural fields has a great potential to lower the phosphorus load. In 2016, a pilot study was started in south-western Finland, where gypsum was spread on 15 km^2 of clayey agricultural fields to reduce phosphorus losses to streams and rivers, and finally to the Baltic Sea. Gypsum is readily dissolved in the soil solution, which elevates the concentrations of calcium and sulfate in the downstream waters. Thus, the environmental effects of gypsum need to be assessed before large-scale applications can take place. Of these two gypsum ions, sulfate has reported to have a harmful effect on riverine biota, when present in high concentrations. An extensive risk assessment study was conducted to reveal the possible effects of the increased sulfate concentrations in a riverine ecosystem. The assessment consisted of an online monitoring of the sulfate levels and measuring the abundance of thick shelled river mussels (*Unio crassus*) and fish species. The laboratory studies included sulfate exposures measuring the growth of greater water moss (*Fontinalis antipyretica*), behavioural activity of adult *U. crassus* and acute survival test of *U. crassus* glochidia. The *in situ* experiments consisted of the measurements of algal biomass, behavioural activity of adult *U. crassus* and the survival and hatching of incubated brown trout (*Salmo trutta*)eggs. Some of the test species responded to the highest test concentrations of sulfate (1100-1200 mg l^{-1}). However, the sulfate concentrations observed in the river after the gypsum spreading did not have statistically significant effects on any of the test species or endpoints. In the river the abundance of some of the fish species declined after the gypsum spreading, but this was likely a result of natural environmental variation and fish stocking practices rather than gypsum spreading. The gypsum treatment of agricultural fields did not seem to pose a threat to riverine ecosystems at the study site. Yet, the sulfate levels of the rivers located in other gypsum spreading areas should be monitored to verify a safe sulfate concentration.

TU053

Sub-lethal toxicities of zinc pyrithione (ZPT), copper pyrithione (CPT) alone and in combination to the indicator mussel species Unio crassus Philipsson, 1788 (Bivalvia, Unionidae)

N. Třešňáková, University of South Bohemia in Ceske Budejovice, Faculty of Fisheries and Protection of Waters; A.C. Gunal, Gazi University / Biology Education; G. Başaran Kankılıç, Kırıkkale University / Department of Biology; E. Paçal, Gazi University; U.N. Tavşanoğlu, Hacettepe Technopolis Technology Transfer Center; R. Uyar, Ankara University / Department of pharmacology and toxicology; F. Erkoc, Gazi University / Biology Education

Zinc pyrithione (ZPT) and copper pyrithione (CPT) are replacement antifouling booster biocides, and are emerging contaminants in marine and freshwater ecosystems and therefore may have ecotoxicological impacts on non-target organisms posing risks. The aim of this study was to determine the potential sub-lethal toxic effects of zinc pyrithione and copper pyrithione separately and in combination (ZCPT) to freshwater indicator mussel species, *Unio crassus* Philipsson, 1788 (Bivalvia, Unionidae, mean length = 54.9 mm). The mussels were hand collected from Karacay, Sinop, Turkey and adapted to laboratory conditions. Control and DMSO solvent control groups were compared with 10 $\mu g\,l^{-1}$ individual biocide and 5+5/10+10 $\mu g\,l^{-1}$ sub-lethalcombination exposure groups, keeping all tanks in the dark for photodegradation. Mussels were kept in 10 L aerated tap water and exposure durations were 48-h and 7-d; at the end of 48-h the animals received the same concentrations once more, after removing the initial media from the tanks. At the termination of exposure times, mussels were weighted, morphological measurements taken and then hemolymph collected by diluting with 4% formaldehyde (1:1) fixative. Haemocyte counts were made using a Thoma counting chamber under a light microscope, results reported as total haemocyte counts (THC/ml). Lipid peroxidation levels were measured as MDA (nmole/g tissue). Tissues were dissected, fixed in Davidson´s fixative, histopathological alterations were observed in digestive gland tissues. Degenerations were more severe at the copper pyrithione and the combination of the compounds groups. Mean THC/ml values differed significantly ($P < 0.001$) among all groups, for both exposure durations. MDA levels were lower than controls, but in the 7-d group increased above 48-h levels, the differences were not significant except for control-CPT 48-h and control-ZPT 7-d. GSH and protein levels were different during 7-d.

TU054

Ascidians as bio-indicators for pharmaceuticals in marine environments

G. Navon, Tel Aviv University / Zoology; A. Kaplan, D. Avisar, Tel-Aviv University / Porter School of the Environment and Earth Sciences; N. Shenkar, Tel Aviv University / School of Zoology

The use of pharmaceutically active compounds (PhACs) is increased every year in human and animal medicine worldwide. Their presence in the marine environment presents a threat to marine organisms and ecosystems. Measures of PhACs concentrations in marine waters and sediments are not sufficient to predict exposure concentration by marine organisms, as they provide only a snapshot in time. Additionally, it does not illustrate the harmful effects and the fate of these compounds within living organisms. Some types of PhACs have been intentionally designed to affect living systems at relatively low doses. As a result, PhACs at environmentally relevant concentrations ($\mu g\ L^{-1}$ to ng L^{-1}), have been recently identified as potentially toxic for aquatic organisms. In addition, bioaccumulation is possible for some specific compounds. This study aims to investigate the use of solitary ascidians, highly efficient filter-feeding sessile invertebrates, as biological indicators for PhACs. Our goal is to exploit the cosmopolitan distribution of invasive ascidians in order to develop a uniform method using the same bio-indicator species, across a wide geographic scale. Our objectives are to evaluate the spatial and seasonal variation of ascidians' ability to accumulate PhACs and to identify protein expression in response to PhACs accumulation using a proteomic approach. We developed an analytical method for detection of PhACs in ascidians' tissues using pressurized liquid extraction and analysis by high-pressure liquid chromatography. We detected three PhACs, Carbamazepine, Bezafibrate and Diclofenac, during preliminary testing. We are currently analysing collected samples in order to present our results at the SETAC Europe 29th annual meeting. Analysis of protein profiles of ascidians under laboratory controlled exposure experiments is also in progress. To our knowledge, this is the first time ascidians are used as bio-indicators for PhACs contamination. Ascidians hold a promising potential for detection of PhACs, before causing irreversible ecological damage. Since ascidians are the closest living relatives of vertebrates, there is an advantage studying their response to PhACs contamination over other marine invertebrates, giving the opportunity to better understand the possible effects on marine vertebrates and on humans.

Bioaccumulation modelling of selected metals (As, Cd, Cu, Ni, Pb, Zn) in coastal and estuarine food webs. Case studies

A. Radomyski, University of Venice / Department of Environmental sciences, Informatics and Statistics; E. Giubilato, University Ca Foscari of Venice / Department of Environmental Sciences Informatics and Statistics; L. Pizzol, University Ca Foscari of Venice / Environmental Sciences, Informatics and Statistics; K. Lei, C. Lin, Beijing Normal University; A. Critto, A. Marcomini, University Ca Foscari of Venice / Department of Environmental Sciences Informatics and Statistics

The study aimed to bring together knowledge gained from the results of the bioaccumulation modelling and field campaigns in order to obtain a more complete picture of bioaccumulation phenomena in aquatic food webs in two case studies. The first one located in estuary of the Lagoon of Venice, Italy and the second one in the coastal area of Liaodong bay, China. Both represent interesting scenarios for ecological exposure modelling due to the availability of local data on metal concentrations in water, sediment and in site specific aquatic species. Also both areas are economically important and affected by long-term and large-scale industrial activities posing potential ecological as well as human risks following the exposure to a multitude of environmental contaminants. MERLIN-Expo was selected to model exposure to metals and metalloids due to its novelty and broad application domain (Ciffroy et al., 2016). The model was dynamically run using observed exposure concentrations (sediments, water), and was parameterised probabilistically with site and organism specific data. Subsequently, the simulation results were evaluated against measured bioaccumulation data in soft tissues of the selected organisms. Finally, the Morris and extended Fourier Analysis (EFAST) were used to account for variability in selected parameters of the bioaccumulation model on the simulated results. We have obtained satisfactory simulation results especially for bioaccumulation of Zn and As, which showed the best agreement with measured values in aquatic organisms. The sensitivity analysis complemented the modelling of bioaccumulation by allowing to identify crucial parameters for simulating the internal exposure of organism to metals. Food assimilation efficiencies of selected aquatic species seem to be the key components of the modelling, driving the variability of internal exposure to the selected metals and metalloids.

TU056

A 16th century shipwreck mercury legacy and present mercury bioaccumulation in intertidal species

H. Vieira, University of Aveiro; J. Rendón-von Osten, Autonomous University of Campeche / EPOMEX Institute; A.M. Soares, F. Morgado, University of Aveiro / department of Biology & CESAM; S. Abreu, University of Aveiro / Dep. Biology & CESAM

Over the centuries, mercury (Hg) has been used for a variety of purposes being employed in the manufacturing of thermometers, barometers, explosives, playing also a significant role in dentistry, pharmaceutical industry and agriculture. Furthermore, Hg is commonly used in gold and silver mining processes to separate the metal particles from the sediments (aquatic and terrestrial) through a process called amalgamation. In Spanish colonial times, the Hg necessary to the mining process was carried in galleons along the Atlantic, from Spain to the New World. However, some of these vessels occasionally sank due to storms or collisions with reefs, potentially releasing the stored Hg. Once in the environment, Hg has the particularity to bioaccumulate and biomagnify in aquatic food webs, this way Hg concentrations found in predator species can be millions of times higher than those observed in surface waters. Furthermore, biomagnification of Hg can lead to toxic concentrations in fish and fish-eating wildlife. It is possible to monitor Hg presence in the marine environment through the analysis of Hg concentrations in the tissues of the organisms that are able to accumulate this pollutant (accumulation bioindicators). There are several criteria for an organism to be considered an accumulation indicator: (1) sessile or at least restricted mobility, (2) ubiquitous and sufficiently abundant in the sampling area, (3) available in all seasons, (4) ease of sampling, (5) large body to provide sufficient material for chemical analysis, (6) high capacity to accumulate contaminants above environment levels, (8) predisposition to retain contaminants for a sufficient time after reduction in the environment. In the present study, the authors focused on the evaluation of Hg concentration in marine sediments and among different marine species (*Asparagopsis armata*, *Ulva lactuca*, *Littorina striata*, *Patella candei*,*Paleamon elegans* and *Pachygrapsus marmoratus*) collected in a bay where a 16th century shipwreck can be found and in other bays without the presence of shipwrecks. The Hg concentrations found in the sediment and in the marine species collected in the shipwreck area was significantly higher in comparison to those found in the other bays. The shipwreck Hg legacy seems to have an influence on the present Hg distribution in the sediments and in the intertidal species.

Temporal changes in dissolved elemental mercury at a coastal aquaculture site in the Grado Lagoon, northern Italy

N. O'Driscoll, Acadia University / Department of Earth and Enviromental Science; S. Covelli, Dipartimento di Matematica e Geoscienze / Dept. of Mathematics and Geosciences; E. Petranich, University of Trieste / Dept. of Mathematics & Geosciences; F. Floreani, University of Trieste / Department of Mathematics and Geosciences; A. Acquavita, ARPA FVG

Mercury can be lost from ecosystems through the process of photoreduction to its volatile elemental form (Hg(0)) in natural waters which is primarily controlled by abiotic reactions with ultraviolet (UV) radiation. There is little mercury photoreduction research available for contaminated coastal marine systems. Grado lagoon, northern Italy, is an aquaculture area with high total mercury concentrations in sediment due to past cinnabar mining activities at Idrija (western Slovenia). Two sites (one highly Hg contaminated, VN1, and one with lower contamination, VN3) located within a lagoon fishfarm were analyzed for temporal changes in dissolved elemental mercury ($Hg(0)_{aq}$) and its relationship with UV radiation in May of 2018. Solar radiation spectra were continuously quantified using an OceanOptics USB 4000 spectroradiometer and aqueous Hg(0) concentrations ($Hg(0)_{aq}$) using a Lumex 915-RA with headspace analysis and an equilibrium partitioning model with temperature-corrected Henry's law constant. It was found that the small pH changes observed were significantly correlated with $Hg(0)_{aq}$ concentrations at both sites however this was likely due to auto correlations with the daily cycle of microbial respiration and carboxylic acid concentrations. It was found that $Hg(0)_{aq}$ concentrations ranged between 237.6 - 401.5 pg L^{-1} (mean = 331.4 pg L^{-1}; SD=42.94; n=13) at the more contaminated site, VN1, and showed a diurnal trend. Total dissolved mercury at this site ranged between 3.85 - 28.22 ng L^{-1} (mean=7.7; SD=6.17 ng L^{-1}; n=13), which resulted in a % Hg(0) ranging between 0.84 – 8.24 %. At the lower mercury site, VN3, $Hg(0)_{aq}$ concentrations ranged between 200.3 – 321.52 pg L^{-1} (mean=279.49 pg L^{-1}; SD=46.99; n=14). Total dissolved mercury at this site ranged between 2.86 – 9.13 ng L^{-1} (mean=5.04; SD=2.06 ng L^{-1}; n=14), which resulted in a % Hg(0) ranging between 2.89 – 8.91 %. In both cases the $Hg(0)_{aq}$ concentrations in water were higher in the central part of the day and positively correlated with incoming UVB and UVA radiation measurements (Site VN1 Pearson r = 0.48, p=0.09, n=13; Site VN3 Pearson r=0.70, p=0.01 n=13). In conclusion, it was found that % Hg(0) relative to total mercury concentrations were similar at the contaminated coastal aquaculture site to other contaminated areas in previous work, but were substantially higher than those observed at other uncontaminated sites.

Salinity influences on mercury photochemistry in estuarine rivers in Minas Basin, Canada

R. Clarke, Acadia University / Biology; N. O'Driscoll, Acadia University / Department of Earth and Enviromental Science; S. Klapstein, Acadia University / Earth & Environmental Science

Mercury (Hg) loss from natural waters can occur through photoreduction that is controlled primarily by ultraviolet (UV) radiation. The retention of Hg in aquatic systems is largely affected by its reduction-oxidation photochemistry, and the chemical characteristics of estuarine water may significantly affect the photochemistry of Hg and its eventual accumulation in food webs as methylmercury, a potent neurotoxin. Currently, there are limited data on Hg photochemical cycling in estuarine ecosystems compared to freshwater ecosystems. To address these knowledge gaps, the photochemical kinetics of mercury speciation with respect to salinity and dissolved organic matter (DOM) were quantified. It was hypothesized that the rate and absolute amount of photochemical Hg reduction in estuarine waters is facilitated by DOM and inhibited by salinity. Water samples from the Cornwallis tidal river estuary in the Minas Basin, Nova Scotia, Canada were taken in July of 2018. Using tangential ultrafiltration, an array of salinity and DOM conditions were attained and then irradiated over an environmentally-relevant range of five UV intensities between 300–400 nm. Gaseous elemental mercury (Hg(0)) was analyzed every five minutes over a period of 24 hours using a Tekran 2573B CVAFS automated mercury analyzer. Gross photoreduction and photooxidation reversible pseudo-first order reaction rate constants and total photoreducible Hg in each treatment were determined using curve-fitting software. These data and the correlations with DOM and salinity change and will be presented. The proposed research will provide fundamental data and rigorous experimental testing which can then be used to predict Hg retention and accumulation in estuaries.

TU059

Mitigating measures to eliminate organochlorine pesticides in surface water of developing countries in Southeast Asia

M. Salingay, IHE Delft, Institute for Water Education / Water Science and Engineering

Importance of pesticides are well recognized, as these were developed for very reasonable purpose. But unknown to some farmers, there are also quite a handful of banned organic pesticides, as these give adverse effect to human and the environment. This study aims to assess and analyse the residual banned organochlorine pesticides unintentionally disposed or transported through surface runoff from farms in the upstream to receiving waters. In the pesticides

assessment, passive samplers were used instead of the traditional grab sampling. The sampling were conducted uninterrupted for 34 days in Cagayan de Oro River, Philippines and Song Can Tho, Vietnam. HPLC, GC-MS MS AND LC-MS MS were used to quantify the pesticide concentrations. The time weight average of the organochlorine restricted pesticides were measured in trace amounts. What is alarming is that these banned organic pesticides were already banned for almost two decades. These were prohibited because these organochlorine compounds persist, bioaccummulate and have adverse effect to human and the environment. It is recommended that responsible government agencies should invest in awareness raising activities on good practices and management of pesticides use to farmers, regular monitoring of pesticides and strict implementation of existing environmental laws and policies.

TU060

Multi criteria assessment to optimize plant protection strategies: A case study with apple orchards

M. Mathis, Agroscope; L. de Baan, Agroscope / Institute for Plant Production Sciences IPS; J. Daniel, Agroscope / Research group Ecotoxicology

Monitoring programmes have shown that pesticide concentrations in surface water have exceeded water quality criteria. Pesticide emission to surface water can be decreased by reducing pesticide use and/or by reducing emission, e.g. via specific risk mitigation measures. Reducing the use of pesticides can be very challenging for the production of crops. E.g. for apples, even in organic production pesticides are applied 20-30 times per year to protect crops against diseases and pests. However, risk mitigation measures alone might not be sufficient to achieve good water quality in small streams in agricultural catchments. Therefore, optimized plant protection strategies are being developed with reduced pesticide use. To quantify the contribution of optimized plant protection strategies on risk reduction and to understand potential economic and environmental trade-offs related to these strategies, a multi criteria assessment method (MCAM) was conducted: ecotoxicological risks as well as environmental and economic impacts were assessed. The MCAM was applied to apple orchards in Switzerland. We compared five different plant protection strategies (low-input, high-input, average organic, optimized organic and risk-optimized chemical scenario) with an average chemical plant protection strategy (reference scenario). For each scenario, ecotoxicological risks in surface water, soil and off-crop habitat were assessed with the model SYNOPS. Environmental impacts were assessed with life cycle assessment (LCA), focusing on ecotoxicity, terrestrial in-crop biodiversity, use of minerals and energy, greenhouse gas potential and eutrophication. For the economic assessment, profitability, resource intensity (capital and workload) and variability (fluctuations in yields and revenue) were considered. Finally, the results from these very diverse quantitative methods were translated into a comparative assessment, where each crop protection strategy was rated compared to the reference scenario. This allowed to assess and compare crop protection strategies from different angles. In this study we show the important role of choice of plant protection strategy for the risk to aquatic and terrestrial environments. Combined with appropriate risk mitigation measures, improvements in water quality can be achieved. The MCAM also supports decision-making by early identification of potential trade-offs with other environmental impacts or economic performance.

Marine debris in Central Chile: Characterization of macroplastics in Concepción Bay

V.G. Aburto, University of Siena / Department of Environmental Sciences; K. Pozo, M. Torres, W. Urbina, Universidad San Sebastián / Facultad de Ingeniería y tecnología; D. Nuñez, Centro de investigación de polímeros avanzados; P. Pribylova, Masaryk University / RECETOX; O. Audy, J. Klanova, Masaryk University / RECETOX Research Centre for Toxic Compounds in the Environment; M. Baini, University of Siena / Department of Physical, Earth and Environmental Sciences; M. Fossi, University of Siena / Department of Physical Sciences, Earth and Environment; P. Oyarzún, Universidad San Sebastián / Facultad de Ingeniería y tecnología

Plastic debris can be transported over long distances from the sites of origin and it accumulates through the ocean currents in oceanic turns. Recent studies have been devoted to characterize the Anthropogenic Marine Debris (AMD) along the Chilean coast, where it has been shown that the most abundant AMD are plastics and cigarette butts which can be attributed to local sources with increase over time. In this study we have characterized plastic debris (PD), in five beaches of Concepción bay in central Chile during two different periods (spring 2017 and summer 2018). Samples of PD were collected and analyzed physically by abundance, shape and colour. The sampling was carried out using three transects and three quadrants (3x3 m) for each beach. The physical analysis was carried out with a high resolution optical microscope with an integrated camera, Leica DM 750 and the chemical analysis was conducted with Agilent Cary 630 Fourier transformed infra-red spectrometer (FT-IR). The preliminary results showed in general, the highest abundance of PD was detected in summer with average values of 3 ± 1.3 items/m^2 and 1 ± 1.4 items/m^2 in spring. The physical characterization showed the most frequent size was PD < 2.5 cm (46%) (mesoplastic), with the most frequent shape for plastic pieces (48%) and others (46%) like pieces of polystyrene and elastic. In addition the predominant PD colour found was white (22%) and others (20%) like purple and orange. The chemical analysis of PD showed that the most frequent plastics identified were mostly polipropilene (38%) and polyethylene (19%). These data are the first information of PD in touristic beaches of the Concepción bay and are also comparable with other studies reported in the scientific literature.

TU062

Mixture of metals in coastal water of Kaldvellfjord, Norway - speciation, bioavailability and uptake in organisms

E. Jarosz, Norwegian University of Life Sciences (NMBU) / Environmental Chemistry; M. Nandrup Pettersen, Norwegian University of Life Sciences NMBU; L. Skipperud, Centre for Environmental Radioactivity - CERAD; R. Wolf, NIVA - Norwegian Institute for Water Research / Section for Ecotoxicology and Risk Assessment; K. Tollefsen, Norwegian Institute for Water Research NIVA / Section for Ecotoxicology and Risk Assessment; H. Teien, Norwegian University of Life Sciences NMBU

Metal rich runoff as a result of deposited iron sulphide-containing bedrock after construction E18 highway in southern Norway entering coastal water in Kaldvellfjord. Thus, aquatic organisms in the costal water were exposed to a number of trace metals. The focus of this study was to identify the interaction of trace elements in mixtures on speciation, bioavailability and on uptake in aquatic organisms in the coastal waters as a function of salinity to improve the risk assessment of Kaldvellfjord. Investigation in Kaldvellfjord demonstrated good correlation between salinity in the surface water and water flow in the river, decreasing during flooding events. Controlled experiment based on mixing runoff water with seawater demonstrated dilution of trace metals, however specific changes in speciation and distribution occurred at increased salinity. Comparison of results with mixing of artificial runoff water containing single metal and mixture of metals demonstrated that the form of metal is different when present alone compared to the mixtures. Thus, metals behave competitively and this affects speciation and the bioavailability. Exposure of fish to the estuarine water demonstrated uptake of several metals. Cumulative risk assessment study, identified aluminum as a main driver in range of several mg/L, however iron (Fe), copper (Cu), nickel (Ni), zinc (Zn) and manganese (Mn) present in the range from 100 to 1500 μg/L were assessed also to have a significant impact on fish and invertebrates. In addition, several rare earth elements from the runoff water was accumulated in fish and assumed to contribute to the cumulative risk.

TU063

Comparison of ASV and ISE methods for predicting Cu bioavailability in seawater

P. Sánchez Marín, Instituto Español de Oceanografia / Ecology and Animal Biology

The bioavailability of dissolved metals is determined by their chemical speciation, in particular on the concentration of free metal ion according to bioavailability models such as the free ion activity model (FIAM) or the biotic ligand model (BLM). In seawater, at constant salinity and pH, the inorganic complexation of divalent metals such as Cu remains constant, and the main factor causing variations in metal speciation is the presence of organic ligands, such as dissolved organic matter (DOM). The two most widely used techniques in Cu bioavailability studies are anodic stripping votammetry (ASV) and potenciometry using Cu^{2+} ion selective electrode (ISE). However, these two techniques do not have the same detection window and have frequently resulted in contrasting results with differences of even several orders of magnitude. This has lead to uncertitude about which technique is giving correct resuls, so that it can be relied on to predict Cu bioavailability in seawater. This presentation will offer a thorough review of the literature about the studies about Cu bioavailability in seawater that have used ASV and/or ISE for the measurement of free or labile Cu, with the aim of compiling evidence about which of the methods works better for the prediction of Cu bioavailability. In addition, some new experimental work will be presented that shows that the results of both methods can be reconciled.

TU064

Possible sources and trophic dynamics of multiple trace metals in coastal food webs from Patagonia and Antarctica

G. Chiang, MERI Foundation / Department of Science; W.E. Espejo, Melimoyu Ecosystem Research Institute / Department of Aquatic Ecosystems; J. Celis, Universidad de concepcion / Departament of Animal Science, Faculty of veterinary science; R. Barra, University of Concepcion / Department of Aquatic Systems; S. Kashiwada, Toyo University / Research Centre for Life and Environmental Sciences; O. Malm, Universidade Federal do Rio de Janeiro / Laboratório de Radioisótopos Eduardo Penna Franca; N. O'Driscoll, Acadia University / Department of Earth and Enviromental Science; K.A. Kidd, McMaster University / Department of Biology and Canadian Rivers Institute

Antarctic coastal biota is diverse, composed mainly of species of molluscs, polychaetes, amphipods, bryozoans, sponges, isopods, crustaceans, ascidians, pycnogonids, fishes, marine mammals and seabirds. On the other hand, food webs in the Patagonian coastal region are even more complex than in the Antarctic, both regions considered pristine ecosystems. There is a lack of information for trace metals fate and effects on those regions of the southern hemisphere. Even more trace metal biomagnification processes in marine food webs in remote/pristine zones in the southeaster Pacific coast, including near Patagonia and in Antarctica are even more scarce. The differences in the composition of the food web structure between Antarctica and Patagonia, along with physical processes and the input of freshwaters to coastal systems might influence trophodynamics of Hg, Cd, Ta, Pb. Most of the scientific research have shown that Hg biomagnifies through food webs and has a positive correlation with higher latitudes. Despite that fact, we showed that freshwater inputs in Patagonia and Antarctica have certain influence on this process, with higher TMS (0.243 and 0.217 respectively) near freshwater outlets (analysing trace metal concentrations vs $d^{15}N$). At the same time other trace metals have been assumed to present similar trophic processes than Hg, but despite evidence shows Cd biomagnifies (TMF, 0.66-2.85), it does only within the macroinvertebrate group in these food webs. When we did include fish in the analysis, we observed a significant dilution of Cd on the higher trophic organisms (TMF −0.81 ± 0.14). Bioaccumulated lead in Patagonian and Antarctica food web have a clear anthropogenic source, since $^{208}Pb/^{207}Pb$ versus $^{206}Pb/^{207}Pb$ signatures differ greatly from the geological background found in the same areas. Even more, trace metals used by industry and exploited far away from the studied sites have been found. Tantalum (Ta) is a Technology-Critical Element (TCE), which we know practically nothing on its fate and possible effects in wildlife. We have shown that there is a trophic transfer of this element with TMS ranging from 0.004to 0.018. All this information has important implications for regulatory purposes, as Patagonia and Antarctica are not regions with industrial development. At the same time these regions are crucial to understand biogeological processes in pristine areas and to assess their possible impacts in wildlife.

TU065

Toxicokinetics and bioacummulation of cadmium and mercury in marine microcrustaceans Artemia sp. and Mysidopsis juniae

.P. Damasceno, Department of Biology & CESAM - University of Aveiro; M. Hortellani, IPEN - Nuclear and Energy Research Institute; J.E. Sarkis, IPEN - Nuclear and Energy Research Institute / Center for Chemical and Environmental Technology; S. Loureiro, University of Aveiro / Biology Department and CESAM; L.V. Lotufo, University of SÃo Paulo USP / Instituto de Ciencias BiomÃdicas

The species used in this study, the marine microcrustaceans *Artemia* sp. and *Mysidopsis juniae* are fairly utilized in Ecotoxicology and they are characterized by low and high sensitivity, respectively, to various contaminant groups. *Artemia* sp. nauplii stage II (48 h old) and juvenile mysids *Mysidopsis juniae* (0-7 days old) were exposed to cadmium (Cd) and mercury (Hg) in water at 50 ɂg Cd.L^{-1} and 5 Ղg Hg.L^{-1} (the mysids No observed effect concentrations (NOEC) for both metals); besides this, mysids were simultaneously exposed to previously contaminated food (Artemia). Organisms were sampled at different time points to determine their internal metal concentration over time. The experiments for *Artemia* sp. and mysids lasted 48 h and 96 h, respectively. The first half time of each species exposure, 24 h for *Artemia* and 48 h for mysids, was considered the uptake phase. At the end of this phase, crustaceans were transported to uncontaminated seawater for the elimination phase outset. An one-compartment model was adopted to describe Cd and Hg kinetics. Bioconcentration factor in *Artemia* sp. nauplii was superior for Cd than Hg. In both species, Cd bioconcentrations decreased at the elimination phase On this phase, Hg concentrations remained stable in *Artemia* sp. and *Mysidopsis juniae*. Accordingly to the bioaccumulation observed, Cd is detoxifiable for both species and Hg was more transferred from Artemia to *Mysidopsis juniae* via food and water than Cd. The results obtained in this study evidenced the high capacity of Hg transference throughout the food chain and its persistence in crustaceans.

TU066

Integrated sediment risk assessment by correlating metal bioaccumulation to DGT passive sampling and varying sediment properties

H. Hetjens, SPHERE / SPHERE; K. de Schamphelaere, University of Antwerp / Department of Biology SPHERE and ECOBE Research Groups; J. Teuchies, E. Amato, L. Bervoets, University of Antwerp / Department of Biology (SPHERE Research Group)

The management and remediation of contaminated sediments is a rather complex subject in which integrated assessment methods have been experienced to be crucial for ensuring a decent balance between reasonable costs and environmental benefits and safety. In this regard, the importance of the actual bioavailability of sediment bound contaminants became more and more apparent during the last decades as highly contaminated sites can be characterized with a low toxic potential due to low ratios of weakly bound or free contaminant fractions. For metals, the analysis of parameters such as pore water concentrations, acid extractable metals (AEM), acid volatile sulphides (AVS) and organic carbon have been experienced to be useful predictors, however with varying effectiveness (especially in more oxidized surface sediments) between the different metals. A promising alternative has been found in passive sampling devices, including Diffusive Gradient in Thin film samplers (DGTs). DGT passive samplers give an indication of metal flux behaviour between the different compartments over time and the concentration of bioavailable metal fractions in the sediment by binding divalent metals, weakly-bound to the sediment or present in the pore water, on a chelex ion-exchange resin. In February and March 2019, a laboratory experiment will be conducted in which the toxic potential of a set of about 20 different natural sediments with known biochemical properties (fresh and brackish) will be tested. This will be done by taking the different indicative parameters into account, including pore water concentrations, AVS, AEM and total metal concentrations. The different parameters will be compared to metal concentrations measured by DGT passive samplers. Furthermore, two mussel species (*Corbicula fluminea* and *Dreissena bugensis*) and two sediment digesting worm species (*Hediste diversicolor* and *Lumbriclulus variegatus*) will be exposed to the sediments over 28d. The former parameters will be compared and correlated to the total metal body burden and mortality of the exposed organisms. The results of this study are expected to increase the insights in metal release behaviour over time, the accumulation of such by benthic organisms, and the ability of DGT passive samplers to predict bioaccumulation concentrations. The study aims at contributing to the improvement of water system management and remediation activities for both freshwater and brackish aquatic systems.

TU067

Biomarkers as indicators of the State of health of Pteria sterna in Ensenada de la Paz, B.C.S. Mexico

M. Olivares Eslava, Universidad Autonoma Metropolitana Iztapalapa; A. Sobrino-Figueroa, Universidad Autonoma Metropolitana, Iztapalapa / Hidrobiology; C. Cáceres-Martínez, Universidad Autónoma de Baja California Sur

The urbanization process of Ensenada de La Paz has increased the contribution of xenobiotics in the coastal zone, causing an increase in the levels of xenobiotics that together with the climatic changes, constitute a risk for the health status of the pearl oyster *Pteria sterna*, resource of great economic importance in this area. In this work an evaluation of the effects of the contaminants present in the cultivation sites, in the health status of *P. sterna* was made by means of the evaluation of biomarkers. Organisms were collected in two locations of Ensenada de la Paz, a site in front of Isla Gaviota (24º17'21.75"N and 110º20'26.9"W) and the other site in the Marina of La Paz (24º09'09.77 " N and 110º19'25.75 "W). 20 organisms were collected from each site during 2 seasons (summer and winter). The condition index was evaluated. The degree of lipoperoxidation (TBARS), the activity of antioxidant enzymes: SOD, CAT, GPx, AChE activity and MN frequency were also determined. The results obtained in the condition index, lipoperoxidation, CAT, AChE and MN in the two sites showed a significant difference ($p < 0.05$). The pearl oysters with the highest growth rate were those of Isla gaviota. A higher degree of lipoperoxidation was observed in the gills of molluscs collected in the Marina. The activity of CAT was greater in these mollusks. AChE activity was lower in pearl oysters of the Marina. The frequency of MN was higher in the pearl oysters of the Marina. The data obtained in the evaluation of lipoperoxidation, AChE, SOD, CAT and MN in *P. sterna* of La Marina could be related to the presence of metals that cause negative effects on their health status.

TU068

Impact of strongly elevated CO2 concentrations on a invertebrate community tested in marine mesocosms

Y. Wei, Wageningen University; L. Plath, Wageningen Marine Research; A. Penning, M. van der Linden, Wageningen University; A. Murk, Wageningen University / Dept of Toxicology; E. Foekema, Wageningen Marine Research

In an effort to reduce harmful emissions and increase energy efficiency, the application of Liquefied Natural Gas (LNG) as fuel for ship engines is being studied in combination with an underwater exhaust system to reduce the ship's water resistance. The exhaust gas from LNG powered ships consists for a substantial part of CO_2, which may significantly increase CO_2 levels in the water around the ship. Most studies on elevated CO_2 concentrations use only moderate CO_2 exposure levels to mimic estimated future global conditions, around 936 ppm in 2100, caused 0.5 units decrease in global average ocean pH. Although the potential impact of underwater exhausted CO_2 is not known yet, it might locally result in higher CO_2 concentrations than usually studied. To gain more insight in the local impact of higher CO_2 concentrations, a benthic mesocosm study was performed under a pH range of 8.6 to 5.8. Community compositions changed with increasing CO_2 concentrations. Benthic polychaetes formed the least sensitive group and were able to take advantage of the reduced competition and became the dominant group at pH levels 7.1 and 6.6. Their larvae dominated the zooplankton community. At the next higher exposure level even the polychaete population collapsed, and a phytoplankton bloom developed probably facilitated by to the lack of grazing and the flux of nutrients from decaying organic material. The periphyton community was not able to take advantage under these conditions. Gastropods that comsuming periphyton suffered directly from higher CO_2 levels as indicated by shell damage, however their growth was not directly related with pH, but was positively correlated with the availability of periphyton. Our study was conducted in relatively small systems without water replacement or exchange, and therefore represents a worst case situation as can occur in an isolated ecosystem. In this situation a clear impact was observed when CO_2 injection resulted in pH levels of 7.1 or lower for 49 days. The impact of underwater release exhaust gasses on the water quality depends on various factors including the local biological and abiotic conditions. This study focused on impact of CO_2 only and future studies will be conducted to gain insight in the impact of other components of actual exhaust gasses. The final goal is to assess the boundaries, where the advantages of underwater exhaust gasses as ship hull lubricant can be applied without negative impact on the marine ecosystem.

TU069
DANUBIUS-RI: Making River-Sea Systems Work
D.A. Vignati, CNRS / LIEC UMR7360; P. Usseglio-Polatera, LIEC Université de Lorraine CNRS; J. Brils, DELTARES; A. Stanica, GeoEcoMar
River-sea systems (RSS) comprise river catchments, estuaries/deltas, lagoons and coastal seas and provide a vast array of valuable services ranging from food supply and flood protection to aesthetic value. Human uses can have several negative impacts on RSS including eutrophication, pollution by microcontaminants, altered river morphology and hydrology, and overall loss of ecosystem services. Our ability to understand and manage such impacts has been constrained by disciplinary boundaries and a lack of interdisciplinary initiatives to undertake, develop and apply the necessary fundamental and integrated research. The International Centre for Advanced Studies on River-Sea Systems (DANUBIUS-RI) will be a pan-European distributed research infrastructure dedicated to supporting interdisciplinary studies of RSS. An associated European Coordination and Support Action project is currently being funded to develop a coherent, effective and relevant scientific agenda for RSS. The DPSIR framework (Drivers, Pressures, State Changes, Impact and Human Response) has been used to identify overarching challenges that the research community will have to address to ensure that RSS remain functional over a long period. Climate change and extreme events along with activities linked to basic human needs and societal functioning (e.g., fisheries, transport, agriculture, power generation, tourism, urbanisation) were identified as key drivers in determining the various pressures affecting RSS and the associated state changes, impacts and possible human responses. Based on the complex network of relationships and feedbacks identified by the DPSIR approach, four overarching challenges in making (or maintaining) RSS functions have been identified: climate change, water sufficiency, sediments and their management, and ecosystem health. This scientifically and societally relevant general framework will allow definition of research questions, needs and practical aspects for preserving RSS and the services they provide.

Fish Model Species in Human and Environmental Toxicology (P)

The fish embryo toxicity test under flow-through conditions - development of a biowellplate for whole-organism bioassays
L. Nuesser, RWTH Aachen University, Institute for Environmental Research / Department of Ecosystem Analysis; E.M. Wielhouwer, Syntecnos Screening Technologies BV; C. Neuser, RWTH Aachen University / Ecosystem Analysis; T. Kouts, Tallinn University of Technology Tartu College; H. Hollert, RWTH Aachen University / Institute for Environmental Research; T. Seiler, RWTH Aachen University / Ecosystem Analysis
Whole-organism bioassays have become important methods in compliance testing of industrial chemicals and plant protection products, but also in the assessment of environmental quality. With few exceptions, these systems are discontinuous. They require exposure in small units, such as multiwell plates, for prolonged incubation periods. Flow-through conditions with a constant renewal of the exposure medium improve the stability of compound concentrations and can also improve the applicability of whole-organism bioassays in large-scale study designs. This study introduces a biowellplate (BWP) designed for the incubation of organisms under flow-through conditions in a multiwell plate format. The BWP was utilized to perform prolonged fish embryo toxicity tests (FET) with zebrafish (*Danio rerio*) embryos. The BWP was CNC-milled from PMMA plates. The design includes 8 single wells with dimensions comparable to standard wells of a 96 well plate. At the bottom side, each well is connected via two bypass channels to an individual inlet port that provides a continuous flow of fresh exposure medium. The wells are enclosed by a temperature channel that provides continuous circulation of warm water through the plate for optimal temperature conditions.The BWP bottom side is sealed to the middle side and the top side is manually closed by a silicon polymer sheet. The BWP was assembled in a customized housing case that can hold all parts necessary for the operation of the BWP and evaluation of the testorganisms. Preliminary tests found the BWP to be tigth and suitable for the utilization of zebrafish embryos for prolonged incubation periods. In a first proof of concept study the functionality of the system under permanent operation will be tested. Initial pretests will test for the optimal flow-rate, which was defined as the maximum medium exchange rate at which zebrafish embryos develop normally until 119 hours post fertilization. After optimization of the setup and configurations, prolonged fish embryo toxicity tests with zebrafish embryos and a set of well described chemicals will be conducted. This will allow for an evaluation of the BWP's performance in comparison to standardized protocols for whole organism bioassays. In this study, we present a novel layout and setup for a multiwellplate that allows for the prolonged incubation of fish embryos under flow-through conditions that also provides wells large enough to conduct behavioral assays with hatched embryos.

TU071
Three- and four-ring PAHs differentially modify ventricular action potentials and ion currents of rainbow trout (Oncorhynchus mykiss) heart
E. Vehniäinen, University of Jyvaskyla / Department of Biological and Environmental Science; J. Haverinen, M. Vornanen, University of Eastern Finland
Polycyclic aromatic hydrocarbons (PAHs) are contaminants that occur frequently in aquatic environments. They have been shown to affect the development and function of the heart in fish. We studied the effects of two three-ring PAHs, phenanthrene and retene, and two four-ring PAHs, pyrene and fluoranthene, on the electrical characteristics of rainbow trout (*Oncorhynchus mykiss*) ventricular cardiomyocytes. Effects on cardiac action potential (AP), and sarcolemmal sodium (I_{Na}), calcium (I_{Ca}) and potassium (I_{Kr} and I_{K1}) currents were studied by whole-cell patch-clamp method. The effects on AP and ion currents varied between compounds, and our results suggest there may be differences between species as well, as in rainbow trout phenanthrene had no effect on AP duration. All studied compounds inhibited I_{Kr}, and they therefore may have the potential of causing bradycardia and arrhythmias in rainbow trout heart. This means that in addition to petrogenic mixtures, also pyrogenic mixtures with high concentrations of pyrene and fluoranthene may disrupt cardiac function in fish. Retene is an AhR agonist, and besides this transcriptomic mechanism of toxicity, it may be cardiotoxic by a direct effect on cardiac ion channels.

TU072
Tissue-specific gene expression of CYP1A1, 3A27 and 3A45 in juvenile rainbow trout
V. Burkina, University of South Bohemia in Ceske Budejovice / Faculty of Fisheries and Protection of Waters South Bohemian Research Center of Aquaculture and Biodiversity of Hydrocenoses Vodnany Czech Republic; M.K. Rasmussen, Aarhus University / Department of Food Science; V. Zlabek, University of South Bohemia in Ceske Budejovice / Faculty of Fisheries and Protection of Waters, LECHB; G. Zamaratskaia, Swedish University of Agricultural Sciences / Department of Food Science
Anthropogenic activity results in continuous exposure of aquatic organisms to low doses of biologically active compounds in natural ecosystems. The Cytochrome P450s (CYP) are an important family of enzymes, with the main function to catalyse reactions involved in oxidative metabolism of endogenous and exogenous compounds. Some of the piscine CYP genes are well characterized, however little is known with respect to their importance. In the present study we examined the expression of three CYP genes, CYP1A, CYP3A27 and CYP3A45 in six rainbow trout tissues: hepatic, gill, intestine, brain, heart and gonad. The mRNA was expressed in all investigated tissues. The CYP1A1 mRNA expression was highest in the liver and gonads. Interestingly, tissue-related expression pattern differed between CYP3A27 and CYP3A45, with CYP3A27 highly expressed in the liver, heart and gonads compared to CYP3A45. For CYP3A45, brain tissue had the highest expression of CYP3A45, among all selected genes. These differences might be related to the physiological function of the specific CYP isoforms in the tissue. Further studies are needed to determine the significance of the observed tissue-specific expression pattern of the investigated CYPs, and how this relates to detoxification of environmental pollutants. ***Keywords:*** cytochromes, detoxification, gene expression, *Onchorincus mykiss* Acknowledgement - The study was financially supported by the Ministry of Education, Youth and Sports of the Czech Republic - projects „CENAKVA "(No. CZ.1.05/2.1.00/01.0024), "CENAKVA Center Development "(No. CZ.1.05/2.1.00/19.0380), "CENAKVA II "(No. LO1205 under the NPU I program), and "Development of USB - International mobility (No. CZ.02.2.69/0.0/0.0/16_027/0008364).

The growing number of emerging chemical contaminants is becoming an increasing concern to water managers due to their potential toxicity to non-target organisms, pseudo-persistence and discharge into surface water systems. The main issue with current approaches to testing the risks these chemicals may pose to human or wildlife is that they rely on live animal testing that is expensive, time consuming and of ethical concern. A promising concept to address this issue is the investigation of the mode of action of a chemical to predict an apical outcome of regulatory relevance; however, there is a need to calibrate and validate this approach by conclusively linking this mechanistic information to toxic outcomes. This study applied a trans-omics approach that aimed to link changes at the gene expression level through multiple organizational levels to physiological and apical changes using 17α-ethinylestradiol (EE2) as the model compound and fathead minnow (FHM) as the model organism. Specifically, FHMs were exposed to 4, 20 and 100 ng/L EE2 from freshly fertilized eggs to the early juvenile stage. Subsamples of FHM embryos were collected 4-days post hatch (dph) for transcriptomic, proteomic and metabolomic analyses, and the rest of the embryos were continuously exposed to EE2 until 28 dph for histological and apical outcome examination. Genes and proteins associated with coagulation, a variety of protein processing and metabolic processes, and necrosis were significantly dysregulated. Gene set enrichment and pathway analyses (GSEA) at the transcriptome and proteome levels showed a number of common overrepresentations corresponding to observed apical outcomes. For instance, EE2 significantly induced vitellogenin (VTG) gene expression, with a complementary induction of VTG isoforms at the proteome level. Histological observations of the liver showed damages that may be linked to overrepresented gene ontologies and pathways such as increased hepatocyte basophilia and the abundance of eosinophilic proteinaceous fluid within the sinusoids which are known responses to estrogen-induced upregulation of VTG, as well as the absence of glycogen-type vacuolation due to increased energy demand. Results suggest trans-omics analyses is a powerful tool in furthering our understanding and predicting phenotypic responses of contaminants. The results of this study contribute towards the realization of the EcoToxChip: a toxicogenomics tool for chemical prioritization and environmental management (www.ecotoxchip.ca).

TU074
Aryl Hydrocarbon Receptor-Mediated Effects of Dioxins on Liver in Zebrafish Embryos
L. Yan, University of Applied Sciences Northwestern Switzerland / School of Life Sciences; A. Zenker, University of Appl. Sc. Northwestern Switzerland / Institute of Ecopreneurship; L. Suter-Dick, University of Applied Sciences Northwestern Switzerland / School of Life Sciences
Exposure to dioxins and dioxin-like compounds, a series of widespread environmental contaminants, could cause adverse health effects, including hormonal problems, infertility and cancer. Increasing evidence suggests that dioxins induce liver damage mediated by aryl hydrocarbon receptor (AhR) signalling. However, limited in vivo and in vitro platforms (with the advantage of time-efficient and cost saving) exist to assess the liver damage by dioxins. Here, we used zebrafish embryos to demonstrate adverse impacts of dioxins on the liver, and explore the relationship between liver damage and AhR signalling. Zebrafish embryos were exposed to the hepatotoxic reference compound-Thioacetamide (TAA) and to three typical dioxin and dioxins-like compounds (Benzo[a]pyrene(BaP); 2,3,7,8-Tetrachlorodibenzo-para-dioxin and PCB126). Histopathology revealed compound and life-stage-specific effects indicative of toxic injury in the livers of zebrafish larvae. Quantitative PCR was used to compare gene expressions related to AhR and liver damage. Using histology analysis, it was observed that low concentrations of BaP could induce liver damage in zebrafish embryos. CYP1A (involved in AhR activation) gene expression was significantly up-regulated in response to the three dioxin treatments; whereas with TAA treatment eliciting acta2 (involved in liver fibrosis) gene expression decreased. The zebrafish embryo model combined with histology and gene markers could be an alternative method to assess the toxicity of dioxins.

Concerns for Di-isononyl phthalate contaminated diet in marine fish: focus on the effects on both the hepatic lipid metabolism and the muscle proteolysis of male gilthead sea bream (Spaurus aurata)
F. Maradonna, I. Forner-Piquer, G. Gioacchini, D. Basili, Università Politecnica delle Marche / Department of Life and Environmental Sciences; C. Mylonas, Hellenic Center for Marine Research / Institute of Marine Biology, Biotechnology and Aquaculture; J. Calduch-Giner, J. Pérez-Sánchez, Institute of Aquaculture Torre de la Sal (IATS-CSIC) / Nutrigenomics and Fish Endocrinology Group; O. Carnevali, Università Politecnica delle Marche / Department of Life and Environmental Sciences
Many chemical compounds used in the production of plastics and resins have the ability to interact with the endocrine system, acting as Endocrine Disrupting Chemicals (EDCs) and thus representing a high-priority research area. In the present study, we analysed the effects of a dietary administration of a common plastic additive tDi-isononyl phthalate (DiNP) on fish physiology metabolism. DiNP was administered for 21 days via the diet (4 and 4000 μg DiNP/kg body weight/day) to adult male gilthead sea bream (*Sparus aurata*), to assess its effects on the hepatic lipid metabolism and muscle proteolysis. Our findings showed the ability of DiNP to alter the hepatic structure and its biochemical composition, as well as modulating the expression level of genes involved in lipid biosynthesis and endocannabinoid metabolism. In addition, since gilthead sea bream represents one of the most valuable species by consumers, given its fillet quality and nutritional properties, changes induced by DiNP exposure on muscle macromolecular structure and its ability to disrupt the proteolytic system were investigated. Results showed that DiNP could substantially change muscle composition and affect fillet tenderization. These results provide a macromolecular fingerprint of the liver and the muscle of fish fed with DiNP and highlight the negative effects of contaminated diet on physiology and metabolism, contributing to assess the potential ecological impact of emerging pollutants in the aquatic ecosystems and their effects on marine food resources. In addition, the results may suggest a set of biomarkers as possible innovative endpoints for the development of novel OEDCS test guidelines.

Tissue Metal Concentrations and Anti-oxidant Enzyme Activity in Atlantic Sharpnose Shark
G.K. Bielmyer-Fraser, Jacksonville University / Chemistry; R. Somerville, Jacksonville University / Marine Science; J. Gelsleichter, S.L. Ehnert, University of North Florida / Biology
Metals occur naturally in the environment; however, anthropogenic practices have resulted in increased metal concentrations in sediments, waterways, and biota. Sharks are important species, both recreationally and commercially. Quantifying tissue metal concentrations in these organisms may reflect metal transfer in aquatic food webs. Extensive research has been conducted on mercury toxicity in sharks; however, reference levels of other metals have not been established in many species. In this study, concentrations of nickel, copper, lead, cadmium, selenium, silver, zinc, and aluminum were measured in the muscle tissue of *Rhizoprionodon terraenovae* (Atlantic sharpnose shark), collected from Virginia to Texas. A total of 165 samples were analyzed for correlations among metals, size/age, gender, and location of capture. Muscle samples were also analyzed for anti-oxidant enzyme activity, and results were correlated with metal concentrations. With the exception of mercury, there are no published data on tissue metal concentrations within this species along the eastern United States. This study provides reference levels of metal contaminants in the muscle tissue of Atlantic sharpnose sharks and provides insight into metal accumulation in this higher-level carnivore.

TU077
Action of two commercial insecticides phenylpyrazole (fipronil and ethiprole) on the levels of lipid peroxidation in livers of Oreochromis niloticus
T.A. Guedes, Sao Paulo State University - UNESP / Departamento De Biologia; J. Evangelista Correia, Unesp - Institute of Biology / Biology; A. Marcato, Sao Paulo State University - UNESP / Department of Biology; A.A. Alves, Centro Universitário da Fundação Hermínio Ometto - FHO; C.S. Fontanetti, Sao Paulo State University - UNESP / Biology
Consumers have never been so concerned about the environment. This social pressure coupled with the efforts of the scientific community to bring to light the deleterious effects of the old and massively used pesticides can cause human health and the environment has motivated the agrochemical industry to manufacture products that are less harmful without losing effectiveness. This is the case of the insecticide ethiprole, produced with the intention of being less toxic than its analogue fipronil. Reactive oxygen species (ROS) are produced from oxidation, a fundamental part of cellular metabolism. When in excess, ROS have harmful effects, such as lipid peroxidation - a process that can cause damage to several cell types. Malondialdehyde (MDA) is one of the most important intermediates during lipid peroxidation, through which it is possible to stipulate levels of lipid peroxidation in an organism. For this reason, this study had as objective to compare the action of these compounds in the levels of lipid peroxidation in liver of fish of the species *Oreochromis niloticus*. For this, a reassessment bioassay was performed, consisting of a control group, with fish exposure to clean water, and different concentrations of two commercial products - the first containing 20% ethiprole (0.1, 0.05 and 0.025 µl / l) and the second containing 80% fipronil (0.1, 0.05 and 0.025 mg / l). The results showed a small increase in MDA levels in all treatments when compared to the control, being more expressive in the highest concentrations of both commercial products; however, this increase was not statistically significant. According to the results presented here, it is evident that the tested concentrations of both commercial products studied did not significantly affect the levels of lipid peroxidation of the studied specimens.

TU078
In vivo measurement of 7-methoxycoumarin-O-demethylase activity in zebrafish (Danio rerio) embryos
A. Lörracher, COS University of Heidelberg / Aquatic Ecology and Toxicology; M. Grethlein, COS University of Heidelberg; T. Braunbeck, COS University of Heidelberg / Aquatic Ecology and Toxicology
Early life stages of zebrafish (*Danio rerio)* are frequently used as alternative

model organism in (eco)toxicological and pharmacological research. Biotransformation turned out to play a critical role for the assessment of teratogenic or toxic potencies of xenobiotics. However, little is known about biotransformation capacities in early life stages of zebrafish. Since quantitative and qualitative differences in biotransformation capacities between distinct developmental stages might lead to an over- or underestimation of toxic or teratogenic potentials of chemicals, a thorough characterization of the intrinsic biotransformation capacity is imperative for a correct interpretation of toxicological data. While spatial and temporal expression patterns of xenobiotic metabolizing enzymes (e.g. cytochrome P450-dependent monooxygenases, CYPs) have previously been investigated at the genome and RNA level, only little is known about protein function or catalytic activities. Consequently, this study was designed to systematically investigate functional CYP-dependent biotransformation activities throughout early zebrafish development. To determine the constitutive spatio-temporal activity pattern and inducibility of CYP-dependent activity, zebrafish embryos (5.5 - 120 hours post-fertilization, hpf) were assessed for *in vivo* 7-methoxycoumarin-*O*-demethylase (MCOD) activity, a CYP2-dependent process in mammals. Results demonstrate that zebrafish embryos display constitutive and inducible CYP2-dependent biotransformation activity from 5.5 hpf onwards. MCOD activity appeared in a dynamic spatio-temporal pattern with activities localized in several tissues and organs (e.g. cardiovascular system, urinary tract, digestive system). In addition, pulse exposure to β-naphthoflavone (aryl hydrocarbon receptor agonist) resulted in a significant increase in MCOD activity. Results clearly indicate biotransformation capacities in zebrafish from very early stages of embryological development. This study was funded by the Ministry for Science, Research and Arts (MWK) Baden - Württemberg.

Assessing the Photoactivity of Polycyclic Aromatic Hydrocarbons (PAHs) in the Presence of TiO2 Nanoparticles

L. St Mary, Heriot-Watt University / EGIS; T. Henry, Heriot-Watt University / The School of Energy, Geoscience, Infrastructure and Society; M.R. McCoustra, Heriot Watt University / School of Engineering Physical Sciences

Polycyclic aromatic hydrocarbons (PAHs) are a class of persistent environmental contaminants with diverse physicochemistry and toxicity. In contaminated aquatic environments, PAHs frequently accumulate in sediments or are sorbed to particulates in the aqueous phase. Certain PAHs are photoactive and have photo-induced toxicity, but little is known about interactions between PAH photoactivity, sorption, environmental fate, and toxicology. Engineered nanoparticles (NPs) can behave as particle agglomerates that participate in sorption/desorption reactions in the aqueous phase, and some NPs (e.g., TiO_2-NPs) also have photoactivity. Aqueous-phase interactions between PAHs and TiO_2-NPs are of interest because they are becoming more environmentally relevant (i.e., as NPs are increasingly released into the environment), and because investigations of sorption/desorption processes, in the context of photoactivation, can provide important new information on physicochemistry of both PAHs and NPs. Our objective is to investigate PAH/TiO_2-NP interactions under UVA irradiation and determine formation of PAH photoactivated by-products (e.g., oxidized polycyclic aromatic hydrocarbons (OPAHs) and their bioactivity. Various combinations of PAH/TiO_2-NP preparations were exposed to UVA, and changes in gene expression of genes involved in Phase I metabolism (cytochrome P450 *cyp1a1* etc.) and Phase II metabolism (epoxide hydrolases *ephx1* and *ephx2* etc.) in early life stages of zebrafish were assessed over time. These data have shown significant induction of *cyp1a*, *ephx1*, *ephx2*, and *sod1* genes in larvae exposed to irradiated PAH/TiO_2-NP solutions, specifically anthracene, benzo[a]pyrene, and fluoranthene, compared to irradiated PAH solutions. Gene expression among the five different PAHs exhibited PAH specific patterns of induction, with phenanthrene and pyrene having little to no amount of gene induction of any of the genes assessed, even in the presence of TiO_2-NPs. Additionally, gas chromatography-mass spectrometry (GC-MS) will be used to identify and quantify photoactivated PAH by-products at specific time points to further support these gene expression data. The exploitation of biological responses and analytical chemistry to investigate changes in PAH physicochemistry and PAH/TiO_2-NP interactions processes will provide novel insight into these processes tested directly within the environmentally relevant concentrations and aqueous phase.

Functions of thioredoxin1 in brain development and in response to environmental chemicals in zebrafish embryos

l. Yang, Chinese Research Academy of Environmental Sciences; M. Takamiya, KIT Karlsruhe Institute of Technology / Institute of Toxicology and Genetics; U. Strähle, KIT Karlsruhe Institute of Technology / ITG Institute of Toxicology and Genetics

Thioredoxin is an evolutionarily conserved antioxidant protein and plays a crucial role for fundamental cellular processes including metabolism, proliferation, differentiation and apoptosis. Growing evidence supports that Thioredoxin has essential functions in the embryonic development and has an influence on cellular response to chemicals insults, particularly those accompanying oxidative stress. We report here that *thioredoxin1* becomes differentially expressed in zebrafish embryos after the exposure to 9 out of 11 environmental toxicants. Changes in *thioredoxin1* mRNA levels were observed at low chemicals concentrations that did not cause morphological defects. *In situ* gene expression analysis showed that *thioredoxin1* was expressed in neurons such as Mauthner and serotonergic Raphe cells, olfactory epithelia, liver and swim bladder under normal conditions. After methylmercury exposure, however, *thioredoxin1* was ectopically induced in the hair cells of the lateral line and in epithelia of the pharynx. Knockdown of thioredoxin1 by antisense morpholinos induced hydrocephalus, concomitant with apoptosis in the brain ventricular epithelium, and exacerbated the toxic effects induced by methylmercury exposure. This study represents the association between hydrocephalus and Thioredoxin1 malfunction in embryonic development and provides valuable information to elucidate the protective role of Thioredoxin1 against chemicals disruption.

Effects of metazachlor and their main metabolite metazachlor OA on early life stages of marbled crayfish (Procambarus fallax)

J. Velisek, A. Stara, E. Zuskova, J. Kubec, M. Buric, University of South Bohemia in Ceske Budejovice / Faculty of Fisheries and Protection of Waters, South Bohemian Research Center of Aquaculture and Biodiversity of Hydrocenoses; A. Kouba, University of South Bohemia in Ceske Budejovice / TFaculty of Fisheries and Protection of Waters, South Bohemian Research Center of Aquaculture and Biodiversity of Hydrocenoses

Growing production of energy crops (mainly maize and rapeseed) in Europe, replacing traditional crops such as grain, have significantly changed patterns of pesticides utilization during the last decades. Chloroacetanilide herbicides are a relatively old class of preemergence herbicides for selective weed control in various field crops. The relatively high water solubility of these chemicals makes them potentially mobile in soil and water. Contamination of aquatic ecosystem by herbicides has become a pressing environmental problem all over the world. The effect of early life stages of marbled crayfish (*Procambarus fallax*) to chronic exposure of metazachlor in concentrations 3.2 μg/L, 22 μg/L (max. real environmental concentration), and metazachlor OA in concentrations 3.2 μg/L (real concentration), and 22 μg/L was evaluated under laboratory conditions. The effects were assessed on the basis of mortality, behavior, growth, development, oxidative stress, antioxidant biomarkers and histopathology. Metazachlor and metazachlor OA in all tested concentrations caused significantly higher mortality, lower growth, delay in ontogenetic development, increased of total distance moved and walking speed of crayfish. Moreover, both tested substances in all concentrations caused changes in antioxidant biomarkers (decrease activity of superoxide dismutase, catalase and glutathione s-transferase) and caused alteration of hepatopancreas and gills of crayfish. In conclusion, this study shows potential risk of metazachlor and their main metabolite metazachlor OA on early life stages of crayfish. *The study was financially supported by the MSMT projects CENAKVA (No. CZ.1.05/2.1.00/01.0024) and CENAKVA II (No. LO1205 under the NPU I program) and project GACR no. 18-03712S.*

Physiological responses of zebrafish Danio rerio to emerging pollutants

A. Sobrino-Figueroa, Universidad Autonoma Metropolitana, Iztapalapa / Hidrobiology; L.I. Ruiz-Narváez, Universidad Autonoma Metropolitana Iztapalapa / Hidrobiologia; A. Perez-Rojas, Universidad Autonoma Metropolitana Iztapalapa / Limnology and geology. D Laboratory. Department of Hydrobiology

Emerging Contaminants are chemical, pharmaceutical and mainly personal care products, which have been found in concentrations of 0.001 to 500 mg in the waters of treatment plants and in natural systems. There is limited information of the effects of these pollutants on the organisms that inhabit the aquatic systems, for this reason, in this study the effects in physiological rates and biomarkers, (oxidative stress, neurotoxicity and genotoxicity) of 2 liquid detergents (Ariel and Mas Color) and 2 softeners for clothes (Downy and Suavitel) were evaluated in the zebrafish *Danio rerio*. Bioassays were carried out with a duration of 15 days where zebrafish adults were exposed to a sublethal concentration (1 mg L^{-1}) of detergents and softeners. At the end of the exposure period, the growth rate, the respiration rate and the O: N index were evaluated. The degree of lipoperoxidation (Tbars), the activity of the enzyme Acetylcholinesterase (AchE) and the genetic damage (frequency of micronuclei) were also determined. In the results obtained it was observed that there are significant differences in the physiological rates of the exposed organisms compared to the control group. The growth rate of organisms exposed to detergents was the lowest. The values of the O:N index varied from 25 to 8 in the fish exposed to detergents and softeners. The most toxic products were the Ariel detergent and the Suavitel softener, the same products were the highest oxidizing effect (4.54 and 3.13 nM Tbars mg^{-1} respectively). In the tests with detergents a decrease of between 12 to 27% of the activity of the enzyme AchE was observed. In the evaluation of genotoxicity, a greater number of micronuclei was observed in the fish exposed to the Ariel detergent (8.2%) and in the Suavitel product (4.1%). The results indicated that all tested products caused deleterious effects on fish in sublethal concentrations.

TU083

Long-term effect of S-metolachlor and metolachlor OA on marbled crayfish
A. Stara, University of South Bohemia in Ceske Budejovice / Faculty of Fisheries and Protection of Waters, South Bohemian Research Center of Aquaculture and Biodiversity of Hydrocenoses
Various pesticides are being used intensively in agriculture and affect almost every system of environment especially aquatic ecosystems and causing risk hazards for aquatic flora and fauna, as well as their residues. They enter in non-targeted animals via food chain threatening the ecological balance and biodiversity of the nature. Long-term exposure of pesticides can induces behaviour, biochemical changes, oxidative stress, histopathological damages, etc. This study evaluates selected parameters during long-term effects of S-metolachlor (S-M) and its metabolite metolachlor OA (M-OA) at concentrations of 4.2 μg/L (environmental concentrations) and 42 μg/L (ten times higher environmental concentrations) for each of them on marbled crayfish (*Procambarus fallax* f. *virginalis*). The samples of crayfish were sampled on day 14, 28 exposure and after another 28-day for recovery period in S-M and M-OA-free water under laboratory conditions. This study shows that 14 and 28 days exposure to S-M and M-OA caused significant changes ($P < 0.01$) in biochemical haemolymph profile (lactate, alanine aminotransferase, aspartate aminotransferase, inorganic phosphate); lipid peroxidation in hepatopancreas; affected antioxidant parameters (catalase, reduced glutathione, glutathione S-transferase) of hepatopancreas and gill which have not been stabilized even after 28 days of recovery of crayfish. As well as rapid lower movement and activity, and histopathology damage of gills and hepatopancreas due to exposure were persisted in crayfish even after being kept in recovery period 28 days respect to control. The data obtained provides a number of data on the harmful effects of S-M and metabolite M-OA on non-target organisms, naturally occurring in the environment. And it provides further information for assessing the hazards of these substances. *The study was financially supported by the MSMT projects CENAKVA (No. CZ.1.05/2.1.00/01.0024) and CENAKVA II (No. LO1205 under the NPU I program), project GACR no. 18-03712S, and project Development of University of South Bohemia: International Mobility MSCA IF (No. CZ.02.2.69/0.0/0.0/17_050/0008486).*

Identification of molecular mechanisms behind increased locomotor response in zebrafish larvae exposed to a human relevant POPs mixture and PFOS.
M. Christou, Norwegian University of Life Sciences (NMBU) / Production Animal Clinical Sciences; T. Fraser, Norwegian University of Life Sciences NMBU / Production Animal Clinical Sciences; J. Kamstra, Norwegian University of Life Sciences NMBU / Basic Science and Aquatic Medicine; E. Ropstad, NMBU-School of Veterinary Science / Department of Production Animal Clinical Sciences
Previously, we observed behavioural effects in zebrafish larvae exposed to a mixture of persistent organic pollutants (POPs) based on average blood levels from the Scandinavian population. This POPs mixture contains 29 chlorinated, brominated and perfluorinated compounds and we identified PFOS as the compound driving the behavioural changes. To further understand the molecular mechanisms behind these effects we exposed zebrafish larvae from the blastula stage until 96 hpf to the POPs mixture or PFOS only. We validated our previous results by performing locomotor behavioural tests on 96 hpf larvae that were exposed to two levels (10x and 70x higher than what is found in human blood), to either the POPs mixture or PFOS only. In order to identify molecular mechanisms we performed RNA sequencing analysis on 96 hpf larvae. Results showed that larvae exposed for 96 hours to the highest concentrations of POPs and PFOS showed hyperactivity in terms of swimming speed. Transcriptomic analysis showed upregulation of genes such as myh4, myh7, myl7, tnnc1, tnni2 and tnnt2, which play a functional role in muscle contraction. Muscle contraction is highly regulated by the availability of calcium in the sarcoplasmic reticulum. Ingenuity pathway analysis showed that one of the affected pathways in larvae exposed to the POPs mixture and PFOS was calcium signaling via the activation of the ryanodine (RyR) receptors. Previous studies have shown that POPs bind and activate different ryanodine receptor (RyR) isoforms increasing the calcium release. Thus, the observed hyperactivity of larval zebrafish we observed in the locomotor test might be linked to increased availability of calcium, which leads to increased muscle contraction. Functional studies with Ryr inhibitors will be performed to substantiate these findings. We also found effect on lipid metabolism in those larvae exposed to the lower concentration of PFOS. Affected pathways indicate downregulation of lipid metabolism in terms of synthesis of lipid, fatty acid metabolism and lower uptake of lipid among others. Lipidomics analysis is being carried out to investigate the effects of POPs mixture and PFOS single exposure on the lipid contents of larval zebrafish. By using omics technology, we observed that the altered behavioral pattern in exposed zebrafish larvae seems to be controlled directly by mechanisms affecting muscle function rather than from mechanisms connected to neurotoxicity.

TU085
Effect directed analysis (EDA) of neuroactive substances in WWTP effluent using Danio rerio embryos and behavioural assays
R. Massei, Helmholtz Centre for Environmental Research UFZ; M. Krauss, W. Brack, Helmholtz Centre for Environmental Research UFZ / Effect-Directed Analysis
In the last years, neuroactive compounds became an emerging issue for human and aquatic life. In a recent study on EU rivers basins, 13% of the detected compounds were classified as neuroactive making neurotoxicity one of the major modes of action (MoA) identified in environmental samples. Despite their potential threat for the aquatic ecosystem, there is still lack of methodologies for the identification of neurotoxicity in environmental samples. Moreover, chemicals are normally present in complex mixtures in the environment resulting in unpredictable outcomes in case of their interactions. However, effect directed analysis (EDA) with a combination of fractionation, chemical analysis and bio testing can identify masking effects and reveal the presence of primarily causative chemicals. In this study, we proposed a workflow for the identification of potential neuroactive substances using *Danio rerio* embryos in a 96 hours test. Water extracts were collected downstream of the waste water treatment plant (WWTP) of Bitterfeld (Germany) using on-site large volume solid phase extraction (LV SPE). Chemical analyses were performed using an LC-RMS with a wide list of possible active target chemicals (580). The sample was subsequently fractionated using a reversed phase semi-preparative C18 column and 20 fractions were collected. In order to identify potentially neuroactive substances, we analysed the embryos behavioural pattern under light/dark conditions. Moreover, we analysed the inhibition of the acetylcholinesterase (AchE) to identify possible organophosphates and carbamates. Preliminary results confirmed the presence of 21 neuroactive chemicals. The 96 hours old embryos showed an increase of the light sensitivity at low concentrations (relative enrichment factor (REF) of 1) followed by a progressive decrease of the locomotion in parallel with increasing concentrations. Moreover, we identified 3 active fractions characterized by hyperactivity and hypoactivity. A common loop diuretic (furosemide) was detected in the fraction which caused hyperactivity while the antidepressant amitriptyline was detected in the fraction generating hypoactivity. Overall, preliminary results confirmed the suitability of Danio rerio embryos for the identification of neuroactive compounds in complex mixtures.

TU086
Assessment of neurotoxicity and oxidative-stress markers in seabass exposed to emerging compounds
s. larroze, I. Pimparel, AquaBioTech Group; T. Teixeira, AquaBioTech Group / Research and Development; C. Gastão, AquaBioTech Group; T. Oliveira, F. Maia, Smallmatek - Small Materials and Technologies, Lda.; J. Tedim, University of Aveiro / Department of Materials and Ceramic Engineering & CICECO; A.M. Soares, University of Aveiro / department of Biology & CESAM; S. Loureiro, Universidade de Aveiro / Biology; R. Martins, Department of Biology, University of Aveiro / department of Biology & CESAM
Nanomaterials and a wide-range of biocides have been regarded as emerging contaminants receiving a remarkable scientific attention in the last decade, particularly in terms of their sub-cellular effects. Biomarkers of effect indicate an early biochemical response that has occurred following exposure of an organism to a contaminant. Oxidative stress and neurotoxicity play an important role in the intracellular biochemical imbalance that can ultimately lead to cellular death. For instance, increase of lipid peroxidation (LPO) levels can indicate oxidative degradation of cell membrane lipids caused by free radicals and reactive oxygen species; changes in enzymatic activities (e.g. catalase (CAT) or glutathione-S-transferases (GSTs) can signalize an impairment of the antioxidant system or in regular biotransformation intracellular mechanisms; inhibition of acetylcholinesterase activity indicates a neurotransmission impairment. The aim of this study was to assess biochemical changes of new or emerging contaminants such as nanostructured materials and biopesticides in marine fish, at sub lethal levels. Juvenile *Dicentrarchus labrax* were exposed to the biopesticides (*Quillaja* saponins at 0.017-4 mg/L), unloaded anionic nanoclays (Zn-Al layered double hydroxides; LDH at 0.11-9 mg/L) and a novel protein adsorption inhibitor (0.03-7.3 mg/L). Individualswere sub-chronically exposed to each chemical for 14 days,following the OECD guideline 204, under semi-static conditions. Range-finding tests were previously performed using acute toxicity tests with *D. labrax* or with embryos of *Sparus aurata.* At the end of the exposure liver samples were used to spectrophotometrically determine protein and LPO levels and to measure GSTs, CAT and AChE activities. Exposure to *Quillaja* saponins and the protein adsorption inhibitor induced significant biochemical changes, however no neurotoxic effects were observed. Saponins induced oxidative stress and activated the detoxification system (LOEC=1.3 mg/L) while CAT was inhibited at lower exposure concentrations (LOEC=0.4 mg/L). Very low exposure concentrations of protein adsorption inhibitor induced oxidative stress and inhibited CAT (LOEC=0.09 mg/L) and promoted an increase of GST at 0.03 mg/L. Finally, Zn-Al LDH exposure caused no significant changes in the tested endpoints. In conclusion, this research confirms that the quantification of biomarkers of effect is a good tool to assess toxicity effects at sublethal levels of chemicals.

TU087
Investigating the effects of nonsteroidal anti-inflammatory drugs (NSAIDs) on sex differentiation in zebrafish
C. Bereketoglu, A. Pradhan, P. Olsson, Orebro University / The Life Science

Center-Biology
Nonsteroidal anti-inflammatory drugs (NSAIDs) are extensively used for their analgesic and anti-inflammatory properties. Due to their high usage, they are continuously being released into the environment. NSAIDs can be toxic even at low concentrations and many of their effects are thought to result from their ability to inhibit cyclooxygenase enzymes (COX-1 and/or COX-2) that causes decreased synthesis of prostaglandins. Prostaglandins, in turn, are involved in several physiological functions, such as cell survival, apoptosis and regulation of the mammalian sexual behavior. The aim of the present study was to examine the possible effects of NSAIDs on zebrafish gonad differentiation, since NSAIDs inhibit the rate-limiting cyclooxygenases enzymes in prostaglandin synthesis. The NSAIDs in the present study were selected based on their COX selectivity (COX-1 selective: acetylsalicylic acid, ketoprofen; COX-2 selective: nimesulide, celecoxib; non-selective: indomethacin, naproxen, ibuprofen). Wild-type and the vas::EGFP transgene juvenile zebrafish were exposed to 100 μg/L NSAIDs in crystallization dishes with 100 mL final volume. Fifteen- and 20-dpf zebrafish were exposed to NSAIDs for 6 days. Thereafter the fish were collected, sacrificed by snap-freezing in liquid nitrogen and stored at - 80 °C for further use in gene expression analyses. To determine if the NSAIDs altered the sex ratios, 15-dpf fish were exposed until 40-dpf and transferred back to the circulating system at the end of exposure. The sex ratios were thereafter determined following dissection and observation of the gonads under a fluorescent microscope at 70 dpf for the vas::EGFP transgene and at 90 dpf for wild-type zebrafish. Preliminary sex ratio data showed that exposure to indomethacin, naproxen, and nimesulide resulted in significantly increased masculinization of zebrafish. Moreover, gene expression analysis at 26-dpf showed decreased expression of prostaglandin synthases *ptgs1*, *ptgs2a* and *ptgs2b* and the female-specific genes *zp2*, *vtg2* and *foxl2.* The results are in agreement with our earlier studies with meloxicam, supporting that NSAID exposure results in male-biased sex ratios. This study will provide detailed information on expression profiles of several sex related genes and pathways, and reveal the mode of action of NSAIDs on the sex differentiation in zebrafish.

The farming of fish inflicts various stresses upon the animals, which may impact their immune system. A reduced capacity to fight pathogenic agents may entail important losses in aquaculture production. Oestrogens are well-known endocrine disruptors that are present in natural forms in fish farms because non-degraded hormones, such as oestradiol, are released by the fish into the water body. Oestradiol is involved in the regulation of numerous physiological functions, including the modulation of immune system function and performance. Hence, we studied the long-term consequences of exposure to environmentally relevant concentrations of oestradiol on fish immunocompetence. Fingerlings of 47 and 60 days post-hatch were exposed to 20ng/L of oestradiol for 7 days and one month, respectively. Water samples were collected and analyzed by radioimmunoassays. Following exposure, each stage was sampled for gene expression analysis to assess the impacts of oestradiol on the ontogenesis of the thymus, which is the primary lymphoid organ responsible for T cell differentiation. After depuration phase, the fish were challenged by intracoelomic injection with *Vibrio harveyi* and cumulative mortality was recorded. Exposure to oestradiol, which was detected in the exposure water, from 47 to 54 days post-hatch caused an increase in sea bass mortality following bacterial challenge. By contrast, oestradiol exposure from 60 to 90 days post-hatch improved the fish resistance to vibriosis. As in mammals, oestradiol seems to have immunostimulating or immunosuppressive effects depending on the critical window of development. The relation between these immunomodulatory effects, thymus development and associated peripheral T cells is currently investigated.

Landscape Endocrinology: Wastewater Reuse, Exposure Risk, and Fish Endocrine Disruption

L. Barber, U.S. Geological Survey / National Research Program; J. Rapp, C. Kandel, S. Keefe, U.S. Geological Survey; J. Rice, Universwity of North Carolina - Charlotte; P. Westerhoff, Arizona State University / School of Sustainable Engineering and The Built Environment; D. Bertolatus, A. Vajda, University of Colorado, Denver / Integrative Biology

Reuse of municipal wastewater treatment plant (WWTP) effluent is an important component in augmenting global freshwater supplies. One of the challenges associated with reusing municipal wastewater is the presence of biologically active contaminants, such as endocrine-disrupting compounds (EDCs), which not only influence human consumption of reused wastewater but also impacts ecosystems which provide hydrologic connectivity between WWTP discharge locations and intakes for drinking water treatment plants. Risk assessment for potential endocrine disruption requires a landscape-based approach that allows investigations from river reach to continental scales. Widespread fish endocrine disruption, in the form of intersex and elevated plasma vitellogenin in male smallmouth bass, has been reported in the Shenandoah River Watershed (SRW). Detailed studies were conducted on the relationship between EDC exposure pathways and biological endocrine disruption effects incorporating wastewater reuse modeling, field sampling of water chemistry, and on-site fish exposure experiments. The amount of WWTP effluent in each river reach (accumulated wastewater ratio -ACCWRatio) was determined and used to predict environmental concentrations for select WWTP derived EDCs, including the steroidal estrogens estrone, 17-β-estradiol, estriol, and 17-α-ethinylestradiol. Mobile laboratory fish exposure and water characterization experiments were conducted at 9 locations to assess different source waters for the presence of EDCs and fish endocrine disruption using vitellogenin induction in male fathead minnows as the biomarker. Although the various source waters had complex mixtures of chemicals, the measured and predicted environmental concentrations of select steroidal estrogens resulted in 17-β-estradiol equivalency quotients ranging from < 0.5 to 5 ng L^{-1}, indicating low-to-moderate risk of fish endocrine disruption. Results from the fish exposure experiments showed minimal estrogenic effects as indicated by the low vitellogenin induction in male fathead minnows.

Thyroid hormone disrupting effects of two UV filter agents (EHMC and BP-3) in zebrafish embryo-larvae and ZFL (zebrafish liver cell line)

S. Chu, Seoul National University; J. Lee, Seoul National University / School of Public Health; J. Kim, Seoul National University; S. Kim, Seoul National University of Science & Technology / Department of Environmental Engineering; B. Kwon, School of Public Health, Seoul National University / Graduate School of Public Health; M. Kim, Seoul National University Hospital / Department of Internal Medicine; B. Oh, Lee Gil Ya Cancer and Diabetes Institute, Gachon University College of Medicine / Department of Physiology; Y. Park, Seoul National University Hospital / Department of Internal Medicine; K. Choi, Seoul National University / School of Public Health

During the last decades, the use of UV filters including 2-ethylhexyl 4-methoxycinnamate (EHMC) and 2-hydroxy-4-methoxybenzophenone (BP-3) has been significantly increased. Widespread use of EHMC and BP-3 has led to frequent occurrences of these compounds in the water worldwide. Previous studies have reported sex hormonal activities of EHMC and BP-3. However, there are knowledge gaps in thyroid hormone disruption of these chemicals in aquatic organisms. In this study, we investigated thyroid disrupting effects of EHMC and BP-3 in the embryo-larval stage of zebrafish and possible mechanisms by using zebrafish liver cells (ZFL). The zebrafish embryos were exposed to 1-30 μM of EHMC or 0.14-1.40 μM of BP-3 for 6 days. Embryo and larval survival, hatchability, malformation rate, and thyroid transcription level were observed. In ZFL experiment, cells were exposed to 1-10 μM of EHMC or 3-30 μM BP-3. Exposure to EHMC or BP-3 significantly altered thyroid hormone systems of zebrafish larvae and ZFL. No significant changes of the embryo and larval survival, hatchability, and malformation rate have resulted following exposure to EHMC, except decreased hatchability observed at 1.40 μM of BP-3.
For *crhb*(≥1μM) and *tg*(>1μM), gene expression was significantly down-regulated ($p< 0.05$). Also, fold change of *tshb*, *tshr*, *nkx2.1*, *ugt1ab*, *sult1st5*, *dio1*, *dio2* and *ttr* were decreased in zebrafish larvae exposed to EHMC. Moreover, *tg*, *ugt1ab* and *dio1*were significantly up-regulated ($p< 0.05$) at 1.40 μM, and fold change of *tshb*, *tpo*, *nis*, *pax8*, *dio2* and *ttr* mRNA expressions were increased in zebrafish larvae following exposure to BP-3. In ZFL exposure, increased regulation of *ugt1ab*(>1.5 fold) was observed, but no genes were changed significantly. Following exposure to BP-3, significant ($p< 0.05$) decrease of *ppara*(≥3 μM) and dose-dependent up-regulation of *ugt1ab*(>1.5 fold) gene were observed in the liver cells. Our observations suggest that exposure to two commonly used sunscreen chemicals could disrupt normal thyroid function by interfering central regulation, synthesis, and metabolism of the thyroid hormones. A different pattern of thyroid regulation was observed from exposure to EHMC and BP-3. Further studies are needed to confirm different modes of thyroid disruption by these frequently used sunscreens and related health consequences.

Potential thyroid disrupting effects of p,p'-DDE in zebrafish larvae, rat pituitary (GH3) and zebrafish liver (ZFL) cell lines

M. Kim, Seoul National University; S. Kim, Seoul National University / Department of Environmental Engineering; J. Kim, S. Chu, Seoul National University; B. Kwon, School of Public Health, Seoul National University /

Graduate School of Public Health; M. Kim, Seoul National University Hospital; B. Oh, Lee Gil Ya Cancer and Diabetes Institute, Gachon University College of Medicine / Department of Physiology; Y. Park, Seoul National University Hospital / Department of Internal Medicine; K. Choi, Seoul National University / School of Public Health

DDT (dichloro-diphenyl-trichloroethane) was one of the most used organochlorine pesticides for public health and agricultural purpose. Although its use has been banned for over 40 years, this pesticide along with its major metabolite *p,p'*-DDE (dichloro-diphenyl-dichloroethylene) are still detected in the biota. While DDT and its metabolites have been associated with thyroid disruption in epidemiological studies, little is known about the thyroid disrupting effects in aquatic organisms. We investigated adverse effects of *p,p'*-DDE in thyroid system of zebrafish embryo-larvae and possible mechanisms by using a rat pituitary (GH3) and a zebrafish liver (ZFL) cell lines. Zebrafish embryos were exposed to 0.01 to 0.3 µM of *p,p'*-DDE for 144 hours post fertilization and measured for embryo and larval survival, hatchability, malformation rate and transcription of genes related to thyroid hormones. GH3 and ZFL cells were respectively exposed to 1 to 10 µM and 0.3 to 3 µM of *p,p'*-DDE, for 48 hours. Key genes regulating thyroid hormone balance were measured in each cell. In zebrafish, larval survival was significantly decreased (< 80%) at 0.3 µM and the *crhβ*, *tshβ*, *nkx2.1*, *tg*, *sult1 st5*, *dio1* and *dio2* genes were significantly up-regulated at the sublethal concentration of 0.1 µM. Adversely, *Tshβ* mRNA transcription was significantly down-regulated at 10 µM in GH3 cells. In ZFL cells, increased pattern of *ugt1ab* gene was observed while not statistically significant. Our results suggest that exposure to *p,p'*-DDE could affect thyroid hormone balance in developing zebrafish. Both *in vivo* and *in vitro* data showed transcriptional change of the genes related to central regulation, which may impact thyroid hormone synthesis and lead to altered hepatic metabolism of hormones. Future studies are needed to confirm the changes in thyroid hormone levels following exposure and to investigate possible adverse outcomes. **<strong style="font-family: 'times new roman', times; font-size: medium;">[Acknowledgement]** This study is supported by a grant (18182MFDS365) from Korean Ministry of Food and Drug Safety (MFDS) in 2018.

TU092

Effects of exposure to perfluorooctanoic acid (PFOA) on the adult Australian native freshwater fish Melanotaenia fluviatilis

A.F. Miranda, School of Science / School of Science; S. Lekamge, C. Trestrail, D. Nugegoda, RMIT University / School of Science

PFOA has been used to manufacture several products and does not degrade easily in the environment. In this study, the Australian native fish Murray River rainbowfish (*M. fluviatilis*) were exposed to four different concentrations of perfluorooctanoic acid (PFOA) (0.01, 0.1, 1 and 10 mg L^{-1}). Changes in the thyroid hormones T3/T4 ratio, vitellogenin, changes in oxidative stress and lipid peroxidation were determined after 14 days of exposure. Activities of catalase (CAT) and glutathione- S- transferase (GST) were significantly increased in the gills and significantly reduced in the liver. Lipid peroxidation was observed in both tissues showing that vital organs could not neutralize the peroxides generated by oxidative stress resulting from exposure to PFOA. Fish exposed to PFOA had altered T3/T4 ratios and vitellogenin was induced in the plasma of male fish. Disruption of the hormonal balance by exposure to perfluorinate compounds (PFCs) in the environment can lead to negative effects on fish, severely compromising their fitness and survival resulting in and failure to adapt to changing environmental conditions.

TU093

Fish mucous barriers respond significantly to pollutants and parasites in shorthorn sculpins (Myoxocephalus scorpius) from 3 sites near a former lead-zinc mine in Maarmorilik, west Greenland

M.T. Dang, Institute for Marine and Antarctic Studies (IMAS), University of Tasmania / Institute for Marine and Antarctic Studies; K. Pittman, University of Bergen / Department of Biology; L. Bach, Aarhus University AU Arctic Research Centre / Department of Biosciences; C. Sonne, Aarhus University AU Arctic Research Centre / Department of Bioscience; S. Hansson, J. Søndergaard, Aarhus University AU Arctic Research Centre; M. Dean, University of Tasmania; B. Nowak, University of Tasmania / Institute for Marine and Antarctic Studies (IMAS)

Sculpins caught near the former lead – zinc mine in Maarmorilik, West Greenland are well documented as being impacted by heavy metal contaminants. In this study, we applied mucosal mapping, a novel, quick and efficient method for stereologically quantifying mucosal responses in fish, to shorthorn sculpins caught in contaminated areas in Maarmorilik, to investigate interactions between the host, parasites and heavy metal exposure (Pb and Zn). We found that the sculpin's mucosal epithelia in the skin and gills reacted in a quantifiable and reproducible manner to environmental heavy metal exposure and parasites. The skin barrier status was not affected by heavy metals but responded continuously to ectoparasite infestation. Skin mucous cells were significantly smallest at station 3 where the skin parasite load was highest and heavy metal residues were lowest. In the two populations of gill mucous cells (filamental and lamellar), the largest and densest filament mucous cells were found at the most polluted station. The density of gill lamellar mucous cells followed a toxicity gradient and was significantly highest at the most polluted station and significantly lowest at the least polluted station. The persistent presence of toxic Pb and Zn levels in the sediment at Station 1 may have induced a small but measurable reduction in the surface area available for respiration and excretion as a result of chronic exposure to these environmental toxins in the shorthorn sculpin. The strong correlation between size of filament mucous cells and liver concentrations of Pb suggests these cells can play an active role in reducing the somatic load of Pb in sculpin. These mucosal epithelial changes can be used to indicate fish adaptations and differential responses to environmental challenges in field studies.

Evaluation of toxic effects caused by surfactants used in nano-medicine on the aquatic environment

I. Hering, Fraunhofer-Institut für Molekularbiologie und Angewandte Oekologie IME; M. Weiler, MJR, PharmJet GmbH, 66802 Überherrn; F. Jung, Fraunhofer Institut für Molekularbiologie und Angewandte Oekologie IME, ProjektgruppeTranslationale Medizin & Pharmakologie (TMP), 60438 Frankfurt/Main; N. Günday-Türeli, MJR, PharmJet GmbH, 66802 Überherrn; C. Schaefers, Fraunhofer IME - Institute for Molecular Biology and Applied Ecology / Ecotoxicology; M. Fenske, German Federal Institute of Hydrology / Biochemistry and Ecotoxicology; M.J. Parnham, Fraunhofer-Institut für Molekularbiologie und Angewandte Oekologie IME, 65926 Frankfurt/Main; M.G. Wacker, Fraunhofer Institut für Molekularbiologie und Angewandte Oekologie IME, ProjektgruppeTranslationale Medizin & Pharmakologie (TMP), 60438 Frankfurt/Main; E. Eilebrecht, Fraunhofer IME / Ecotoxicology

Surfactants are used in various fields such as personal care products and detergents. For the production of nano-formulations, surfactants are applied to change surface properties of nano-particles or to stabilize the colloidal system. Such nano-medicines could also enhance the specific accumulation of pharmaceuticals in tumor cells or increase the passage of physiological barriers such as the blood-brain-barrier. However, surfactants could also inhibit enzymes and cause the lysis of cells due to alteration of the cell membrane. Surfactants used in nano-medicine can enter the aquatic environment via production or incorrect disposal where they can cause toxic effects and changes in behavior. Therefore, it is essential to examine possible negative effects of surfactants on the aquatic environment. The aim of this study is thus to identify surfactants which lead to the least negative effects in aquatic organisms. For this, the zebrafish embryo *Danio rerio* is used in the Fish Embryo Toxicity test (zFET). The following surfactants were tested: polyethylen-polypropylen glycole (here: Pluronic® F127 und Pluronic® F 68)**,** polyoxyl-40 hydrogenated castor oil (Cremophor® RH40) and polyethylen-glycol-1100-mono(hexadecyl/octadecyl)-ether (Cremophor® A25). For Cremophor® A25, an EC_{50}-value of 0,001 % was determined at 72 hours post fertilisation (hpf). Cremophor® A25 caused approximately 100 % mortality at a concentration of 0.05 % (72 hpf). At a concentration of 0.5 %, Cremophor® RH40 leads to 100 % mortality (72 hpf) and the EC_{50}-value was 0.007 % (72 hpf). Embryos which were exposed to Pluronic® F127 and Pluronic® F68 displayed sub-lethal deformations of the head, the tail and the chorda. The EC_{50}-values of Pluronic® F68 and Pluronic® F127 were 1.152 % and 0.808 %, respectively, at 72 hpf. Interestingly, the chorion of embryos exposed to Pluronic® F68 and Pluronic® F127 was deformed at the lowest concentration of 1.5 % within a few minutes after the start of exposure. Based on the EC_{50}-values, we can conclude that Cremophor® RH40 and Cremophor® A25 cause one to two times higher toxic effects on aquatic organisms than the group of polyethylen-polypropylen glycole (Pluronic® F68 und Pluronic® F127). From an eco-toxic point of view, the polyethylen-polypropylen glycole are thus more appropriate for the production of nano-medicines. Funded by Deutsche Bundesstif-tung Umwelt (AZ32725)

Simple energy-budget model for yolk-feeding life stages; a case study for Atlantic cod

T. Jager, DEBtox Research / Dept of Theoretical Biology; R. Nepstad, SINTEF Ocean / Monitoring and Modelling; B. Hansen, J. Farkas, SINTEF Ocean / Environment and New Resources

The early life stages of organisms are of considerable interest in ecotoxicology as they constitute a vital aspect of population dynamics and often display considerable sensitivity towards toxicants. Furthermore, embryo and early-life stage toxicity tests for vertebrates (i.e., fish and amphibians) are increasingly being suggested as alternatives for testing with the later (and legally-protected) life stages. To interpret the patterns of effects observed in toxicity test, and to extrapolate such results to field conditions, requires mechanistic models. Such models should consider both the toxicokinetic (TK) and toxicodynamic aspects (TD) of toxicity. Substantial research efforts are currently concentrating on the molecular level. However, we are convinced that molecular-level approaches need to be combined with energy-budget models to allow for a causal link between exposure and the whole-organism life-history traits (as represented by AoPs). The reasons for this are twofold. Firstly, any AoP will require knowledge about TK: how the internal concentration (in specific parts of the organism) develops over time. TK will be influenced by how the various biomass components (e.g., structure and yolk) develop over time, which is served by energy-budget models. Secondly, life-history traits are connected through the energy budget (e.g., structural growth and development are causally linked to the available yolk and to respiration rates), and feedbacks at this level cannot be explained from the molecular level up. Unfortunately, there have so far only been few attempts to apply energy-budget models to yolk-feeding stages. In this contribution, we report on the first stage of our attempts to do so, applying the simple DEBkiss model. In this first stage, we tested the basic model (in absence of toxicant stress) on extensive data for the yolk-feeding stages (and subsequent larval starvation) of Atlantic cod (*Gadus morhua*). The model provided an excellent explanation for the development of total weight, yolk content, respiration and larval length over the development of the egg and the yolk-sac fry. We include model simulations to predict how toxicant stress is expected to affect these development patterns. In a later stage, we will use our model to interpret toxicity data and to attempt a link with gene expression and metabolomics.

Ecotoxicology of Nanoplastics: Mechanistic Approaches to Understand Their Risk for the Environment and Human Health (P)

TU096

Polystyrene microbeads' uptake, tissue distribution and toxicity on zebrafish embryos, and their sorption capability for triclosan

C. Parenti, University of Milan / Biosciences; A. Ghilardi, University of Milan / Department of Biosciences; C. Della Torre, State University of Milano / Biosciences; S. Magni, University of Milan / Department of Biosciences; L. Del Giacco, University of Milan; A. Binelli, University of Milan / Department of Biosciences

Few studies related to microplastic (MP) contamination focus on ingestion and effects on freshwater species and even less is known about the potential action as carrier for some aquatic contaminants. The present study aims to investigate the microplastics' ingestion, tissue distribution and toxicity on zebrafish. Embryos were exposed for 48 h to virgin polystyrene microbeads (50 mg/L) with a dimension of 0.5 μm. Further, the possible absorption of chemicals on MPs was evaluated by the quantification of the absorbed concentration of triclosan (TCS), a common used antibacterial agent. MP uptake and tissue distribution were evaluated with the advanced confocal microscopy technique. The potential effects due to the ingestion of MPs were assessed through the analysis of P-glycoprotein (p-gp) transporter efflux and cyclooxygenase (COX) activity, while the oxidative stress was assessed by the analysis of reactive oxygen species (ROS) production, protein carbonyl content (PCC) and the activity of antioxidant/detoxifying enzymes glutathione S-transferase (GST), catalase (CAT), glutathione peroxidase (GPx) and superoxide dismutase (SOD). The adsorption of TCS on MPs was assessed mixing a MP powder in a TCS working solution. To quantified the absorbed concentration of TCS, an aliquot of treated-MPs was extracted in hexane, ultrasonicated and analysed using a high-resolution GC-MS system. Imaging observations confirmed MPs' uptake, distinctly showing embryos with beads inside the gastrointestinal tract and some of them migrating outside the intestinal epithelium. Moreover, some images showed the existance of potential alternative uptake routes, such as neuromasts or gills. The overall biomarker results revealed only a slight toxicity of MPs. Adsorption analysis showed that TCS can adhere to MP surface and this outcome underlined a potential synergistic effect of MPs on aquatic organisms. This study highlights the need of more deepened analyses evaluating the risk associated with MP infiltration and the interaction between microplastics, associated contaminants and organism.

Quantitative analysis of the impacts of microplastics on the freshwater duckweed Lemna minor

A. Mateos Cardenas, University College Cork / School of Biological, Earth and Environmental Sciences; F. van Pelt, University College Cork / Department of Pharmacology and Therapeutics; J. O'Halloran, University College Cork / School of Biological Earth and Environmental Sciences; M. Jansen, University College Cork / School of Biological Earth and Environmental Sciences Environmental Research Institute

Microplastic pollution has been widely reported in marine ecosystems all around the world. The intake of microplastics by different marine species has also been described in both wild caught and laboratory exposed samples. However, data on the presence of microplastics in the freshwater environment are scarce and the effects on aquatic species are not clear. In this study, the potential impacts of plastic microbeads on the freshwater plant *Lemna minor* were investigated. The interaction and potential effects of 1 μm polystyrene (PS), 1 μm polyethylene (PE) and 10-45 μm polyethylene (PE) beads on the physiology of the widely distributed freshwater duckweed *Lemna minor* were firstly investigated. The adsorption of 10-45 μm PE beads per surface area was quantified at five time points (3, 24, 72, 168 and 240 h) by using light and fluorescence microscopy. The fate of 1 μm microbeads within the plant tissue was further examined using confocal laser scanning microscopy. In addition, a thorough study on the growth and physiology of *L. minor* following a seven-day exposure to PS or PE microbeads was quantified following OECD parameters: frond and colony number, root length, chlorophyll *a* fluorescence and relative growth rate. Our results indicate that microplastic binding on plant tissue is time-dependent, however, despite the significant strong binding of microbeads to the duckweed surface over time, no negative effects on the physiology of *Lemna minor* were found. The strong microbead binding to duckweed tissue suggested *L. minor* as a potential vector for the transfer of microplastics to invertebrates. These results indicate that although microplastics interact with duckweeds, they do not have an effect on plant physiology, growth or photosynthetic efficiency

TU098

Secondary nanoplastics released from biodegradable microplastics severely affect freshwater organisms

M.G. Pleiter, M. Tamayo Belda, Universidad Autónoma de Madrid / Biology; G. Pulido-Reyes, Universidad Autónoma de Madrid; G. Amariei, Universidad de Alcala; F. Leganes, Universidad Autónoma de Madrid / Biology; R. Rosal, University of Alcala; F. Fernandez-Piñas, Universidad Autónoma de Madrid / Biology

Despite the recent advances in the field of plastic ecotoxicology, the ecological impact of nanoplastics in the environment remains poorly understood. Here, we have investigated the effects of secondary nanoplastics of polyhydroxybutyrate (PHB), polylactic acid (PLA) and polycaprolactone (PCL), biodegradable plastics, to representative organisms of aquatic ecosystems. Regarding PHB, secondary nanoplastics were produced from PHB microplastics by abiotic degradation under environmentally representative conditions. We have performed a complete physicochemical characterization confirming the presence of secondary PHB-nanoplastics in the 75 – 200 nm range. PHB-nanoplastics induced a significant decrease in cellular growth and altered relevant physiological parameters in all organisms. We investigated whether the observed toxicity was exerted by secondary PHB-nanoplastics themselves or by other abiotic degradation products released from PHB microplastics. An experiment was run in which secondary PHB-nanoplastics were removed by ultrafiltration; the resulting supernatant was not toxic to the organisms, ruling out the presence of toxic chemicals in the PHB microplastics. Results with PLA and PCL are still preliminary but we have also found the formation of a nanometric fraction from abiotic degradation of both polymers, toxicity evaluation is under way. All results put together indicated that secondary nanoplastics released as a consequence of abiotic degradation of microplastics seem to be harmful for aquatic organisms, suggesting that biodegradable plastic does not mean safe for environment. \n *Acknowledgement* - This research was supported by CTM2016-74927-C2-2-R grants from MINECO/FEDER EU and the Dirección General de Universidades e Investigación de la Comunidad de Madrid, Research Network S2013/MAE-2716. Chronic toxicity study of two-sized microplastics in marine copepod Tigriopus japonicus

Y. Jung, Korea Institute of Toxicology; J. Choi, Korea Institute of Korea KIT; J. Park, Korea Institude of Toxicology

Microplastic particles are ubiquitous in the environment and are growing concern nowadays. In this experiment we performed chronic exposure of two sized polystyrene microplastics, 50 nm and 2 um, to marine copepod Tigriopus japonicus. Exposure was started from the Nauplius stage and conducted for 30 days to identify the effect on growth, and another 10 days exposure was performed to egg sac bearing adult female to examine the reproductive effect. Mortality of 30 days exposure presented 30 day-LC50 value 0.1 mg/L for 50 nm PS sphere, and 3.9 mg/L for 2 um PS sphere. Another individual level effects on development time (nauplius to copepod, N-C, nauplius to adult, N-A), fecundity (number of clutch, number of nauplii/clutch, hatching period, number of nauplii/10days, hatching failure) was also examined. There was no significant effect on development or fecundity, but female exposed in the 10 mg/L above concentration showed higher hatching failure. For evaluation of molecular level effects, we also measured ROS and NO levels and gene expression changes that related with oxidative stress, inflammation, molting, and reproduction. The molecular effects caused by microplastics were significantly different from the control group.

TU100

Cellular effects of natural and synthetic microparticles in marine invertebrates

. Korez, Alfred Wegener Institute / Functional Ecology; L. Gutow, R. Saborowski, Alfred-Wegener-Institute, Helmholtz Centre for Polar and Marine Research / Functional Ecology

Coastal and estuarine invertebrates are exposed in their habitats to various natural particles, such asłfine sand grains, diatoms shells, cellulose fibres, or chitinous fragments. Additionally, they encounter anthropogenic litter and synthetic micro-particles. Especially the latter are of interest in ecotoxicological research as they were reported to induce cellular stress and, finally, damages of biomolecules. Comparative studies on the cellular effects of natural and synthetic particles are yet lacking. Therefore, we will perform feeding experiments with two ecologically and commercially important invertebrate species from the coastal North Sea. Blue mussels (*Mytilus edulis*) and brown shrimps (*Crangon crangon*) will be collected from the field, acclimated to the laboratory conditions, and exposed to various types of natural and synthetic particles. Incubations will last 6, 24, and 48 hours, respectively. A series of microscopic and histological analysis will localize the ingested particles in the digestive organs. Biochemical and histochemical analyses will be used to measure stress markers in the cells. The goal of this doctoral work is to identify, understand, and to distinguish biological effects of microparticles of anthropogenic and natural origin. The findings will help to better understand and estimate the hazard of microplastics to marine invertebrates and to define their actual threat boundaries._

TU101

Responses of nematodes to microplastic exposure - direct or indirect effects?

S. Höss, Ecossa / Animal Ecology; M. Mueller, H. Füser, W. Traunspurger, Bielefeld University / Animal Ecology

Apart from global warming, microplastic pollution is currently one of the biggest environmental concerns. Since plastic debris is not biodegradable, it accumulates, rather than decomposes in the environment. Secondary microplastics are a result of the breakdown of larger plastic items caused by weathering via mechanical action, oxidative weathering or biological degradation. Microplastics (The aim of this study was to assess the toxicity of polystyrene (PS) beads of various sizes (0.1 to 10 μm) on the reproduction of the nematode *Caenorhabditis elegans*. Direct effects were related to the ability of the nematodes to ingest the PS beads, which is dependent on the bead diameter and the buccal cavity size of *C. elegans*. Moreover, the link of effects to the ratio of food bacteria and PS beads was studied to evaluate the impact of food availability as an indirect toxicity pathway. *C. elegans*ingested PS beads of 0.1, 0.5, 1.0 and 3.0 μm, whereby 6.0 and 10.0 μm were not found in the nematode's intestine.Toxic effects of the tested PS bead sizes on *C. elegans*' reproduction occurred dose-dependently, with EC50-values ranging from 0.2 to 8.8 mg PS beads ml^{-1}. While the toxicity based on concentrations (mg ml^{-1}) decreased with bead diameter, toxicity based on total surface area (cm^2ml^{-1}) was not dependent on bead size (EC50 ranging between 30 and 100 cm^2ml^{-1}), suggesting that the toxicity mechanism is induced by the surface area of the beads, irrespective of their uptake into the nematodes. Nevertheless, neither oxidative stress nor the potential toxic effects of leachates (e.g. the monomer styrene) could explain the toxicity of the PS beads. The reduction of food availability by the presence of PS beads, however, might at least partly explain the inhibited reproduction of *C. elegans*. Therefore, it is advised to consider also indirect food web effects in studies dealing with the ecological risk of microplastics.

TU102

Effects of polystyrene microplastics and two organic pollutants in different life stages of brown trout (Salmo trutta f. fario)

H. Schmieg, Tübingen University / Animal Physiological Ecology; S. Krais, University of Tubingen / Animal Physiological Ecology; J. Burmester, K. Reitter, F. Rezbach, University of Tuebingen / Animal Physiological Ecology; A.S. Ruhl, Technische Universität Berlin / Chair of Water Quality Control; H. K�hler, University of Tubingen / Animal Physiological Ecology; R. Triebskorn, University of Tuebingen / Animal Physiological Ecology

Plastic debris is ubiquitously distributed in aquatic and terrestrial environments. Microplastics are all plastic items with a size smaller than 5 mm. Despite the number of studies on effects on freshwater organisms having increased during the last years, the risk of microplastics exerted to freshwater organisms remains unclear and more studies about potential effects of microplastics on organisms are needed. The aim of our study is to investigate effects of polystyrene microplastics (cryogenically milled granules, fractionated to < 50 μm), alone and in combination with organic pollutants, in different life stages of brown trout (*Salmo trutta* f. *fario*). We conducted two fish early life stage tests (FELST) according to OECD 212 and investigated heart rate, hatching success and mortality. After resorption of the yolk sac contents by the fish larvae we, additionally, evaluated behaviour, biometric parameters, the oxidative stress level and the activity of acetylcholinesterase. In the first experiment, effects of polystyrene microplastics alone (100, 10 000 and 100 000 particles/L) were assessed. In a second experiment, we examined effects of polystyrene particles (100 000 and 1 000 000 particles/L) alone and in combination with the antidepressant amitriptyline (300 μg/L). Additionally, we performed two experiments with juvenile fish (9 - 11 months old). In the first experiment, trout were exposed to 10 000 particles/L alone and in combination with the pesticide methiocarb (2 mg/L). In a second experiment, juvenile trout were exposed to either 10 000 or 100 000 particles/L, 100 μg/L amitriptyline or a combination of particles and the antidepressant. In these experiments, behaviour, mortality rate, biometric parameters, the oxidative stress level, the induction of the 70 kD stress protein family (Hsp70) and the inhibition of acetylcholinesterase were under investigation. Furthermore, we recorded histopathological effects in gills and liver of trout. Results showed an effect of microplastics at a concentration of 1 000 000 particles/L on the behaviour of brown trout larvae. Apart from that, microplastics failed to exert any effect or any modulation of methiocarb or amitriptyline effects in different life stages of brown trout. Further analyses are in progress. The present study is part of the joint research project "MiWa" (microplastics in freshwater systems) funded by the German Federal Ministry of Education and Research (no. 02WRS1378).

TU103

Effects of microfibers and tyre debris on freshwater invertebrates

T.C. Schell, S. Martinez, R. Dafouz, IMDEA Water Institute / Ecotoxicology; R. Hurley, NIVA - Norwegian Institute for Water Research; A. Rico, IMDEA Water Institute / Aquatic Ecotoxicology; M. Vighi, IMDEA Water Institute / Earth and Environmental Sciences

The majority of studies assessing the toxicity of microplastics (MPs) have focused on the effects of microbeads on marine species. Recent monitoring studies indicate that there is a huge variety of shapes and types of MPs in freshwater and marine ecosystems and that microbeads are not necessarily the most abundant nor problematic ones. Synthetic fibres and tyre debris are emitted in large quantities into the environment and are likely to cause deleterious physical effects due to their elongated or irregular shape. The effects of these MP particles on aquatic organisms, however, are largely unknown. This study aimed to determine the acute and chronic effects of PET fibres and tyre particles on freshwater invertebrate species with different habitat preferences and feeding strategies (i.e., *Daphnia magna*, *Asellus aquaticus*, *Hyalella azteca* and *Lumbriculus variegatus*). Fibres of a length between 101 and 2194 μm (IQR: 493-992 μm) and a width of 29 μm were produced through washing polyester (PET) fleece blankets. Tyre debris was milled from end-of-life passenger tyres (Genan, Denmark) and sieved to obtain a final particle size between 25 and 75 μm. Acute and chronic toxicity studies were carried out based on respective standard protocols (OECD 202/211/225 and ASTM E1706-05). According to their different habitats, the test organisms were exposed to MPs in the water phase (*D. magna and H. azteca*) or mixed into sediment (*A. aquaticus, H. azteca* and *L. variegatus*). A range of concentrations was tested, including environmental relevant concentrations (water exposure: 0, 0.00015, 0.0015, 0.015, 0.15 g/L; sediment exposure: 0, 0.002, 0.02, 0.2, 2 g/kg). For acute exposure, ingestion and immobility or mortality were recorded, while for chronic exposure also reproduction and growth were assessed. All test organisms ingested fibres and tyres, except for *D. magna* which only ingested tyre debris. For the considered endpoints, no adverse effects at the tested MP concentrations were observed, except for *D. magna* reproduction, which was significantly reduced (51%, $p < 0.05$) at the highest test concentration (0.15 g/L). These findings indicate that although freshwater organisms ingest fibres and tyre debris, they do not accumulate within the organisms and do not seem to negatively influence their survival, growth or reproduction at environmentally relevant concentrations.

TU104

The translocation of microplastics to lipid droplets of Daphnia magna is an artefact

C. Schuer, Goethe University Frankfurt / Dpt. Aquatic Ecotoxicology; S. Rist, DTU (Technical University of Denmark) / DTU Environment; A. Baun, N.B. Hartmann, Technical University of Denmark / DTU Environment; M. Wagner, Norwegian University of Science and Technology NTNU / Bioanalytical Toxicology Group

Micro- and nanoplastic particles have been reported to cross the biological barriers of the digestive tract and translocate to other tissues in a number of species. They then could cause inflammatory reactions, making this a relevant topic of investigation. Most prominently, Rosenkranz et al. (2009) described the translocation of 20 nm and 1000 nm polystyrene particles to the lipid droplets of *Daphnia magna.* These findings lack biological plausibility due to the peritrophic membrane in arthropods that would prevent particles larger than 300 nm from interacting with the epithelial layer. The aim of our study therefore was to replicate these findings while covering additional experimental scenarios. We exposed *Daphnia magna* neonates to the same particle types (fluorescent polystyrene spheres of 20 nm and 1000 nm diameter) at two concentrations (2 μg/L and 2 mg/L) for two time periods (4 h and 24 h). Additionally, we adapted a tissue clearing method to the use with *Daphnia* to improve visibility of particles inside the specimen. We used confocal laser scanning microscopy to investigate the translocation of particles from the gut to other tissues, including lipid storage droplets. This is supplemented by experiments regarding the leaching of the dye from the particles. At the higher particle concentration we detected fluorescence in the lipid droplets for both particle types. At least for the 1000 nm particles fluorescence was clearly separate from particles. Our findings suggest that the tissue translocation to the lipid storage droplets reported previously is an experimental artefact caused by the leaching of the dye. This is supported by additional experiments regarding the conditions under which the dye could leach from the particles. This has implications for other studies since fluorescently labelled, commercially available plastic beads are the main method to investigate tissue translocation in aquatic organisms. Additionally it underlines the importance of questioning biological plausibility even in long-standing research.

TU105

Uptake and effects of polystyrene nanoparticles on the early development and life cycle of Tisbe battagliai: role of surface functionalisation

A. Georgantzopoulou, Norwegian Institute for Water Research NIVA; A. Macken, NIVA / marine pollution; A. Lillicrap, NIVA / Environmental Toxicology; T. Gomes, Norwegian Institute for Water Research (NIVA) / Ecotoxicology and Risk Assessment

Plastics are prolific environmental contaminants, widely identified in marine and freshwater ecosystems. Progressive fragmentation of larger plastics leads to the formation of smaller-sized particles whose further degradation will likely result in the formation of plastic particles in the nanoscale (< 100 nm according to nanoparticle definition) with altered physicochemical characteristics that could differ greatly from the original material. Currently there is limited knowledge on the effects of nano-sized plastics, their fate, behaviour and interaction with cellular membranes and organisms. The aim of this study is to better understand the uptake and effects of polystyrene plastic particles in the nanoscale and assess the uptake, bioaccumulation and subsequent developmental and life cycle effects on the marine harpacticoid copepod *Tisbe battagliai*. In this study, the effects on the naupliiar development of *T. battagliai* were assessed over a 6-day exposure period. The mortality and developmental stage of the organisms was assessed daily. At the end of the exposure period, the animals were transferred to clean seawater and the development of the copepodids, adult survival and reproduction was further assessed (assay was terminated on day 21). Due to the current analytical challenges of plastic nanoparticle detection in the environment, polystyrene NPs were used as model particles. Initial investigations focussed on the study of aminated and carboxylated polystyrene particles (PS, PS-NH_2, PS-COOH, 50 nm, Sigma Aldrich and Phosphorex) to assess the impact of surface functionalisation. Characterization of the particles in seawater was performed with dynamic light scattering (DLS) and nanoparticle tracking analysis (NTA). Moreover, potential nanoplastic uptake, internationalisation and intracellular localisation is evaluated with confocal microscopy and flow cytometry. Surface-dependent effects were observed, both PS-NH_2 and PS-COOH affected the early life development of *T. battagliai* while no effects were observed for the non-functionalised PS particles. A decreased developmental rate was observed at 5 mg/L PS-NH_2 (88% compared to control) and 10 mg/L PS-COOH (73% compared to control). The number of organisms developing to copepodids was decreased significantly (EC_{50} of 4.4 mg/L and 11.4 mg/L for PS-NH_2 and PS-COOH, respectively). Ongoing studies focus on mechanistic understanding of the observed effects and increasing environmental relevance of the exposures.

TU106

Characterization of cell response in Rhodomonas salina exposed to PMMA nanoplastics

T. Gomes, Norwegian Institute for Water Research (NIVA) / Ecotoxicology and Risk Assessment; A. Almeida, Norwegian Institute for Water Research NIVA / Ecotoxicology and Risk Assessment; A. Lillicrap, NIVA / Environmental Toxicology; A. Georgantzopoulou, Norwegian Institute for Water Research / Ecotoxicology and Risk Assessment

Due to their small size (< 100 nm), nanoplastics (NPLs) possess specific properties which can potentiate their toxicity towards aquatic organisms depending on surface characteristics and interactions with the surrounding environment. Still, their presence and behavior in the aquatic environment, as well as any toxic mechanisms are, to a large extent, unknown. As primary producers, microalgae play an important role in the functioning of marine ecosystems, producing oxygen and energy and recycling nutrients on which many organisms within the ecosystem rely on. For this reason, negative effects of NPLs in microalgal species will likely have an impact not only on the algae themselves, but potentially also impact other levels of the aquatic food chain. With this in mind, the main objective of this study was to evaluate the cell response of the marine microalgae *Rhodomonas salina* upon 72 hours exposure to plain and carboxylated PMMA (PMMA and PMMA-COOH, 50 nm). Analysed endpoints included growth rate, natural pigments content, cell size, cell complexity, cell viability and cell cycle, reactive oxygen species (ROS) formation, mitochondrial membrane potential, lipid peroxidation (LPO) and DNA content. Additionally, photosystem II (PSII) performance was analysed by PAM fluorometry, to provide further information on the absorption, distribution and use of energy in photosynthesis. PMMA behaviour in exposure media was evaluated using dynamic light scattering (DLS) and nanoparticle tracking analysis (NTA). Results obtained showed a different behaviour of PMMA NPLs in exposure media over time, with PMMA forming micro-scale aggregates (2266 ±260 nm) while PMMA-COOH maintained its nominal size range (57.1 ± 0.4 nm). Several differences were seen in terms of toxicity between both PMMA NPLs. PMMA exposure caused a significant effect in cell viability, ROS formation, LPO, pigment content and photosynthetic performance in exposed *R. salina*, probably associated with particle interaction with the cellular membrane. On the other hand, a higher impact of PMMA-COOH was observed in terms of algal growth, photosynthetic performance, cell viability and metabolic activity, with negligible effects seen for ROS formation and pigment content. Overall, surface chemistry and size seem to be key parameters for the interaction and impact of PMMA NPLs in microalgae, and future experiments focusing on the in-depth characterization of the mode of action of these particles are underway.

TU107

Chronic exposure to nanoplastics results in developmental and reproductive toxicities in Caenorhabditis elegans

T. Luk, National Taiwan University; V. Liao, National Taiwan University / Department of Bioenvironmental Systems Engineering

Scope: Plastic debris is an emergent global environmental issue. The ultimate product of plastic debris is nanoplastics which are plastic particles less than 100 nm in size that are of particular concern. Due to their enormous quantity, recalcitrant nature, and unique physicochemical properties, nanoplastics exposure to organisms might be chronic posing potential toxicity risk to the ecosystem. **Methods:** We investigated chronic exposure to nanoparticles on the developmental and reproductive toxicities by comparing three types of polystyrene nanoparticles with its: pristine form (NPs-bulk), carboxyl-modified form (NPs-COOH), and amino-modified form (NPs-NH_2) in the nematode *Caenorhabditis elegans*. **Results**: The results showed that all three forms of nanoparticles in moderately hard reconstituted water (EPA water) have a much smaller hydrodynamic diameter than that in K medium. The NPs-bulk did not induce growth defects at the examined concentrations (1, 10, 50 mg/L in EPA water) in *C. elegans*. However, both NPs-COOH and NPs-NH_2 caused a significantly decreased body length in *C. elegans* at 10 and 50 mg/L in EPA water. The NPs-NH_2 did not cause reproductive toxicity in *C. elegans* at the examined concentrations (1, 10, 50 mg/L in EPA water), whereas the total brood size in *C. elegans* was reduced in NPs-bulk and NPs-COOH (50 mg/L for NPs-bulk and 10, 50 mg/L for NPs-COOH, respectively, in EPA water). **Conclusions**: Our results provided evidences that chronic exposure to nanoparticles results in developmental and reproductive toxicities in *C. elegans* and different modified forms of nanoparticles might exert varied degree of toxicity.

TU108

Ecotoxicity of carboxylated nano-polystyrene from laboratory exposures to freshwater organisms

A. Minet, F. Clergeaud, J. Ferriol, ECOLAB UMR 5245 CNRS; J. Gigault, University of Rennes 1 / Laboratoire Geosciences; J. Leflaive, ECOLAB UMR 5245 CNRS; F. Mouchet, ECOLAB UMR 5245 CNRS / Integrative ecotoxicology; E. Pinelli, ECOLAB UMR 5245 CNRS; L. Rowenczyk, IMRCP CNRS; J. Silvestre, L. Ten-Hage, ECOLAB UMR 5245 CNRS; A. Ter Halle, IMRCP CNRS / Chemistry; L. Evariste, ECOLAB UMR5245 CNRS UPS INPT; L. Gauthier, ECOLAB UMR 5245 CNRS

If plastic pollution in the marine environment is now recognized by scientists as a threat to the balance of its ecosystems in terms of abundance, composition, sources and impact in the ocean, it is then surprising to note that plastic pollution in inland waters is largely unknown. Although the sources, nature, concentration, presence, fate and effects of micro- and nano-plastics have not been well characterized in freshwater systems to date, evidence from the marine environment suggests that micro- and nano-plastics could be considered as emerging contaminants. The production sources and almost all the life cycle of plastics are mainly continental (atmospheric, plastic waste, landfills, agricultural plastics, production and recycling sites, etc.). Thus, for the majority of them, they must transit through the terrestrial and/or fresh water compartment, before reaching the oceanic gyres, where they concentrate, to form the so called “7th continent”. \n In this context, the objective of this work is to provide new data to acquire the knowledge bases, in terms of hazards on freshwater ecosystems exposed to this type of contaminant, which is a prerequisite for a realistic assessment of the risks associated with the presence of plastic debris in our environment. As an example, the potential ecotoxicological effects of commercial dispersions of carboxyled nano-polystyrene (PS-COOH) of 50 and 350 nm in diameter (from 0.1 to 100 μg/L) was studied from laboratory exposures to different freshwater organisms selected for their ecological representativeness (primary and secondary producers *i.e.* different species of microalgae, and consumers *i.e.* larvae of chironomids and amphibian filter-feeders larvae) and for their use as ecotoxicological bioassays. In order to implement the tools necessary to acquire this knowledge, dispersions of PS-COOH were also characterized. Results showed (i) neither mortality nor genotoxicity but a light significant growth inhibition of the size of amphibian larvae exposed to PS-COOH of 50 nm whatever the concentration and to 10 and 100μg/L of PS-COOH of 350 nm, (ii) no effects in terms of mortality, growth inhibition and teratogenicity in chironomus larvae exposed to both PS-COOH, (iii) a significant growth inhibition to both PS-COOH depending on the exposed algae species. Results were obtained in the framework of the French National Program for Environmental and Occupational Health of Anses (EST/2017/1/219), EMPEC.

TU109

Food transfer and uptake of micro- and nanoplastic particles in a two-species marine system

N. Oturai, Roskilde University / Dept of Science & Environment; A. Mammen, Roskilde University; L. Rowenczyk, IMRCP CNRS; A. Ter Halle, IMRCP CNRS / Chemistry; O. Vang, Roskilde University; K. Syberg, Roskilde University / Dept of Science and Environment

Research has shown that smaller size plastic particles (< 100nm) are increasingly available for biological uptake on a cellular level. In this context, present study investigates the food transfer of polystyrene particles in two sizes (2μm and 50nm) in a maritime set up with key species *Mytilus edulis* and *Carcinus maenas* of Roskilde Fjord, Denmark. The study was conducted in order to assess the importance of food as source for plastic particles (microplastic (MP) and nanoplastic (NP)) and to what extent the size of particles influenced translocation over biological barriers in the digestive systems of both organisms and thus will be detectable in tissue apart from the stomach such as haemolymph, hepatopancreas and gills. \n Seventy *M. edulis* were exposed through their diet to two concentrations, 500 mg/L and 50 mg/L, of polystyrene particles in two sizes, 2μm and 50nm. The fluorescent particles, coated with an amino function to hinder aggregation, were added to 300 ml artificial seawater (ASW) for each mussels along with algae *Rhodamonas salina* for optimal filtration efficiency for 1h after 30 min depuration. Subsequently, 35 females of the system top predator *C. maenas* were given 1h to acclimate to 1 L ASW and were then left to feed on one *M. edulis* apiece for 1h. After the treatment the 20 crabs and 20 mussels fed with exposed mussels, along with 10 crabs plus 10 mussels as positive controls and 10 negative controls were sampled for detection of micro- and nanoparticles. Four tissue samples for the crabs, (1) gills, (2) hepatopancreas, (3) hemolymph and (4) stomach), and three for the mussels, (1) gills, (2) stomach and (3) the remains, were analysed by fluorescence measurements in a microplate reader and confocal microscopy to determine the presence of the fluorescent polystyrene particles.

TU110

Transfer of Chlorpyrifos from microplastics alters locomotor activity in larval zebrafish

N. Kämmer, F. Zindler, T. Braunbeck, University of Heidelberg / Centre for Organismal Studies COS

Microplastics (MP) have become ubiquitously distributed in aquatic environments and have been speculated to cause adverse effects on organisms *via* the transfer of potentially adsorbed pollutants. In the present study, the behavior of zebrafish larvae, which has been proposed as a sensitive tool to estimate the impact of chemicals on physiological and neuronal integrity, was assessed in response to microplastics loaded with the acetylcholine esterase inhibitor chlorpyrifos (CPF; log K_{ow} = 4.96). Embryos at the age of 2 hours were exposed to high-density polyethylene particles (HDPE; 100 particles/ml, 4-6 μm) for 96 hours, which had been incubated in either 0.5 or 5 mg/L CPF solution plus 0.1 % DMSO, respectively. Swimming activity of embryos was detected via video tracking in a light/dark transition assay. Individuals exposed to non-loaded (virgin) microplastics did not show any significant difference in behavior compared to controls, whereas individuals exposed to MP incubated with 5 mg/L CPF showed significantly reduced activity during the dark phases; embryos treated with MP + 0.5 mg/L CPF showed no effects on behavior. The reduction in activity in the MP + 5 mg/L CPF treatment was similar in magnitude to the effects seen in individuals exposed to the positive control (water-borne 0.05 mg/L CPF). Therefore, the HDPE particles may be assumed to have ± quantitatively adsorbed CPF, which was then made bioavailable to the zebrafish embryos. Thus, the present study provides evidence that video-tracking methods for the detection of behavioral changes in zebrafish embryos can be applied for the investigation of pollutant release from MP. In fact, behavior has been shown to be highly sensitive to a wide range of (neurotoxic) pollutants and seems to be more susceptible than morphological parameters.

TU111

Influences of polystyrene microplastic particles on the toxicities of thiacloprid and methiocarb for the non-biting midge Chironomus riparius: mortality and biochemical responses

S. Krais, University of Tubingen / Animal Physiological Ecology; H. Schmieg, T. Schwarz, University of Tuebingen / Animal Physiological Ecology; A.S. Ruhl, Technische Universität Berlin / Chair of Water Quality Control; H. Köhler, R. Triebskorn, University of Tuebingen / Animal Physiological Ecology

Microplastics (MP) are of particular interest in ecotoxicology because they potentially interfere with organic substances like pesticides or pharmaceuticals, modulate their toxicity and in addition, may mechanically affect exposed organisms. Whereas in the past, most of the studies on MP toxicity have focused on the marine environment, the number of freshwater studies with respect to MP and dissolved contaminants has recently increased. The aim of the present study is to examine the influence of polystyrene (PS) particles (cryogenically milled granules, fractionated to < 50 μm) alone and in combination with the pesticides thiacloprid (TH) and methiocarb (MET) on the sediment dwelling larvae of the non-biting midge *Chironomus riparius.* \nIn the first experiment, 3rd - 4th instar larvae of *C. riparius* were exposed to PS particles (150,000 particles/L; MP), the insecticide TH (1μg/L) or the mixture of both (Mix) for 96 h. As endpoints, mortality rate and neurotoxicity (acetylcholinesterase inhibition) were investigated. The results showed a significantly increased mortality in all treatments containing TH (TH and Mix), compared to the negative control and the MP group. Furthermore, the Mix treatment showed a significantly lower mortality rate than the TH treatment, indicating that PS particles are able to reduce the lethality of TH. This effect has been shown in all five runs that have been performed. However, the underlying mechanism is not clear yet, and therefore, further investigations are necessary. The analyses of acetylcholinesterase activity showed no differences between the treatments. In a second experiment, we investigate the impact of different concentrations of the molluscicide MET alone and in combination with PS particles and TH on the health of *C. riparius*. The results will be presented on the poster. The study is part of the joint research project MiWa ('microplastics in the water cycle') funded by the German Federal Ministry of Education and Research (funding number: 02WRS1378).

TU112

Influence of differently functionalized polystyrene microplastics on the toxic effects of TiO2 NPs towards marine algae Chlorella sp.

V. Thiagarajan, I. V, S. R, C. N, A. Mukherjee, VIT University / Centre for Nanobiotechnology VIT Vellore

Increased utilization of titanium dioxide nanoparticles (TiO_2 NPs) for commercial as well as industrial purposes resulted in NPs accumulation in the marine system. Microplastics being an emerging secondary pollutant in the marine ecosystem have an impact on the toxic effects of TiO_2 NPs which has not been evaluated up to date. So it is important to assess the toxic effects of both these pollutants on marine environment.The present study examines the impact of differently functionalized microplastics on the toxic effects of P25 TiO_2 NPs to marine algae *Chlorella* sp. Tendency of NPs to undergo aggregation in artificial seawater was observed with increase in time. The median effective concentration for TiO_2 NPs was found to be 6.5 mg L^{-1} which indicates higher toxic effects of NPs toward algae. In contrast, microplastics irrespective of their difference in functionalization had minimal toxic effect of about 15% at their higher concentration tested. Plain and aminated polystyrene microplastics enhanced the TiO_2 NPs toxicity which was further validated with oxidative stress determination studies like reactive oxygen species and lipid peroxidation assays. Negatively charged carboxylated polystyrene microplastics decreased the TiO_2 NPs toxicity with possible heteroaggregation between TiO_2 NPs and microplastics in the system. The toxicity data obtained for the mixture was further corroborated with the mathematical model, Abbott.

EVALUATION OF IN-VITRO PLANT METABOLISM AS A TOOL TO AID IDENTIFICATION OF METABOLITES FROM CROP METABOLISM STUDIES

R. Mumford, Smithers Viscient ESG Limited / Physical Chemistry; S. Swales, Smithers Viscient ESG Ltd / Environmental Fate and Metabolism

The identification of metabolites from crop studies can present a significant challenge analytically due to the complexity of the matrices involved and generally low concentrations observed. In the case of the confined rotational crop study (OECD 502) this is compounded by the fact that degradation may occur on the soil before uptake during the aging period and a general drive for lower application rates. In situations where if extensive metabolism is observed many metabolites can be generated, while the majority may be at or below the trigger value for identification (>50 ppb) many metabolites are found to be present at the characterisation requirement (10-50 ppb) level. According the study guideline characterisation does not necessarily include identification, however, if a residue definition is required it becomes necessary to identify these low level metabolites and it can be difficult to achieve accountability for the majority of the residue. While there have been many technological advances in analytical chemistry, particularly in the field of mass spectrometry and 2-dimensional chromatography which help with the identification of these metabolites the challenge of a complex matrix still remains. The identification of metabolites can become akin to looking for a needle in a haystack and clean-up procedures can be inefficient and costly. The use of *in-vitro* techniques may not produce metabolites in the same ratios that are observed in the whole plant, however, it is expected that the same metabolites are observed. An advantage of *in-vitro* incubation of plant cell cultures is that it allows the exposure rates of the agrochemical in question to be increased. This combined with near perfect growing conditions used for the incubation should produce metabolites in greater concentrations, in a cleaner matrix and in a shorter time than required to repeat the study (or part of) at a higher application rate. This presentation examines the viability and effectiveness of *in-vitro* plant metabolism techniques to provide a source of metabolites to aid metabolite identification in confined crop rotation studies.

TU114

Effects of graphene oxides on plant germination and growth

L. Ji-Yeon, Konkuk University; m. kim, Korea University; H. Chung, Konkuk University

Graphene oxide has a wide specific surface area and has excellent mechanical and thermal properties. Due to its superb material characteristics, GO has a high potential to be applied in various environmental fields. GO may enter the soils and groundwater as a result of such applications, but there is not much research on how GO may affect plants when they enter terrestrial ecosystems. To assess the impacts of GO on the germination and early growth of diverse plant species, we studied the response of radish, cucumber, lettuce, alfalfa, and perennial ryegrass to GO treatment. GO was treated to the seeds at the concentration of 0, 0.2, 0.4, 0.8, 1.6 mg ml^{-1} and we analyzed the germination rate and growth of plants. The germination rate of lettuce decreased as GO concentration increased. On the other hand, the effects of GO were not significant on the germination of other plants. The root and shoot growth of lettuce, radish, and alfalfa decreased with exposure to higher concentrations of GO. More specifically, the shoot and root length of lettuce decreased by 87% and 86%, respectively, at 1.6 mg ml^{-1}. Our results show that high concentrations of GO can inhibit the germination and early growth of plants. Therefore, we expect this study can help supplement the legal regulations for safe use of nanomaterials.

TU115

An assessment of levels of cyanide and heavy metals in mine soils and their effect on maize growth.

N. Basopo, National University of Science & Technology / Applied Biology and Biochemistry; N. Hleruka, National University of Science and Technology / Applied Biology and Biochemistry

We investigated the levels of cyanide and heavy metals in mine effluent and assessed their effects on maize growth. Soil samples were collected from a dump site of an operating mine and were tested for heavy metal residues and cyanide levels. Maize seeds were planted and allowed to grow in soil collected 200 m from the dumpsite for five weeks. Some maize seeds were planted and grown in control soil samples and irrigated with cyanide concentrations (0.05mg/L, 0.5 mg/L and 5 mg/L). The control maize seeds were planted and grown in control soil and were irrigated with tap water. The endpoint parameters for assessing growth were measurements of plant and leaf length. Oxidative stress was assessed by measuring the activities of catalase and superoxide dismutase. High concentrations of copper, zinc, cadmium and iron, recorded as; 401.59 mg/kg, 283, 85mg/kg, 22.855 mg/kg and 7353mg/kg respectively in soil from the mine dump site were observed. Cyanide concentrations of 1.25. mg/kg and 0.5 mg/kg from the mine dumpsite and soil collected 200 m from the dumpsite respectively were also recorded. Significant levels of heavy metal residues were observed in maize after five weeks of exposure to mine dump soil. Presence of cyanide and heavy metals had a negative effect on maize growth as growth was slowed when compared with the control plants. Antioxidant enzyme activity enzyme activity, both catalase and superoxide dismutase was significantly enhanced by exposure to contaminated mine soil. Our results show that contaminated mine soil impacts negatively on the health of plants grown in this soil.

TU116

INFLUENCE OF Cd2+ ON STRUCTURAL AND FUNCTIONAL PARAMETERS OF HALOPHYTE SUAEDA SALSA

O. Rozentsvet, Institte of Ecology of the Volga River basin; V. Nesterov, E. Bogdanova, V. Rozentsvet, Institute of Ecology of the Volga Basin of the Russian Academy of Sciences

Halophytes comprise an ecological-physiological group of plants with a high potential for biological resistance to salinity. The resistance of halophytes to NaCl is associated with a variety of physiological and molecular mechanisms: limiting the flow of ions; salt extraction through glands; salt accumulation in vacuoles; participation of enzymes and low-molecular compounds in countering oxidative stress with antioxidant protection. Many of these mechanisms are also found in plants exhibiting high resistance to heavy metal ions (HM).The effect of Cd^{2+} ions on the structural and functional parameters of the halophyte *Suaeda salsa* was studied. The research task was to study the content of pigment, the intensity of lipid peroxidation (LPO) and the composition of membrane lipids. The objects of study were the leaves of *S. salsa* plants grown under laboratory conditions and wild-growing (Sw) plants collected under natural conditions in the basin of Lake Elton in southern Russia, and plants were grown in Green-House conditions (20–22 ° C, 1200 μmol / m^2 s^{-1}; containing Cd $(NO_3)_2$ 200 μM /L). The plants were divided into two groups: control (SK) and test samples (SCd).An assessment of the effect of NaCI and Cd^{2+} ions on plants of *S. salsa* did not reveal any visual signs indicating the toxicity of these two abiotic factors. The leaves of the SK and Sw plants are characterized by a high level of water content – 91–94 % of the fresh weight. The introduction of Cd^{2+} into the soil led to a decrease in water content in the roots of SCd. The highest content of ?hlorophylls and carotenoids was observed in plants grown on medium containing Cd^{2+}. Halophytes, which grew in natural conditions, were characterized by a lower content of photosynthetic pigments compared to the laboratory plants. In the leaves of SCd plants, a twofold increase in the intensity of POL was observed compared to SK. The total content of lipids in the leaves of the studied plants is 4.2–6.0 mg/g of fresh weight. In the composition of the main components forming the thylakoid membranes were observed rearrangements. The reaction of the pigment fund and lipids, responsible for the membrane structure, to the effects of Cd^{2+} ions in laboratory experiments was similar to the effect of soil salinity on plants under natural growing conditions.Thus, the mechanisms of resistance to NaCl and Cd^{2+} ions in halophytes are realized due to structural rearrangements of the membrane apparatus and activation of oxidative processes.

Predominance of gas exchange reduction over its recovery under heat and drought reflected in incomplete recovery of growth of spring oilseed rape even after exposure to elevated CO2 conditions

A. Diksaityte, A. Virsile, Institute of Horticulture, Lithuanian Research Centre for Agriculture and Forestry; J. Zaltauskaite, Vytautas Magnus University / Department of Enviromental Sciences; I. Januskaitiene, Vytautas Magnus University

In view of the current and growing impacts of climate change, the occurrence and severity of heat waves with extended drought periods undoubtedly will increase. Because of unique response of plants to combined treatments, recent studies highlight the importance of studying the impact of abiotic stresses on plants. So far, little it is known about the mitigating effect of elevated CO_2 on crop resistance to these stressors' combination. Hence, this study is aimed at the investigation of how an agronomical important crop spring oilseed rape (*Brassica napus* L.) will be able to cope with combined impact of heat wave (21/14 ºC *vs.* 33/26 ºC day/night) and drought with elevated CO_2 (400 *vs.* 800 μmol mol^{-1}) treatment and to what degree will manage their recovery after stress. The experiment was conducted in growth chambers under precisely controlled environment. Treatments were imposed at 13^{th} BBCH growth stage for 7 days and, after the cease of stress, plants were left for 7 days to recover under ambient climate conditions. The obtained results revealed that, at early vegetative stage, *B. napus* have rather high upper limit to temperature increase that allowed to perform them even better under +12 ºC heat wave compared to ambient climate conditions, in the presence of adequate water supply. However, the rate of recovery of gas exchange parameters of plants experienced combined heat and drought stress was significantly slower than its rate of reduction during the period of treatment that reflected in incoplete recovery of plant growth. Elevated CO_2 diminished the negative impact of drought stress, under heat wave conditions, on A_{sat} and shoot growth to a considerably extent. However, it had only a little effect on the recovery of A_{sat}, when additional CO_2 after stress treatment was also removed. After recovery period, both leaf area and shoot dry weight in drought-stressed spring oilseed rape's grown under heat wave conditions were significantly lower compared to control ones, regardless of CO_2 level.

TU118

Toxicity of MCPA herbicide on physiological laterations of lichen Ramalina fraxinea (L.) Ach.

G. Sujetoviene, K. Gasauskaite, Vytautas Magnus University

Phenoxy herbicides have been commercially available for over 60 years and are the most widely used family of herbicides worldwide. 4-Chloro-2-methylphenoxyacetic acid (MCPA) has been used in the United States, but has been the more widely used phenoxy herbicide in Europe, where it has been extensively used in forest management. The study aims to quantify the effects of increasing concentrations (0-100 mg/l) and the duration of exposure (0 and 24 h) of MCPA (phenoxy acid herbicide) on physiological status of the lichen *Ramalina fraxinea*. Results showed that MCPA exposure induced reduction in maximum capacity of PSII (F_V/F_M), chlorophyll *a* content along with chlorophyll degradation and adverse effects on cell membrane integrity. Measurements of physiological parameters indicated toxicity which was related with dose and time.

TU119

Measuring reproductive parameters in terrestrial plants - methods and challenges

C. Mihan, Bayer CropScience AG / Ecotoxicology; J. Davies, Syngenta / Environmental Safety; M. Geiger, BASF SE

EFSA's Scientific Opinion addressing the state of the science on the risk assessment of plant protection products (PPP) for non-target terrestrial plants (2014) raises awareness of assessing for adverse effects on plant reproduction. Currently, effects of PPP on terrestrial plants are evaluated in seedling emergence and vegetative vigour studies completed in accordance with OECD and OCSPP guidelines. These tests involve pre- or post-emergence applications and subsequent maintenance of young plants up to 4 weeks under glasshouse conditions, during which time assessments are made of vegetative parameters, e.g. shoot height and biomass. In contrast, the measurement of reproductive endpoints requires maintenance of adult plants until seed set and harvest. As such, reproductive tests are significantly longer, more complex and challenging than the current guideline tests. The challenges surrounding the development of reproductive test methods include: Species selection: the diversity of reproductive strategies across plant families creates complexity for species selection. Specifically, consideration should be given to life-cycle (e.g. biennials may be less suitable than annuals), pollination requirements (e.g. insect pollination may be difficult under glasshouse conditions) and flowering/germination requirements (e.g. dormancy-breaking treatments, vernalisation). Maintenance of healthy plant growth: consideration needs to be given to provision of optimum nutrients over the test duration as well as practicalities (i.e. space requirements) of maintaining mature plants for long periods. Prolonging the cultivation period will significantly increase pest and disease pressure and may necessitate the use of control measures. Endpoint measurement: reproductive endpoints are numerous and diverse across species (e.g. flower numbers and morphology, fruit and seed numbers and weight, time to flowering and seed set, F1 seed viability) although the relative contribution of each parameter to the survival of the population is unclear. Selection of suitable endpoints requires consideration of the feasibility of measurement (e.g. seeds within fruits are difficult to count) and measurement of the same endpoint across all species may neither be possible nor practical. This presentation is intended to raise awareness of the challenges regarding reproduction testing in terrestrial plants.

TU120

A comparison between vegetative and reproductive endpoints for two non target plant studies with non-crop species in greenhouse and field

A. Duffner, Eurofins Agroscience Services Ecotox GmbH / Terrestrial Ecotoxicology Lab; D. Ripperger, P. Mack, Eurofins Agroscience Services Ecotox GmbH; S. Knaebe, EAS Ecotox GmbH / Ecotox Field

Terrestrial plants are providing a broad spectrum of ecosystem services such as provisioning of e.g. food and natural medicines or the regulation of air quality (MEA 2005). Plants in the agricultural ecosystem can be divided into three basic groups: crop plant, target plants for herbicides (weeds) and non-target terrestrial plants (NTTP's). The main refuges for NTTP's in intensively used agricultural areas are field margins representing a semi-natural habitat. Since agriculture is the dominating land-use in the temperate zone protection of non-target plants is a regulatory aim. Using herbicides to reduce weed competition in agricultural areas can adversely affect non-target terrestrial plants growing at field margins. For a more realistic assessment of effects there are several suggestions to include also non-crop species in the testing scheme from the list provided in OECD guidelines (OECD 208 and 227) and to assess the life-cycle with flowering and seed production. The general objective of this work was to assess if a greenhouse and a field study with a similar experimental design results in a comparable outcome for vegetative and reproductive endpoints. The experimental design used in booth studies consists of one control and four herbicide application rates with the same herbicide product. In the greenhouse 6 replicates per tested rate were used while in the field 8 replicates were used to account for the higher variability in the field. Furthermore in the greenhouse species were grown individually while the field study consisted of plant communities established from seeds. The four rates included the field rate down to a 3% drift rate. Assessed were biomass and plant height at the vegetative and generative growing phase of the plants. The number of flowers and seeds and germination of the harvested seeds were assessed for selected species to evaluate differences in flowering and germination. Additionally, in the field study effects on plant community were assessed with multivariate analysis. MDDs were calculated for individual endpoints to see what the effect levels are that can be detected. The presented results will focus on the recovery of the vegetative endpoints biomass and plant height over time and on the reduction of seed production in both studies and the reduction plant frequency in the field study References: Millennium Ecosystem Assessment (MEA) (2005) Ecosystems and human well-being: synthesis. Island, Washington, DC

TU121

Predicting plant uptake of ionic chemicals: Redefining the dominant processes

C. Kjaer Jensen, DTU (Technical University of Denmark) / Environmental Engineering; S. Trapp, Technical University of Denmark DTU / Department of Environmental Engineering

Several tools exist to predict uptake of neutral chemicals into plants. For most of them, partition coefficients (Kow and Kaw) are highly relevant input parameters, and dominant processes are sorption and volatilisation. A few of the prediction tools are also considering chemical speciation (based on log D, pKa, pH) and are therefore, supposedly, applicable to ionizable chemicals (like most pharmaceuticals and pesticides). However, successful applications are rarely reported. We suspect that the reason for this lack is that polar, ionizable substances undergo, to a much higher degree, processes which are not well described. The dominant processes for ionic species are no longer sorption and evaporation, but rather: i) transformation / metabolism ii) ionization / ion trap / electrical interactions So far, both i) and ii) can hardly be predicted. A physically-based complex dynamic plant uptake model has been developed describing the uptake of ionizable chemicals down to a cellular level. Such a model holds the potential to describe the uptake and distribution in plants in a site- and chemical specific way. But it comes with the price of very many input parameters, i.e. complexity rather than parsimony. Sensitivity analyses reveal that the most sensitive parameters are not the usual suspects as hydrophobicity, volatility, growth rate and transpiration rate, but rather pH inside sap streams and cells, cell permeability to ions and descriptors of protein adsorption. Furthermore, also reaction and transformation rates are highly sensitive, in particular for polar and ionic compounds. These new sensitive parameters are not well described, leading to wide uncertainty ("semi-chaotic" behavior) and thus bad prediction power of the model - despite high effort. The same wide range of results can also be seen when comparing experimental results from literature. Work is currently being done to reduce the input parameter space and to minimize the uncertainty. The model is being improved and tested against various datasets. The present version of the model can be downloaded for free in an excel implementation from https://homepage.env.dtu.dk/stt/2017Release_Plant_Model/index.htm

TU122

Influence of drift interception by canopies on herbicide effects on non-target terrestrial plants

L.S. Ortego, Bayer AG Crop Science Division / Environmental Toxicology and Risk Assessment; R.J. Isemer-Kellner, Bayer Ag / Environmental Safety Ecotoxicology; D. Moore, Intrinsik Ltd; T. Xu, Bayer AG Crop Science Division / Environmental Fate; J. Tang, Bayer AG Crop Science Division / Environmental Exposure Assessment; T. Hall, Bayer CropScience / Environmental Toxicology and Risk Assessment; I.M. Rodea Palomares, Bayer AG Crop Science Division; A.C. Chapple, Bayer AG Crop Science Division / Environmental Safety; Y. Yang, BayerCropScience / Environmental Fate; J. Hanzas, STONE EnvironmentalEngineering & Science,Inc. / Agrochemical Fate and Exposure; B. Brayden, K. Watson, Stone Environmental, Inc.; S.I. Rodney, Intrinsik Environmental Sciences Inc / Biology; C. Banman, SynTech Research, Inc. / Ecotoxicology

This field study was designed to determine the distance downwind from a treated area at which the biomass of non-target terrestrial plants (NTTP) is no longer significantly affected by applications of an herbicide formulation ("no observed effect distance"). In addition, influence of downwind vegetation on the effects of the herbicide on NTTPs was assessed. Navy bean and lettuce plants have been shown to be sensitive to the herbicide under investigation in standard greenhouse studies. Potted plants of each species (n = 25 for each species) were placed downwind of an application area on either bare ground (worst-case exposure) or in the off-crop edge vegetation (typical exposure). The field portion of the study was done in October 2018 at an agricultural site in Stilwell, KS; USA in Johnson County using a ground boom sprayer and coarse spray nozzles. Potted plants were placed in staggered rows at locations approximately 1.5, 3, 6, 15 and 30 m (5, 10, 20, 50, and 100 ft) downwind from the edge of the application area. For each exposure scenario, there were four spray swaths perpendicular to the off-field transects. Following spray application, the potted plants were transported to an indoor greenhouse area and maintained for an additional 21 or 28 days. Biological measurements were monitored per standard vegetative vigour guideline (EPA). Clear differences were observable in the effects for both test species between the test plants placed in edge vegetation and those plants placed on bare ground. Results suggest that typical exposure of NTTPs in vegetated off-field areas by herbicide drift leads to less pronounced effects than predicted by exposure on bare ground. Furthermore, this study supports the conclusion that standard greenhouse studies may seriously over-predict the effects of herbicide drift onto non-target plants.

TU123

A graphical user interface for applying the plant community model IBC-grass in ecological risk assessments

J. Reeg, University of Potsdam / Plant Ecology and Nature Conservation; S. Heine, Bayer Ag / Effect modelling; C. Mihan, Bayer AG Crop Science Division / Ecotoxicology; S.P. McGee, Bayer CropScience LP / Environmental Health Sciences; T.G. Preuss, Bayer AG Crop Science Division / Environmental Safety; F. Jeltsch, University of Potsdam

Ecological risk assessments aim at estimating the potential risk for the environment via a tiered approach. If standard greenhouse tests on individual-level fail, higher tier options can be conducted to more accurately evaluate potential undesirable effects on populations or communities. In the EFSA opinion on potential higher tier options for non-target terrestrial plants, modeling studies are mentioned. However, ecological models are often very complex and good modeling knowledge is necessary in order to use such models. In addition, regulators are often not modelers and a lack of modeling experience may lead to hesitation by regulators to use model predictions in their decision making. Thus, there is an increasing need in facilitating the use of ecological models for risk assessors and regulators. In the last few years, we refined the plant community model IBC-grass to be a useful tool for extrapolating individual-level effects based on standard greenhouse experiments to community-level. To facilitate the application of the model in risk assessments of non-target terrestrial plants, we developed a graphical user interface (GUI), which can be used also by people not familiar with ecological models. The software is available for free and comes with the user manual and the good modeling practice (GMP) document. The GMP document gives the user an overview of the model development, processes included in the model, outcomes of sensitivity analyses and validation of the model. It should help regulators to understand the model and to decide whether to use the model for their decision making. In this poster presentation we will introduce the GUI and show an exemplary application.

TU124

Simulation model to study percolation toxicity of pesticides, isolated and in mixtures, in Raphidocelis subcapitata

L.P. Figueiredo, University of Sao Paulo - USP; D.B. Athayde, University of São Paulo / Núcleo de Ecotoxicologia e Ecologia Aplicada; R.A. Moreira, University of São Paulo / São Carlos School of Engineering; H. Sarmento, Federal University of Sao Paulo; M. Daam, CENSE & New University of Lisbon, Lisboa; E.G. Espindola, University of São Paulo USP / Hydraulics and Sanitation

Pesticides have been recognized worldwide for their importance in the global loss of biodiversity in aquatic environments and the functioning of ecosystems. In the aquatic environment, algae play an important role as the basis of the food chain and effects on their communities can impact higher trophic levels by altering the functioning of the ecosystem as a whole. However, even with these environmental impacts, Brazil is the largest consumer of pesticides in the world, which justifies the need to study the toxicity of these compounds in the biological community. Another crescent preoccupation is about the global warming and impact in ecosystems, once, the temperature can alter the distribution environmental contaminants. Considering that, this research was to assess the effects of pesticides Kraft®and Score®(isolated and simple mixture) largest used in Brazil, on *Raphidocelis subcapitata*. The experiments were carried out with four treatments (Kraft, Score, Kraft+Score and Control), in simulators filled with 0.1 $m^3$of soil, which received an application of 4.8µL Kraft and 1.3µL of Score, diluted in 1L, being reapplied every seven days, following manufacturer's application instructions, and performed at two temperatures of 23ºC and 33ºC. On the experimental units, 6 rains (twice a week) were simulated, in which the percolated material of the rains was used to carry out the tests with the algae, following the ABNT NBR 12648, and analyzed population growth rate by flow cytometry. Data were analyzed using Analysis of Variance (ANOVA), followed by Dunnett. Analyzing the physical and chemical variables, it was verified that they have remained within the established for the test species. For nutrients, total nitrogen, total phosphorus, nitrate, ammonia, total phosphorus dissolved were analyzed to characterize percolate, and even with high values, between 1000 - 10000, were almost the same for both temperatures tested. The results showed high Kraft toxicity, in both temperature tested. In 23ºC, were significant difference of control in two experiments (2 rains) realized, in the first application the pesticide mixture affected algae growth and in third, all the treatments were different from the control. To 33ºC, the growth of *R. subcapitata*was affected by Kraft in the first and in the second application, even as in the mixture. Which indicate that the temperature interferes in the pesticides toxic effect under non-target organisms.

TU125

Evaluation of the effect of caffeine on the green microalgae Monoraphidium sp. (chlorophyta)

A. Sobrino-Figueroa, Universidad Autonoma Metropolitana, Iztapalapa / Hidrobiology; S. Alvarez-Hernandez, Universidad Autónoma Metropolitana-Iztapalapa / Applied Ficology Laboratory. Department of Hidrobiology

In this study the effects in: growth, chlorophyll concentration, carotenoid concentration, phenol concentration and lipoperoxidation degree (Tbars) of the green microalgae *Monoraphidium* sp. caused by exposure to caffeine were determined, because at present, caffeine is considered an emerging pollutant. Static bioassays were performed with a duration of 72 hours. The microalgae were exposed to 5 caffeine concentrations (0.025, 0.05, 0.5 5, 50 and 100 mg L^{-1}) in triplicate to determine the EC_{50} (effective concentration 50). Subsequently, a sublethal bioassay was carried out where the microalgae were exposed to concentrations of 0.025, 0.05, 0.5, 50 mg L^{-1} plus a control group for 8 days. At the end of the exposure period, the population growth, the concentrations of chlorophyll *a* and *b*, carotenoids, phenols and degree of lipoperoxidation were evaluated. The results obtained showed that there were significant differences between the responses of the control group and the microalgae exposed to caffeine ($p < 0.05$). The lowest levels of total chlorophylls were obtained in the concentration of 0.025 mg L^{-1}, but an increase in the concentration of chlorophylls (a and b) in the concentrations of 0.5, 5 and 50 mg L^{-1} was observed. A higher production of carotenoids compared to the control group was detected in all the cases. An increase in the production of phenols was recorded in the tests with caffeine concentrations of 0.05, 0.5, 5 and 50 mg L^{-1}. The average levels of Tbars recorded in the bioassays with the concentrations of 0.05, 0.5, 5 and 50 mg L^{-1}., were similar to those recorded in the control group. Caffeine did not affect the growth of microalgae at the concentrations tested in this study.

TU126

Comparative sensitivity of Lemna gibba and Lemna minor to 3,5-dichlorophenol

J.R. Rana, M. Kamle, D. Patel, A. Rai, Jai Research Foundation / Ecotoxicology; N. Pawar, Jai Research Foundation (JRF) Global / Ecotoxicology; N. Khan, Jai Research Foundation / Chemistry

Assessment of environmental risk requires toxicity test on aquatic plant to determine potential impact of contaminates using primary producers. Many research have proved the difference in sensitivity across phylogenetic groups of plant. In the present study, an ecological impact of 3,5-dichlorophenol (DCP) was assessed using the aquatic floating vascular plants, *Lemna gibba* and *Lemna minor*. The sensitivity of several ecologically relevant parameters namely presence of DCP in test media, primary measurement variable, number of fronds and one other measurement variable, dry weight were compared after 7 day exposure to DCP. Cultures were assessed visually for plant development. Yield and growth rate inhibition for frond and dry weight were calculated at the end of experiment. Results indicate concentration of 3,5-dichlorophenol was maintained >80% in test medium throughout the experiment. Doubling time of frond number of *L. gibba* and *L. minor* in the control was 1.93 (corresponding to 12.5 times increase in seven days) and 1.58 (corresponding to 21.39 times increase in seven days) days, and an average specific growth rate of control was 0.36/d and 0.44/d, respectively. *L. gibba*, growth rate and yield inhibition EC_{50} for frond was 10.46 and 6.92 mg/L, respectively while for dry weight was 7.27 and 5.44 mg/L, respectively. Based on results of the statistical analysis, the NOEC and LOEC for growth rate and yield of frond were 2.7 and 4.4 mg/L, respectively and for growth rate and yield of dry weight were 4.4 and 7.0 mg/L, respectively. *L minor*, growth rate and yield inhibition EC_{50} for frond was 2.75 and 1.61 mg/L, respectively while for dry weight was 1.54 and 1.16 mg/L, respectively. Based on results of the statistical analysis, the NOEC and LOEC for growth rate of frond were 0.7 and 1.5 mg/L and yield of frond were 0.3 and 0.7 mg/L, respectively. The NOEC and LOEC for growth rate and yield of dry weight were 0.3 and 0.7 mg/L, respectively. Finding postulates that *L. minor* ismore sensitive than *L. gibba* for DCP. Through testing the phytotoxicity of DCP to *L. gibba* and *L. minor*, it is evident that there are considerable differences in sensitivity among species and that the selection of species is necessary to provide an acceptable margin of safety in evaluating the hazard untaken by the chemicals to the aquatic environment.

TU127

Impacts of contaminants in freshwater macrophyte species

Gonçalves, University of Aveiro / department of Biology & CESAM; J.C. Marques, MARE - Marine and Environmental Sciences Centre, Dep. of Life Sciences, Faculty of Sciences and Technology, University of Coimbra / MARE, Dep. of Life Sciences, Coimbra University; A. Gonçalves, MARE - Marine and Environmental Sciences Centre, Department of Life Sciences, Faculty of Sciences and Technology, University of Coimbra & Dep. of Biology and CESAM, University of Aveiro / MARE (Marine and Environmental Sciences Centre), Department of Life Sciences, Faculty of Sciences and Technology / Dep. of Biology and CESAM

In the last decades, the use of pesticides has been intensified mainly in European Mediterranean regions, and in some cases exceeding the limits of regular legislations established by the European Union. The intensive use of the chemicals on agricultural fields surrounding aquatic systems may comport consequences to the ecosystems and communities. Primextra® Gold TZ is one of the most used herbicides in corn crop fields of the Mondego valley, according to the information from agricultural cooperatives. The main active ingredients of the herbicide are s-metolachlor and terbuthylazine. Moreover, copper based formulations, such as copper sulphate, are also quite used in the agriculture practice. Thus, this work pretended to evaluate the effects of these chemicals (s-metolachlor, terbuthylazine and copper sulphate) in the non-target species *Lemna minor* and *L. gibba*, two freshwater macrophytes, reported as a standard species in ecotoxicological bioassays. In a first step, the organisms were exposed to the contaminants under laboratory conditions, after which the biochemical analysis to determine changes on the nutritional value was performed through the determination of fatty acids, polysaccharides and free sugars profiles. The results showed *L. gibba* ($LC_{50Copper}$ =0.459 mg/L; $LC_{50S\text{-}Metolachlor}$ =0.087 mg/L) was more tolerant than *L. minor* ($LC_{50Copper}$= 0.207 mg/L; $LC_{50S\text{-}Metolachlor}$ =0.043 mg/L) when exposed to copper and s-metolachlor. However, the opposite trend was observed when macrophytes were exposed to terbuthylazine, with *L. minor* (LC_{50TBZ} =0.0934 mg/L) demonstrating higher sensitive to this chemical action than *L. gibba* (LC_{50TBZ} =0.0439 mg/L). Furthermore, the composition on lipids and carbohydrates was also changed with the exposure to all compounds for both species. Therefore, biochemical biomarkers are important tools and endpoints in ecotoxicological studies and may be used as early-warning indicators of the presence of contaminants at the ecosystems and on the determination of potential effects in their communities. This study was supported by Fundação para a Ciência e a Tecnologia (FCT) through the strategic projects UID/AMB/50017/2013 granted to CESAM and UID/MAR/04292/2013 granted to MARE. FCT funded A.F. Mesquita, A. M. M. Gonçalves, C. Nunes and A. P. Cuco (SFRH/BD/139831/2018; SFRH/BPD/97210/2013; SFRH/BPD/100627/2014 and DPA 17-781). The research was partially supported through the project Ref. POCI-01-0145-FEDER-022127.

Mode of action and adverse effects of gamma radiation in the aquatic macrophyte Lemna minor

L. Xie, NIVA - Norwegian Institute for Water Research / Environmental Toxicology; K.A. Solhaug, Norwegian University of Life Sciences; D.A. Brede, Norwegian University of Life Sciences / Centre for Environmental Radioactivity; O.C. Lind, Norwegian University of Life Sciences / Faculty of Environmental

Sciences and Natural Resource Management; Y. Song, Norwegian Institute for Water Research (NIVA) / Ecotoxicology and Risk Assessment; B. Salbu, Norwegian University of Life Sciences; K. Tollefsen, NIVA / Ecotoxicology and Risk Assessment

Ionizing radiation has been reported to cause adverse effects in different primary producers including both autotrophs and heterotrophs. Upon exposure, high dose rates of ionizing radiation can reduce reproduction and growth, cause damage to DNA and other biomolecules. However, the physiological responses and toxicity mechanisms occurring at low doses and dose rates are still poorly understood in aquatic plants. This study aimed at characterizing the biological effects of ionizing (gamma) radiation from a cobolt-60 (^{60}Co) irradiation source using a combination of Mode of Action (MoA) characterization and determination of adverse (apical) effects in duckweed (*Lemna minor*). Chronic toxicity was assessed as inhibition of growth after 7 days exposure to 1-70 mGy/h according to the OECD test guideline 221 (OECD,2006). The MoA of gamma radiation was determined as oxidative stress (ROS and lipid peroxide formation) and DNA damage in combination with physiological responses such as oxidative phosphorylation (OXPHOS) and Ca^{2+} release, photosystem II (PS II) activity, CO_2 assimilation, antioxidant responses (total GSH), and pigment changes (Chlorophyll *a*, Chlorophyll *b* and carotenoids). The results indicated that changes to tGSH, pigments, CO_2 uptake, Ca^{2+} release and DNA occurred at dose rates between 1 and 14 mGy/h, whereas ROS formation and lipid peroxidation (LPO) together with decrease in OXPHOS and growth parameters were only observed at dose rates of 24 mGy/h and higher. An Adverse Outcome Pathway (AOP) network was developed to portray causal relationships between gamma radiation induced physiological responses and adverse outcomes in *L. minor*.

TU129

Simple CA and IA models underestimate the phytotoxicity of micropollutants caffeine and nonylphenol

M. Lane, University of Helsinki / Faculty of Biological and Environmental Sciences; P.T. Kajankari, University of Helsinki / Department of Environmental Sciences; O. Penttinen, University of Helsinki / Faculty of Biological and Environmental Sciences

Given the prevalence of micropollutants in aquatic systems, the assessment of mixture effects is vital to a complete understanding of the effects of chemicals in the environment. Caffeine and nonylphenol are among the most commonly detected micropollutants in freshwater systems but come from different chemical classes and differ greatly in their individual potencies. Two major models dominate the assessment of mixture toxicity: concentration addition (CA), which is typically applied to chemicals with the same mode of action, and independent action (IA), which is applied to chemicals with different modes of action. Single chemical tests and an equitoxic binary mixture test were performed with the aquatic macrophyte *Lemna minor* to assess the potential for interaction between these commonly co-occurring chemicals. Seven day exposures were conducted with endpoints including frond number, frond area, fresh weight and chlorophyll content. Concentration-response curves from the single chemical tests were used to select equitoxic mixture ratios for the mixture test, and the results were then compared to the predicted mixture effect based on CA and IA models. In the single chemical tests, caffeine did not have high phytotoxicity on its own, indicating effects at environmental concentrations are unlikely. The toxicity of nonylphenol was greater but limited by nonylphenol's water solubility and associated with higher variability. Significant growth inhibition, tissue necrosis and chlorophyll alterations were detected at only one order of magnitude from the highest reported environmental concentrations, suggesting environmental effects from nonylphenol exposure are possible. IA underestimated the toxicity of the caffeine-nonylphenol mixture by at least a factor of two at all effect levels. CA also underestimated the mixture toxicity, but the model deviation ratio was under two for the tested effect levels and wide confidence intervals overlapped with the mixture regression obtained from experimental data. Based on these results, synergistic interaction between caffeine and nonylphenol is possible. However, CA cannot be ruled out as an effective model if the uncertainty could be reduced. The ambiguity of the results indicates the difficulty of choosing suitable mixture models in non-ideal cases.

TU130

Modelling growth of Lemna exposed to Metsulfuron-methyl using a dynamic energy budget approach

J. Klein, Fraunhofer IME - Institute for Molecular Biology and Applied Ecology / Ecotoxicology; U. Hommen, Fraunhofer IME

The exposure of pesticides are dynamic and variable in time. However due to the complexity of the exposure profile, it is not possible to study every exposure in a laboratory experiment. To allow extrapolation to any predicted exposure profile, we model effects on growth using a simplified dynamic energy budget model (based on DEBkiss). This model is a mechanistic approach relying on mass and energy balance, which is suitable for the sublethal toxicity endpoint growth. We compare our model's performance with another *Lemna* model, developed by Schmitt et al. 2013. As a case study, we consider the sulfonyl-urea herbicide Metsulfuron-methyl (MSM).

Old herbicide in new light: filling the data gap of mecoprop-p for dicotyledonous macrophytes

C. Périllon, Umweltbundesamt / IV 2.5 FSA; M. Feibicke, R. Gergs, Umweltbundesamt; B. Alscher, I. Janthur, R. Schmiediche, L. Hoenemann, German Environment Agency; S. Mohr, German Environment Agency / IV

The fate and concentrations of the auxin phytohormon herbicide mecoprop-p (MCPP-P) in the aquatic environment is well documented but little toxicity data of dicotyledonous aquatic macrophytes have been published so far over the last decades. To fill up this data gap, the German Environment Agency (UBA) conducted a microcosm study in order to test the sensitivity of 10 different macrophytes (mainly dicotyledonous species). Ten macrophyte species (*Callitriche palustris, Ceratophyllum demersum, Hottonia palustris, Hydrocotyle leucocephala, Hydrophila polysperma, Ludwigia repens, Myriophyllum spicatum, Nymphoides peltata, Ranunculus aquatilis*, and *Veronica beccabunga*) were exposed to MCPP-P in 7 concentrations ranging from 8 μg/L to 512 μg/L for 21 days in each one microcosm. Two further microcosms served as controls. For each species, ten individuals were planted separately in plant pots, which were filled up with 2 layers of sand (bottom and top) and a middle layer of a mixture of commercial pond soil and sand. Plant preparation and endpoints were adapted to each species but in general fresh weight, dry weight, length of main shoot, and number of leaves/whorls were measured at the start and at the end of the experiment. Eight species proofed to be sensitive to MCPP-P. For 5 species it was possible to generate EC_{50} values ranging from 47 to 444 μg/L MCPP-P with *M. spicatum* being one of the most senstive species. On base on data of this study, it was possible to construct a species sensitivity distribution (SSD) model combining other published data. The results will be critically discussed. Our test confirms the reliability of the use of *M. spicatum* as representing dicotyledonous species, as it proved to be one of the most sensitive species in our study for the tested auxin herbicide. Regarding the new low RAC concentration of MCPP-P, it has to be highlighted that uses like in bitumous roofing felts are not in the focus of any regulation so far. This application, however, can lead to high run-off concentrations entering surface waters exceeding the RAC values.

TU132

Macrophyte Toxicity Testing: Influence of Growth Form on Sensitivity

E. Wiredu, Eurofins Agroscience Services Ecotox GmbH / Aquatic Ecotoxicology; G. Gonsior, GG BioTech Design

The importance of macrophytes in maintaining biodiversity in the ecosystem cannot be understated. They provide food, habitat and affect the physical and chemical properties of aquatic systems. The current guidance on tiered risk assessment for plant protection products for aquatic organisms in edge-of-field surface waters involves performing toxicity test on macrophytes, green algae, additional non-green algae, and on *Lemna* species. In case the herbicide simulates a plant growth hormone or if *Lemna* species is not sensitive to the herbicide, then testing with *Myriophyllum spicatum* is recommended. Testing on *Glyceria maxima* is also recommended in case the action of the herbicide is primarily on monocots. Furthermore, additional aquatic plants can be tested in case the uncertainties in the outcome of the risk assessment were high in order to refine the risk assessment process. In the current study, toxicity tests were performed using six rooted aquatic macrophytes. These were namely *Myriophyllum aquaticum, Hygrophila polysperma, Limnophila sessiliflora, Callitriche pallustris, Nasturtium officinale and Heteranthera zosterifolia.* These aquatic plants can grow emersed for example during periods of drought and for example submersed during flooding. Also the different forms can be built in the same habitat. Based on these findings, the different growth forms of these species were tested. The aquatic plant species were obtained from commercial sources and adapted in both their emersed and submersed states prior to the test. 3,5-Dichlorophenol (DCP) was used as the test substance and the EC_{50} of the mean growth rates and yields were determined and compared for each species. The results obtained showed that, the different growth forms of the plants had an influence on the sensitivity of the plant species to the test substance. Preliminary results also indicated that, most aquatic plant species which were adapted to the emersed state demonstrated lower sensitivity to 3,5-DCP compared to those adapted to the submersed state.

TU133

A draft OECD Test Guideline for the emergent macrophyte, Glyceria maxima, in a water-sediment system: results of a ring-test with Imazapyr

J. Davies, Syngenta / Environmental Safety; G. Arts, Wageningen Environmental Research (Alterra) / Environmental Risk Assessment; J. Kubitza, BASF SE; K. Kuhl, Bayer AG / Crop Science Division; M. Ratte, ToxRat Solutions GmbH & Co. KG; R. Wedeking, Bayer Ag

Data requirements introduced under EU Directive 1107/2009 stipulate that tests with aquatic plant species other than *Lemna* may be required for plant protection products which show selectively higher toxicity to either dicotyledonous or monocotyledonous plant species in terrestrial plant tests. In these cases, the recommended dicot and monocot species are *Myriophyllum* and *Glyceria*, respectively. OECD Test Guideline 239 for testing *Myriophyllum spicatum* in a water-sediment system was adapted to facilitate growth of the emergent, reed grass, *Glyceria maxima*, and ring-tested in 13 laboratories during 2016 and 2017 with the herbicide, isoproturon. Results from this ring-test were used to adapt the test protocol in terms of plant propagation recommendations, test system specification, test duration, assessment parameters and draft validity criteria. This revised protocol was used in a second ring-test with the herbicide, imazapyr in 11 laboratories during the Summer/Autumn of 2018. In addition, this work was submitted to OECD for consideration as a new Test Guideline in November 2018. This presentation will summarise results from the imazapyr ring-test and discuss progress towards delivery of an OECD Test Guideline.

Regime shifts in freshwater ecosystems exposed to multiple stressors by increasing temperature, fertilizers and pesticides (CLIMSHIFT)
E.M. Gross, University of Lorraine / Laboratoire Interdisciplinaire des Ecosystemes Continentaux; J. Allen, Université de Toulouse / ECOLAB UMR CNRS 5245; N. Kipferler, Ludwig-Maximilians-University Munich / Department of Biology; B.H. Polst, Helmholtz centre for environmental research - UFZ / Department of Bioanalytical Ecotoxicology; V. Vijayaraj, Universite de Lorraine / Laboratoire Interdisciplinaire des Ecosystemes Continentaux LIEC UMR CNRS; F. Hölker, Leibniz Institute of Freshwater Ecology and Inland Fisheries / Ecohydrology; J. Leflaive, ECOLAB UMR 5245 CNRS; M. Schmitt-Jansen, UFZ - Helmholz Ctre Environm. Research / Bioanalytical Ecotoxicology; H. Stibor, Ludwig-Maximilians-University Munich / Department of Biology; S. Hilt, Leibniz Institute of Freshwater Ecology and Inland Fisheries / Ecosystem Research Division
This poster will present the aims and first results of our French-German collaborative project CLIMSHIFT. Shallow freshwater habitats provide vital ecosystem functions but are threatened by multiple stressors. While a response to global climate change might be gradual, abrupt changes are possible when critical thresholds by additional effects of local stressors are exceeded. The difficulty in analysing effects of multiple stressors is to account for complexity, as stressors may act additive, synergistic or antagonistic. CLIMSHIFT aims for a mechanistic understanding of stressor interactions acting on shallow aquatic systems, which are especially vulnerable to climate warming and agricultural run-off due to their high surface to water ratios, large riparian interface and groundwater connectivity. Complex interactions between different functional groups of benthic and pelagic primary producers and associated consumers result in alternative stable regimes. Multiple stressors may trigger non-linear shifts between those regimes, with far-reaching effects on crucial ecosystem processes and functions. Our main hypothesis is that increased temperature will enhance negative effects of agricultural run-off, containing nitrates, pesticides and copper. Submerged plants, periphyton and phytoplankton as primary producers will be combined with the second trophic level, consumers, composed of the snail Lymnaea, consuming periphyton and plants, and benthic and pelagic phytoplankton filter-feeders, Dreissena and Daphnia. We will apply exposure scenarios at two different spatial scales to understand effects at the individual, community and ecosystem level. Investigations in microcosms at laboratory scale will be upscaled to larger, outdoor mesocosms. We will use an integrative dynamical model approach to simulate potential outcomes and critical thresholds, and predict stressor interactions. We expect that combined stressors will lead to sudden shifts in community structure in highly coupled systems. Macrophytes are expected to be replaced by phytoplankton or benthic algae, with major consequences for important ecosystem functions. Common ecotoxicological stress indicators such as growth and biomarkers of the different organisms will be combined with functional community/ecosystem response factors. The outcome of our project will support de definition of “safe operating spaces” for a sustainable agriculture and management of shallow aquatic systems in a changing world.

Phytotoxic effects of the hydrolate of three aromatic plants with pesticidal properties
D. Ballestero, J. Val, San Jorge University; M. Pino, San Jorge University / Facultad ciencias de la salud; E. Langa, San Jorge University; A.M. Mainar, Universidad de Zaragoza; J. Navarro, CITA
The TECHNOBIOCROP Project (Biopesticide development by chemical and biotechnological tools) focuses on the identification of biopesticides that could be a good alternative to pesticides of synthetic origin because of their effectiveness but also because their effect could be less harmful to the environment. In the process of extracting essential oils by vapour pressure extraction, there are other products, such as the hydrolates, that have been usually considered as by-products and are less studied. These aqueous extracts have water-soluble volatile compounds and recently showed numerous bioactive ingredients. In this study, we analyzed the phytotoxic effect of the hydrolates from three aromatic plants that have shown interesting properties as plant/fungal/agriwaste-based crop protectants: *Artemisia absinthium, Lavandula luisieri and Satureja montana*.The phytotoxicity of these hydrolates was studied through monitoring their impact on the root growth of onions (*Allium cepa* L.). The three hydrolates were able to inhibit the root growth of *A.cepa* at very low concentrations, within a range of LC_{50} values between 0.022 to 0.054 v/v. The phytotoxicity of the hydrolates from the highest to the lowest was: *Lavandula luisieri*> *Artemisia absinthium*> *Satureja montana.* This study allows continuing with the research of the effects of new biopesticides from hydrolate fractions on the environment and especially on non-target organisms, such as plants, in order to follow the regulations that will allow their commercialization. The authors thank the financial support of MINECO-FEDER (CTQ2015-64049-C3-2-R) and Gobierno de Aragón-FSE (GATHERS E39_17R).

New Insights into Chemical Exposures over Multiple Spatial and Temporal Scales (P)

TU137
Spatial and temporal distribution of 41 pharmaceuticals in European rivers
J. Wilkinson, The University of York / Natural and Built Environments; A. Boxall, University of York / Environment and Geography Department
Despite significant research over the last two decades, the spatial and temporal resolution of active pharmaceutical ingredients (APIs) occurring in wastewater, their removal in water treatment and fate in the aquatic environment remains unclear. Here we conduct targeted monitoring of 41 APIs in seven rivers in: Odense, Denmark (n=1), Dulman, Germany (n=1), Santiago de Compostela, Spain (n=1) and York, Barnsley and Durham in the United Kingdom (n=4) over one year. In addition to river water, influent and effluent samples were collected from wastewater treatment plants (WWTPs) discharging to all rivers except in the York catchment. Wastewater samples were also collected quarterly from sewers discharging from hospitals and residential areas in Odense, Santiago de Compostela and Durham. All samples (n=337) were 10mL of water collected from a total of 36 sampling locations on a monthly basis between March 2017 and February 2018. Samples were filtered with a glass microfiber syringe filter (0.7 μm pore size) then frozen on dry ice in the field before analysis at the University of York, York, UK. Shipment occurred overnight on dry ice and samples were stored at -20?C until analysis. Quantification was achieved using an in-house validated method for HPLC-MS/MS. Significant differences in the composition of wastewater by therapeutic class of API were observed in both waste- and river water between all the studied waste and rivers systems. No clear difference was observed in the composition of wastewater by therapeutic class between sewers originating from hospitals and residential areas respectively. Furthermore, these compositions and concentrations remained relatively unchanged between sewers and WWTP influent and were consistently dominated by the anti-hyperglycaemic drug metformin and analgesic paracetamol. Overall mean API removal efficiencies at WWTPs ranged from 83% (Dulman, Germany) to 35% (Barnsley, UK). Clear spatial and temporal patterns emerged in the monitored rivers, largely driven by WWTP discharge and variation in flow/ seasonal changes in API use respectively. Highest sum concentrations were observed in the River Sar (Santiago de Compostela) with a mean 17.6μg/L total concentration while the lowest was observed in the York catchment (Rivers Ouse and Foss) with a 2.1μg/L total concentration. These data indicate that both temporal and spatial considerations are needed to develop a complete picture of API fate in the built and aquatic environments.

TU138
Simulating behaviour of petroleum products during sewage water treatment
N. Thunnissen, Radboud University Nijmegen / Environmental Science; D. van de Meent, Association of Retired Environmental Scientists ARES / Environmental Science; J. Struijs, Association of Retired Environmental Scientists ARES; J.A. Hendriks, Radboud University Nijmegen / Department of Environmental Science; R. van Zelm, Radboud University / Environmental Science
Petroleum products are complex mixtures of chemical compounds. The physical-chemical properies of these compounds show a wide variety and as a result, will behave differently, but predictable, upon release to the environment. An approach to assess the risk of petroleum products is the hydrocarbon block method (HBM). With the HBM and the multimedia model SimpleTreat, distribution and elimination of petroleum products can be predicted in aerobic wastewater treatment plants (WWTP). A major feature of this model is that it only requires a few basic properties of the chemical to calculate emissions to air, surface water and in produced sludge (sometimes applied to agricultural soil). Furthermore, in recognition of the complexity of petroleum products, more advanced treatment processes are constructed in WWTP. So, it would be of value to upgrade SimpleTreat with more advanced treatment processes, such as dissolved air flotation (DAF). DAF is a process for removing suspended particles from liquid by bringing the particles to the surface of the liquid. When this process is added to SimpleTreat, it is important to understand how including DAF affects the concentration predictions of petroleum products. The aim of this study is to adapt SimpleTreat for simulating behaviour of petroleum products during sewage treatment. The intended use of this re-parametrized model is focussed on risk assessment of petroleum products. Modelling was performed using SimpleTreat 4.0 and the CONCAWE library. In SimpleTreat 4.0 a simulation of DAF was

included. Furthermore, chemical fate in WWTP of the library compounds was modelled for SimpleTreat 3.1, SimpleTreat 4.0. The latter with and without simulation of DAF. Comparison of model outcome o will give insight in the effect of changes in SimpleTreat. It appeared that the upgrade of SimpleTreat to 4.0 has an effect on the fate in WWTP. The most influencing parameter for these calculations seemed to be the hydraulic retention time. However, the outcome of these calculations still needs to be validated. The influence of including the DAF process in the model will also be shown. Our study explains the added value of using an up-to date multimedia model to get a more reliable insight in the risk of petroleum products.

TU139

Quantification of 9 bisphenol analogues in total blood, plasma and urine samples from a cohort of workers through a DLLME extraction followed by GC-MS determination

N. González, Universitat Rovira i Virgili; S. Cunha, University of Porto; J.O. Fernandes, REQUIMTELAQV Instituto Superior de Engenharia do Porto; C. Monteiro, University of Porto; M. Marques, Universitat Rovira i Virgili / Chemical Engineering; M. Nadal, Universitat Rovira i Virgili / School of Medicine, IISPV; J.L. Domingo, Universitat Rovira i Virgili / Laboratory of Toxicology and Environmental Health

Endocrine disruptors (ED) are a wide group of chemicals that can interfere with the normal function of the endocrine system, causing harmful effects on human health. Among them, there is the group of bisphenols (BPs), synthetic chemicals widely-used for the manufacture of polycarbonate plastics and epoxy resins. Due to their hardness, transparency and high strength over a wide range of temperatures, BPs are extensively used by the industry in food contact materials, such as coatings and linings of drink cans and reusable bottles, medical equipment and thermal paper. Due to the widespread use of these chemicals, exposure cannot be avoided; therefore, an accurate exposure assessment is required for the protection of human health. The aim of this study was to assess the exposure to 9 bisphenols (A, AF, F, B, S, AP, P, S and Z) in total blood, plasma and urine samples from a cohort of workers at a hazardous waste incinerator located in Tarragona (Catalonia, Spain). Free and conjugated BPs were determined through a dispersive liquid-liquid microextraction (DLLME) which combines extraction, derivatization and concentration in only one step. This was followed by a gas chromatography coupled to mass spectrometry. Only BPA was found in all biological matrices. In urine, free BPA was detected in 5 out of 25 samples (20%) and 8 samples presented values below the limit of quantification (< 0.1 μg/L). In turn, total BPA (conjugated + free) was found in 13 samples in concentrations ranging from 0.1 to 2.820 μg/L. For the total blood samples, free BPA was detected in 11 samples (0.27 – 1.65 μg/L) while total BPA was detected in 13 samples (0.04 – 1.52 μg/L). BPB was also detected in 3 blood samples in higher concentrations than BPA (2.51, 2.81 and 2.53 μg/L). Total BPB was only detected in a single sample of blood (2.69 μg/L), while BPA was detected in 3 out of 5 plasma samples, in concentrations ranging from 1.06 to 13.4 μg/L. BP concentrations were correlated with available data regarding levels of some organic compounds and heavy metals, previously determined in the same samples of plasma, urine and blood.

TU140

Bisphenol A: Reassessment of sources and emission pathways for FlowEQ-model assisted estimation of surface water concentrations

I. Dlugi, B. Fischer, Ramboll Environment & Health GmbH; M. Bunge, Covestro Deutschland AG; M.J. Bock, Ramboll / Ecological Services; B. Lenselink, Trinseo Netherlands B.V.; B. van Sikkelerus, SABIC; R. Hunziker, S. Tenbrock, Olin, BC Switzerland GmbH; G. Mueller, Hexion Specialty Chemicals GmbH; S. Gestermann, Covestro Deutschland AG

*Flow*EQ, a hybrid fate and transport model that combines the flow network of the MORE/MONERIS model with a Level III fugacity-based model, was previously used for the assessment of Bisphenol A (BPA) in the environment. Best estimate emissions revealed total loadings of approximately 9 t/a into surface waters in Germany. As *Flow*EQ is parametrized to test the impacts of various pathways, the model results indicated that emissions from municipal wastewater dominate in virtually all geographic areas and have a much larger contribution to surface water concentrations than industrial and manufacturing emissions. While specific sources could not be identified, a follow-up study was performed considering updated market segment ratios and applied BPA release rates into water for interior and exterior use scenarios of polycarbonate (PC) and epoxy resin (EpR) based articles. *Flow*EQ results based on existing migration data suggested that PC and EpR based articles contribute to only about 1 % of total BPA loadings to surface water during their use phase and disposal. In a recent, extended campaign, measurements for > 20 wastewater treatment plants (WWTPs, influent/effluent, sewage sludge) and > 50 leachate samples from > 20 landfills were performed. In addition, >> 100 articles covering 18 article classes were analyzed for their BPA content. Highest influent BPA concentrations (up to 905 μg L^{-1}) were found in WWTPs affected *i.a.* by discharges from paper processing (*e.g.*, recycling), simultaneously leading to highest concentrations in sewage sludge (up to 200 mg kg^{-1} d.w.). Most WWTPs showed BPA removal rates in the range of 80-100 %, significantly lower rates were observed in four WWTPs. The reason for such low performance is not clear. BPA levels in landfill leachates were largely different (up to 52,000 μg L^{-1} prior treatment) and correlated with the starting date of landfilling for still operating sites. Of the >> 100 article samples analyzed, highest BPA concentrations were detected in various articles made of recycled PVC (up to 1,691,700 μg kg^{-1}), in recycled PVC granules (up to 204,800 μg kg^{-1}) and products made from recycled paper (up to 48,400 μg kg^{-1}). *Flow*EQ modeling using refined input parameters is able to attribute a significant part of the annual BPA emissions and the resultant concentrations in surface water to specific sources. It may thus serve as an important tool to model alternative emission scenarios and explore how concentrations change as usage patterns and treatment technologies change.

TU141

Different Sources of PCBs Generation in Wastes and their Presence at Dilijan Landfills (Republic of Armenia)

A. Aleksandryan, Ministry of Nature Protection of the Republic of Armenia / Head of Hazardous Substances and Wastes Policy Division; A. Khachatryan, Environmental Monitoring and Information Center / Division of waste inventory, classification and technology investigation; Y. Bunyatyan, Environmental Monitoring and Information Center / Persistent Organic Pollutants Monitoring Division

Polychlorinated biphenyls (PCBs) are a group of organic compounds with a wide distribution, high toxicity, persistence and ability to long-distance migration. PCBs differ by unique properties: temperature stability; high boiling point; non-combustibility; resistance to chemical and physical influences; high dielectric constants. Such features allow PCBs versatile application as heat transfer fluids in heat exchangers, dielectrics in transformers and capacitors, fluids for hydraulic systems, plasticizers in lacquers, plastic masses, printing inks, copy paper, lubricants, insulating materials for cables and wires, fungicides for protection of building structures and wood, fillers for pesticides, additives to household chemicals, substitutes for wax, resins and rubber for impregnating fabrics. Sources of PCBs generation and spread in the environment are diverse, as they are used not only in the energy sector. Landfills of Dilijan district, where wastes are disposed without prior separation, were investigated. Determination was carried out on Shimadzu chromatograph with an electron capture detector. Separation of substances was done on a 60 m glass capillary column with DB-5MS UI. The results of analyses (n=560) were usually focused on the total concentrations: dioxin-like PCBs, non-dioxin-like PCBs, common PCBs. Sampling was done at the old (NN 1-9) and new (NN 10-20) landfills. Conclusions: 1. Dumps of municipal waste of Dilijan, both the old and new sites, are active sources of PCBs accumulation and spread; 2. In soil samples from both landfills excess concentrations of PCBs were found in 100% of cases compared to normative level, and the summary concentrations of the latter multiply exceeded the normative; 3. The problems of PCBs-related environmental pollution are of great concern because the emergence and spread of PCBs in nature is not always subject to control and regulation, as the sources of PCBs formation are diverse.

TU142

Understanding children's exposure to perfluoroalkyl acids - a modelling approach

F.G. Balk, Department of Environmental Science and Analytical Chemistry / Department of Environmental Science and Analytical Chemistry; K. Winkens, Swedish Museum of Natural History / Department of Environmental Research and Monitoring; A. Ribbenstedt, Stockholm University / Department of Environmental Sciences and Analytical Chemistry (ACES-O); J. Koponen, National Institute for Health and Welfare / Environmental Health Unit; M. Filipovic, NIRAS Sweden AB / UFZ; I.T. Cousins, Stockholm University / Department of Environmental Science and Analytical Chemistry

The exposure to per- and polyfluoroalkyl substances (PFASs) is of high concern due to their observed toxicity in animal studies and associated health impacts found in human epidemiological studies. Adults are mainly exposed to PFASs via ingestion of food, drinking water, inhalation of air and ingestion of dust, whereas for children the exposure to PFASs is largely unknown. This modelling study aimed to elucidate children's exposure to perfluoroalkyl acids (PFAAs) after cessation of breastfeeding. The studied PFAAs were perfluorooctanoic acid (PFOA), perfluorooctane sulfonic acid (PFOS) and perfluorohexane sulfonic acid (PFHxS). A dataset from a Finnish child cohort study was utilized, which comprised measurements of PFAA blood concentrations. PFAA concentrations in dust and air from the children's bedrooms and literature data on dietary PFAA concentrations were used to calculate the estimated daily intakes (EDIs) of the studied PFAAs. The EDIs served as input in a one-compartment pharmacokinetic (PK) model that reconstructed serum PFAA concentrations from 1 to 10.5 years of age. The contribution of biotransformation of precursors in the body (indirect exposure) was assessed for both PFOA and PFOS, while for PFHxS this was not possible due to a lack of data on its precursors.\n\nThe model showed that the direct exposure via dietary intake was the major exposure route for the total PFAAs exposure of the Finnish child cohort, while inhalation of air and ingestion of dust were of minor importance, as was the indirect exposure to PFOS and PFOA. The one-compartment PK model reconstructed median PFOA and PFOS serum concentrations well compared to corresponding measured median serum concentrations. For PFHxS, the modelled serum concentrations were consistently underestimated compared to measured serum concentrations. The derived EDIs for PFOA and PFOS for 10.5-year-olds were in agreement with respective EDIs for adults from other studies, while the derived EDI for PFHxS was substantially lower compared to EDIs of PFHxS from the literature. The derived EDIs are compared with tolerable daily intakes from European authorities. The model results show that children's exposure to PFOA and PFOS after breastfeeding is similar to that for adults, which implies a higher health risk for children due to their lower body weight. More efforts should be made to investigate children's exposure to PFHxS including its precursors and to generate improved PK parameters for this compound.

TU143

Use of Regulatory Models in a Refined, Spatially Explicit Pesticide Ecological Aquatic Exposure Assessment

H. Rathjens, STONE EnvironmentalEngineering & Science,Inc. / Environmental Modeling Systems; M.F. Winchell, STONE EnvironmentalEngineering & Science,Inc. / Environmental Systems Modeling; L. Padilla, STONE EnvironmentalEngineering & Science,Inc.; P. Whatling, FMC Corporation / Global Regulatory Affairs

Recent risk assessments concerning the effects of currently registered insecticides on aquatic species have adopted regulatory aquatic exposure models and scenarios to represent a wide range of species and habitat characteristics. The application and parameterization of these models to date has been largely at a screening level in terms of the conservativeness of assumptions and the spatial specificity of the exposure model inputs and predictions. The best available spatial datasets provide the information necessary to improve the parameterization of regulatory aquatic exposure models such as the PRZM landscape and VVWM receiving water models, and their resulting exposure estimates. To evaluate the practical use of these models and datasets in a national scale refined ecological risk assessment, 100 different species across a range of taxonomic families, occupying static and flowing habitat, were assessed. The static water modeling approach focused on independently evaluating yearly realizations of crop data to represent multiple cropping configurations surrounding small static water bodies. The proximity of crops to water refined the drift exposure and the distribution of soil types and weather refined the runoff potential. The flowing water modeling approach took advantage of a high-resolution catchment network to determine contributing watershed areas for each distinct catchment within a species range. The catchment network and associated flow length and flow velocity attributes determined the lag-times of pesticide loads contributing from upstream catchments and determined the duration of chemical degradation. The flowing water modeling also considered multiple independent years of crop data to generate an ensemble of cropped area realizations in each catchment and upstream watershed. In both the static and flowing habitat modeling, historical pesticide use data was used to estimate the fraction of catchments receiving insecticide applications for each crop group, which was varied for each of the five crop years modeled. This exposure modeling approach resulted in species-specific EEC distributions that could be further filtered according to habitat characteristics (flow rate, water body size), grouped according to contributing watershed characteristics, and mapped explicitly to locate regions within a species range that are likely to experience exposure levels of potential concern.

ChemTHEATRE promotes utilization of the published or public data of environmental contaminants for chemical exposure and risk assessment

K. Nakayama, Ehime University; B. Lin, National Institute of Advanced Industrial Science / Research Institute of Science for Safety and Sustaintability; T. Isobe, National Institute for Environmental Studies Japan / Center for Marine Environmental Studies CMES; S. Uno, Kagoshima University / Faculty of Fisheries; I. Handoh, Niigata University / College of Creative Studies; N. Ohno, University of Hyogo / Graduate School of Simulation Studies; T. Kunisue, Ehime University / Center for Marine Environmental Studies

There is a general trend toward the growing importance of open data worldwide. It appears to be essential that development of scientific data repositories be accelerated. In the field of environmental chemistry and ecotoxicology, a huge number of monitoring data on chemicals in various environmental and biological specimens have been reported in scientific journals. However, comprehensive, public repositories to store such valuable data set of the chemicals do not exist; researchers are forced to spend lots of time and cost in collecting and utilizing the published data, when modelling environmental behavior and fate of, and performing the risk assessment for, the chemicals of interest. Therefore, it is desirable that various stakeholders in the field should work together to improve and promote secondary use of the data. To this end, we have created a platform to register and visualize the monitoring data of environmental contaminants, named 'ChemTHEATRE' (Chemicals in the THEATRE: Tractable and Heuristic E-Archive for Traceability and Responsible-care Engagement). To date, data described in more than 66 projects have been registered on the platform. Users can find e-archived chemical concentration data in the environmental and biological specimens each with associated metadata such as sampling date and location, species, and biometrics, in addition to the detailed description of experimental methods. Bridging ChemTHEATRE to AIST-MeRAM (Multi-purpose Ecological Risk Assessment and Management Tool) storing chemical property and/or hazard/toxicity information provides us high accurate and transparent assessment of ecological risk of chemicals. Much effort is currently being devoted to visualizing e-archived data sets, and enhancing available data-model interfaces to simulate global dynamics of chemical pollution, with Finely-Advanced Transboundary Environmental model (FATE), and to promote a series of integrated exposure and effects analyses. It is thus expected that ChemTHEATRE will be not only a dedicated follow-up and forecasting tool of international regulations on pollution control in the light of traceability and responsible-care engagement of chemicals, but also a 'communication theatre' where a variety of stakeholders can improve their risk literacies and develop new projects through open data access.

Transgenerational Inheritance of DNA Hypomethylation in Daphnia magna in Response to Salinity Stress

G.A. Jeremias, University of Aveiro / department of Biology & CESAM; J. Barbosa, University of Ghent / Laboratory for Environmental Toxicology and Aquatic Ecology (GhEnToxLab); S.M. Marques, University of Aveiro / department of Biology & CESAM; K. De Schamphelaere, Ghent University (UGent) / Environmental Toxicology; F. Van Nieuwerburgh, D. Deforce, University of Ghent / Laboratory of Pharmaceutical Biotechnology; F.J. Gonçalves, J. Pereira, University of Aveiro / Department of Biology & CESAM; J. Asselman, Ghent University / Laboratory for Environmental Toxicology and Aquatic Ecology GhEnToxLab unit

The salinization of freshwaters is a serious ecological issue that has been receiving increased attention by the scientific community. Salinity is a serious threat to freshwater ecosystems and a relevant form of environmental perturbation affecting freshwater biodiversity through, for example, the impairment of organisms' development and fecundity. Environmental change can induce epigenetic marks in organisms, which in turn influence their responses. Although the transgenerational inheritance of epigenetic marks has been experimentally shown or theoretically postulated, this phenomenon remains barely explored in aquatic species. An example of this knowledge scarcity are the epigenetic responses in *Daphnia*, which is a key organism in studies addressing the ecology of freshwater lentic ecosystems, as well as in aquatic toxicology, including within regulatory frameworks. In the present study, we exposed one generation of *Daphnia magna* to high levels of salinity and found that the exposure provoked specific methylation patterns that were transferred to three subsequent non-exposed generations. These transgenerational effects reflected in the hypomethylation of six protein-coding genes (PAXIP1-associated glutamate-rich protein; Small nuclear ribonucleoprotein G; Prefoldin subunit 3; 60S ribosomal protein L36; Coenzyme Q-binding protein COQ10 B, mitochondrial; Uncharacterized protein) with important roles in the organisms' response to environmental change: DNA damage repair, cytoskeleton organization and protein synthesis. Our results bring to light that epigenetic marks are affected by environmental stressors and can be transferred to subsequent unexposed generations. Accordingly, this work highlights the relevance of epigenetics in environmental sciences and the potential role of epigenetic transgenerational inheritance for gene × environment interactions in *Daphnia*.

TU147

The impact of exposure to environmental stressors on global DNA 5-methylcytosine in zebrafish (Danio rerio) embryos during early development

P. Robinson, H. Littler, J. Viana, University of Exeter / Biosciences College of Life and Environmental Sciences; H. Baulf, University of Exeter; R. Van Aerle, Centre for Environment Fisheries and Aquaculture Science Cefas; E. Dempster, University of Exeter / Medical School; J. Mill, University of Exeter / Exeter Medical School; E.M. Santos, University of Exeter / Biosciences College of Life and Environmental Sciences

Aquatic systems are affected by a wide range of stressors including chemical pollutants and alterations in abiotic factors. Some stressors have been shown to affect the epigenome, leading to persistent effects that can manifest long after the exposure period. In vertebrates, embryos undergo extensive reprogramming events during early development, allowing the formation of totipotent cells and avoiding inheritance of deleterious alterations from parental exposures. We hypothesise that the epigenome of developing embryos is particularly sensitive to stressors during these reprogramming periods. This study aims to determine if common environmental stressors disrupt the methylome of zebrafish (*Danio rerio*) embryos during the reprogramming period, and whether this life stage is particularly sensitive compared to other periods. Initially, we generated dose-response curves for a number of toxic metals (copper, silver and methylmercury), abiotic factors (hypoxia and temperature), and 5-azacytidine as a positive control, to determine the physiological effect of these stressors on embryos exposed from 0 to 24 hours post fertilisation (hpf). In parallel, we conducted dose-response curves during a later developmental period (4 to 28 hpf) to investigate the relative sensitivity of embryos when exposures encompass the period of reprogramming compared to those initiated after reprogramming is complete. In initial experiments, we used a LUMA (LUminometric Methylation Assay) of unexposed embryos to confirm the timing of reprogramming in zebrafish under our experimental conditions. We then used the dose-response curves to determine the effective concentrations that caused 50% effect at 24 hpf (EC50 values) for use in further methylation experiments. For metals, using mortality as an endpoint, these values were 75.77μg/l, 25.51μg/l and 63.71μg/l for copper, silver and methylmercury respectively, under our experimental conditions. For abiotic factors, parameters related to developmental delay were used to define effective concentrations, and these were determined as 20% air saturation for hypoxic conditions and 25°C and 31°C for temperature. We are now testing the effects of each stressor on the global 5-methylcyotsine level in blastocyst embryos using LUMA. The data gathered will identify stressors with the potential to affect methylation profiles during the period of reprogramming in zebrafish embryos, which could cause long-lasting health effects via epigenetic mechanisms.

The fungicide, tebuconazole, causes persistent changes to the DNA Methylome of Zebrafish (Danio rerio)

C. Miller, University of Lethbridge / Biological Sciences; Y. Ilnytskyy, I. Kovalchuk, University of Lethbridge; S. Wiseman, University of Lethbridge / Biology

Exposure to environmental stressors during early stages of development can impair physiology of sexually mature adults. One mechanism of these intra-generational effects is mitotically stable alterations to the DNA methylome that result in permanent reprogramming of gene expression. Tebuconazole (TEB) is an agricultural fungicide used globally to control pathogenic fungi found in fruits, vegetables, and grains. Exposures of aquatic organisms to TEB occurs when rain closely follows application of the pesticide, causing it to mobilize and result in elevated concentrations in nearby waterbodies. In the current study, zebrafish (*Danio rerio*) embryos were collected prior to 1-hour post-fertilization and exposed to either 0 μg/L (control), 10 μg/L, or 1000 μg/L of TEB. Exposures ran until 24-hours post-hatch (hph) in order to target DNA methylome reprogramming and the entire period of embryogenesis. Embryos were then transferred into clean water containing no TEB to be reared until sexual maturity. This exposure resulted in significant alterations to the DNA methylome and the enzymatic machinery that maintains the methylome. At 24-hph there was a significant increase in mRNA abundance of the enzyme ten-eleven translocase (*tet*) *3* in embryos exposed to 10 μg/L of TEB, and a significant increase in mRNA abundance of DNA methyltransferase (*dnmt*) *3b1*, *tet 1*, *tet 2*, and *tet 3* in embryos exposed to 1000 μg/L. In sexually mature adults, mRNA abundance of *tet 1* was significantly decreased in gonad tissue of males exposed as embryos to 1000 ug/L of TEB. In brain of sexually mature adults exposed as embryos to 10 μg/L of TEB, there was a significant decrease in mRNA abundance of *dnmt 2* and *dnmt 3b4* inmales and a significant increase of *dnmt 3a2* and *dnmt 3b1* in females. In brain of sexually mature adults exposed as embryos to 1000 μg/L of TEB, there was a significant decrease in mRNA abundance of *dnmt 2, dnmt 3b4, tet 1*, and *tet 2* in males, and asignificant decrease of *dnmt 3a1, dnmt 3b2, dnmt 3b4, tet 1*, and *tet 2* in females. Using reduced representation bisulfite sequencing, 16 differentially methylated regions (12 hypomethylated and 4 hypermethylated) were identified in gonads from females exposed as embryos to 10 μg/L of TEB. Analysis is currently being performed to identity loci-specific changes in DNA methylation in gonads from females exposed to 1000 μg/L. Implications of changes in DNA methylation for physiological performance of zebrafish will be discussed.

TU149

The critical window of exposure of CMIT/MIT, a biocide, in zebrafish Danio rerio: Morphological, Behavioral and Epigenetic approach

H. Lee, University of Seoul / School of Environmental Engineering; N. Chatterjee, University of Seoul / Environmental Engineering; J. Choi, University of Seoul / School of Environmental Engineering

Hynho Lee, Nivedita Chatterjee, Jinhee Choi School of Environmental Engineering, University of Seoul, 163 Seoulsiripdae-ro, Dongdaemun-gu, Seoul 02504, Republic of Korea In present study, we aimed to find out the critical developmental stage for exposure(s) of a widely used biocide, CMIT/MIT, (5-Chloro-2-methyl-3(2H)-isothiazoloneand 2-methy-3(2H)-isothiazolone) in the model system, zebrafish (Danio rerio) embryo. We exposed to various developmental stages (0-24h, 24-48h, 48-72h, 72-96h) and endpoint analysis were carried out either at 96 hpf or 10 dpf. At first, we found out the EC values (EC20, EC50 and EC90) from a range of exposure concentrations (based on coagulation endpoint) and EC20 and EC50 doses were chosen for further analysis. We mainly used two endpoints – morphological (96 hpf) and behavioral alterations (at 10 dpf) and to explain the underlying altered phenomena, we used proteomics and global DNA methylation (with its regulating gene machineries). The early developmental period (0-24h) was found as most sensitive window in respect of morphological (tail bending) as well as behavioral (altered locomotion) endpoints. Moreover, significant number of differentially regulated proteins were evident, specifically, in 0-24h of exposure period. Altered global DNA methylation status (hypermethylation at early window and hypomethylation at later windows of exposures) were also evident which were further supported by DNA methyl-transferase gene expressions. Taken together, the current study shows that exposure window is critical for CMIT/MIT exposure and at early life stage is most vulnerable period in zebrafish model. Though the results are preliminary to translate to in human health scenario, nonetheless, these data could serve as risk assessment of CMIT/MIT for human exposure. This work was supported by the Mid-career Researcher Program through the National Research Foundation of Korea (NRF) funded by the Ministry of Science and ICT (NRF-2017R1A2B3002242).

Epigenetic, transcriptional and phenotypic responses in Daphna magna after short-term exposure to gamma radiation

J. Thaulow, NIVA - Norwegian Institute for Water Research / Freshwater Ecology; Y. Song, Norwegian Institute for Water Research / Ecotoxicology and Risk Assessment; L. Xie, NIVA - Norwegian Institute for Water Research / Environmental Toxicology; L. Lindeman, Norwegian University of Life Scienc / Faculty of Veterinary Medicine; J. Kamstra, NMBU / BaSam; Y. Lee, Norwegian University of Life Sciences / Faculty of Biosciences; J. Asselman, Ghent University / Laboratory for Environmental Toxicology and Aquatic Ecology GhEnToxLab unit; P. Aleström, Norwegian University of Life Sciences; K. Tollefsen, NIVA / Ecotoxicology and Risk Assessment

Daphniids are a widely-used model organism for detection of environmental stressors. However, radioactive studies have mainly been focused on vertebrates. This study examined a 7-day cobalt-60 gamma radiation exposure on the crustacean *Daphnia magna* with multiple dose rates and sampling points. Investigated endpoints included histopathology, reproduction, lipid and cellular reactive oxygen species (ROS), global methylation, histone modifications (H3K9) and gene expression of key genes within the One Carbon Cycle linked to methylation and functional genes linked to ROS. Global methylation showed an increase with increasing dose rate (control, 0.4, 1 and 10 mGy/h), with changing ROS from increasing at 2-d, stable at 4-d and increasing at 7-d. Functional genes linked to ROS were all down regulated. In response to the increased global methylation, DNMTs were down regulated and the counteracting genes GNMT and TET2 were upregulated. Reproduction showed no direct effect yet Vitellogenin and Methoprene-tolerant genes showed upregulated activity with increasing dose rate indicating increased reproductive response affective after 7 days. However, histopathology showed cell damage and deformations indicating future reduced reproduction. Cumulatively, the results indicate a gamma radiation induced pathway response in *D. magna* transcending from epigenetic to gene to cellular with indication of future reproductive restriction. Longer exposure time may be needed to induce histone modifications and direct reproductive responses, yet, this study provides valuable insight into multilevel gamma ration induced response in an invertebrate.

TU151

Effect of a biocide, CMIT/MIT on epigenetic modification and phenotypic changes in Daphnia magna: A multigenerational study

J. Gim, University of Seoul; N. Chatterjee, University of Seoul / Environmental Engineering; J. Choi, University of Seoul / School of Environmental Engineering

Epigenetic changes in diverse species, including cladocerans, have been reported to be induced by environmental stress factors and could be transgenerationally inherited without direct exposure at the descendant generation (s). Besides, 'Transgenerational epigenetics' is important in terms of inheritance of a modified phenotype and evolution, but it is still in immature stage of exploring in proportion to 'Intragenerational epigenetics'. CMIT/MIT (5-Chloro-2-methyl-3(2H)-isothiazoloneand 2-methy-3(2H)-isothiazolone) is a known biocide widely used in water treatment processes and is highly toxic to freshwater organisms. In this study, we tested the hypothesis that epigenetic mechanisms, if they are operating, are associated with a heritable modified phenotype. To test the hypothesis, we investigated reproduction, behavior, morphological change, growth and DNA damage to evaluate transgenerational toxicity and epigenetic alteration, such as DNA methylation and histone methylation under various exposure scenarios. We identified that there is transgenerational effects in reproduction, behavior, growth and DNA damage and DNA methylation is highly correlated with growth, showing more dynamic and immediate responses to CMIT/MIT than DNA damage. Our results suggest CMIT/MIT exposure has potential for alteration of epigenetic mechanism, however, more detailed study, such as, gene specific DNA methylation and ChiP-seq studies would needed to understand the roles of epigenetic alteration in inheritance of modified phenotype.

Histone methylation associated transgenerational toxicity in the nematode Caenorhabditis elegans

J. Gim, University of Seoul; J. Yang, J. Choi, University of Seoul / School of Environmental Engineering

Epigenetics, phenotypic characters without modification of DNA sequence, possess reversibility as well as the heritable transgenerational transfer of epigenetic marks. The aim of the present study was to evaluate the role of histone methylation in transgenerational response to environmental chemical exposure in the nematode, *Caenorhabditis elegans*. C.elegans were exposed to environmental chemicals, such as, biocide and crude oil, and transgenerational toxicity was investigated in *C. elegans*on the exposed (P0) and three consecutive unexposed generations (F1-3). We found true trans-generational inheritance of toxicity caused by the crude oil in the unexposed generations. Next, we examined response to chemicals exposure using histone methylation related mutants, such as, *mes-2* (H3K27 di-/trimethyl transferase), *met-1* (H3K36 and H3K9 trimethylase), *met-2* (H3K9 and H3K36 trimethylase), *jmjd2* (H3K9/H3K36 demethylase), *set-2* (H3K4 methyltransferase), *spr-5* (H3K4me2 demethylase) and *utx-1* (H3K27 demethylase). Decreased methylation of histone H3 marks (i.e., H3K9) was subsequently found in the oil-exposed generation, however a heritable diminution in reproduction did not occur in the H3K9 histone methyltransferases (HMT) mutant, *met-2(n4256)*, suggesting a potential role for the HMT of H3K9 in transgenerational toxicity. Our overall results suggest that chemical toxicity could be heritable and histone methylation may be associated with the transmission of the inherited phenotypes. Epigenetic-associated genes in Caenorhabditis elegans are potential toxicity biomarkers for metals and per- and poly-fluorinated alkyl substances

M. Stylianou, Orebro University / The Life Science Centre-Biology; N. Rai, Orebro University / The Life Science Centre,s School of Science and Technology; H. Fiedler, UNEP/DTIE Chemicals Branch / MTM Research Centre School of Science and Technology; P. Olsson, Orebro University / The Life Science Center-Biology; J. Jass, Orebro University / SCHOOL OF SCIENCE AND TECHNOLOGY

Cancer, autism, obesity and asthma are epigenetic-associated disorders and syndromes. While numerous studies have correlated exposure to pollutants such as metals and persistent organic pollutants, with epigenetic changes, it remains a poorly understood area. This study aimed to explore the possible transcriptional deregulation of epigenetic-associated genes in *Caenorhabditis elegans* exposed to per- and poly-fluorinated alkyl substances (PFAS) and metals during larvae development, from (L1) to pre-adult (L4) stage. *C. elegans* was the first animal whose genome was fully characterized and is a valuable *in vivo* model for PFAS and metal toxicity studies. PFAS and metal exposure of *C. elegans* resulted in changes in expression patterns of epigenetic-associated genes. *C. elegans* exposure to PFAS, resulted in altered expression of genes encoding for histone methyl- and acetyl- transferases, as well as histone deacetylates and demethylases. However, *C. elegans* exposure to a metal mixture and soil leachate comparatively altered the transcription of fewer epigenetic-associated genes, indicating differential effects on epigenetic markers. The present results suggest that the transcriptional responses of epigenetic-associated genes, makes them valuable as potential biomarkers. The present study motivates further investigations into the mechanisms associated with epigenetic effects of pollutants in the environment.

TU154

Genetic, epigenetic, and developmental toxicity of Chironomus riparius raised in metal-contaminated field sediments: A multi-generational study with arsenic as a second challenge

J. Im, N. Chatterjee, J. Choi, University of Seoul / School of Environmental Engineering

Jeongeun Im, Nivedita Chatterjee, Jinhee Choi School of Environmental Engineering, University of Seoul, 163 Seoulsiripdae-ro, Dongdaemun-gu, Seoul 02504, Republic of Korea Ecotoxicity tests conducted under well-controlled lab conditions often do not reflect the real environmental conditions. To this end, we designed an ecotoxicity test using an aquatic midge, *Chironomus riparius* (*C. riparius*), raised in metal-contaminated field sediments (MCFS), which reflect the real environmental conditions, for five consecutive generations (F0–F4) followed by a toxic response to arsenic exposure (as a second challenge). The toxic responses (i.e. DNA damage, DNA methylation, stress response gene expression, and mortality) were compared to those organisms reared in lab sediments (LS). Under the MCFS condition, increased adult emergence of the larvae was observed for the first two generations (F1 and F2), while a decreased tendency was evident thereafter (F3 and F4) compared to that of F0. When comparing *C. riparius* raised in MCFS or LS exposed to arsenic, increased sensitivity (declined survival) was observed in the larvae from F2, whereas, such a tendency was not present in F4 of the MCFS midges, indicating a possible physiological adaptation. Increased DNA damage was observed in the MCFS-exposed organisms compared to the those exposed to LS, particularly at F0. Arsenic exposure induced hypermethylation at F0 and, in contrast, hypomethylation at the later generations (F2, F4) in the MCFS-exposed organisms. Global DNA methylation results were supported by related methylation enzymatic gene expressions. Moreover, alterations in oxidative stress related to gene expressions showed that significant oxidative stress and perturbation of glutathione reserves occurred under the MCFS and the subsequent arsenic exposure conditions. Overall, our results suggest that multigenerational rearing under MCFS conditions resulted in physiological adaptation of *C. riparius* to metal exposure, specifically at later generations, which in turn modulated its response to arsenic stress through possible genetic and epigenetic mechanisms. This work was supported by the Mid-career Researcher Program through the National Research Foundation of Korea (NRF) funded by the Ministry of Science and ICT (NRF-2017R1A2B3002242).

Toxicity of neonicotinoids and other pesticides to Chironomus riparius: pulse, chronic and multigenerational tests

V. Carrasco Navarro, University of Eastern Finland / ENVIRONMENTAL AND BIOLOGICAL SCIENCES; J. Sorvari, University of Eastern Finland

Neonicotinoid insecticides (NNIs) were included in the EU watch list substances for emerging water pollutants (Decision 2015/495) and recently, three of them have been banned from outdoor use. They are very persistent contaminants in soils, with DT_{50} reaching thousands of days. From soils, NNIs leach to water bodies due to their solubility and are found extensively around the globe. Additionally, they are toxic to beneficial organisms, especially insects. In our study, we investigated the toxicity two NNIs and other pesticides to the aquatic insect *Chironomus riparius* (Diptera: Chironomidae). The types of tests used include growth, emergence and second-generation growth tests with both chronic and pulse exposures. Insects were exposed in water-sediment systems to the neonicotinoid thiacloprid as the main compound. Thiamethoxam, propiconazole, triasulfuron, azoxystrobin and MCPA were added subsequently to test the toxicity of mixtures. Concentrations of the single compounds never exceeded $2\mu g\ L^{-1}$ and $10\mu g\ L^{-1}$ in the chronic and pulse exposures, respectively. Although survival was not affected, every single combination of the pesticides tested caused an inhibition in the growth of *C. riparius* over 10d tests when compared to unexposed larvae. A mere $0.5\mu g\ L^{-1}$ of thiacloprid caused a significant inhibition of growth. During the emergence experiment, larvae were exposed to chronic or pulse concentrations of the same combinations of pesticides as in the growth tests. Adult emergence, sex ratio and number of eggs per female were recorded. In general, pulse exposures affected the emergence and sex ratio of adult chironomids more than the chronic exposures. Emerged adults of each pesticide treatment were transferred to specific breeding cages for oviposition. After hatching, larvae resulting from parents with different exposure history were grown in clean and thiacloprid-contaminated scenarios. However, the results showed no major differences in the growth among any of the second-generation larvae despite the conditions in which the first generation were reared. Overall, the present study adds important information about the toxicity of NNIs and pesticide mixtures to aquatic insects, raising questions about the importance of pulse exposures in the risk assessment of pesticides. Moreover, it highlights the need of more studies on the toxicity of pesticides to several generations of insects to establish a link with the real status of insect populations.

TU156

Response to AHR ligands in liver slices cultured from naïve and pre-treated chicken embryos; does epigenetics play a role?

J. Head, McGill University / Natural Resource Sciences; K. Mittal, McGill University / Dept of Natural Resource Sciences; C. Goncalves Athanasio, University of Birmingham / Biosciences

Lipophilic environmental contaminants such as dioxin-like compounds (DLCs) and polycyclic aromatic hydrocarbons (PAHs) can be found in high concentrations in the eggs of wild birds. We are interested in how this early-life exposure to contaminants affects sensitivity to re-exposure later in life, and whether sensitivity to re-exposure is regulated by epigenetic mechanisms. In the current study, the DLC, tetrachlorodibenzo-*p*-dioxin (TCDD), or the PAH, benzo[*k*]fluoranthene (BkF) was injected into fertilized chicken eggs prior to incubation. At embryonic day 19, livers were harvested and slices of the tissue were grown in culture. These liver slices were then re-exposed to graded concentrations of each of the test chemicals. Both BkF and TCDD were associated with dose-dependent induction of several genes associated with the aryl hydrocarbon receptor (AHR) response pathway including *cyp1a4, cyp1a5,* and *ahrr* (but not *ahr* or *arnt*). A large degree of variability was observed in the responsiveness of liver slices cultured from different individuals. Interestingly, liver slices from individuals exposed to BkF *in vivo* were more sensitive to induction of *cyp1a4*, *in vitro*. This did not appear to be a carry-over effect from the initial egg injection; PAHs such as BkF are known to be rapidly metabolised by avian embryos, and the levels of *cyp1a4* mRNA expression in the untreated liver slices suggested that any induction due to the *in vivo* treatment was transient. Exposure to BkF was also associated with small but significant increases in methylation of the CYP1A4/5 shared promoter. Ongoing work is examining the role of histone acetylation in the response to re-exposure to AHR ligands at this locus. Epigenetic marks associated with genes involved in xenobiotic metabolism may be useful as biomarkers describing an association between early life exposures to environmental contaminants and sensitivities to subsequent exposures later in life.

TU157

Genotoxicity of active compounds mesotrione and s-metolachlor and their commercial formulations in Vicia faba L.

L. Andrade-Vieira, I. Alvarenga, Federal University of Lavras; S. COTELLE, LIEC - Université de Lorraine - CNRS

Pesticides is a task of major concern and Brazil is the country that consumes more pesticides in the world since 2011. Corn is the second culture more cultivated in Brazil and for weeds control some herbicides are used. Amongst them are the herbicides based on the active principles mesotrione and s-metolachlor. These substances can persist on the environmental and contaminate non-target organisms. Therefore, it is of interest to study the toxicological risk of such compounds. Hence, the aim of this study was to investigate the effects of active pure compounds mesotrione and s-metolachlor and their respective commercial formulations through *Vicia faba* L. (broad bean) micronucleus bioassay. The experiment was plotted following the 48 h-protocol of ISO 29200. A range of dilutions of the active principles and the commercial formulations was tested from 1.56 to 50 mg L^{-1}. The Hoagland's solution was used as negative control and Maleic hydrazide as positive control. The micronuclei frequency and mitotic index were recorded in the F1 cells of the secondary roots of *V. faba* and expressed in each 1,000 cells evaluated. A total of 6,000 cells was recorded (1,000 cells per root tip and 6 roots per treatment). For the pure compounds, a decrease on mitotic index was observed. Mesotrione significant reduced ($p< 0.05$) the frequency of cell in division in concentrations > 12.5 mg L^{-1}. For S-metolachlor a significant reduction ($p< 0.05$) was noticed only in the highest concentrations (50 mg L). In addition, the frequency of micronucleus increased significantly ($p< 0.05$) in the treatment with 3.125 mg L^{-1} of Mesotrione and 6.25 to 25 mg L^{-1} of S-metolachlor. On the other hand, the treatments with the commercial formulation containing the same concentrations of active compounds do not damage plant DNA. All together, the results demonstrate that in commercial formulations, combined effects of the pure compounds and the solvents or other substances could occur and interfere on the genotoxic potential of the active compounds. Moreover, the cytotoxicity of S-metolachlor and Mesotrione was in the same order of magnitude, while Mesotrione alone is more genotoxic than S-metolachlor.

TU158

Phenotypic and genotypic adaptations in a riverine green alga (Chlorophyceae, Selenastraceae) as a response to long-term exposure to chemical stress

M. Karlsson, University of Gothenburg, Sweden / Department of Biology and Environmental Sciences; O. Johansson, University of Gothenburg Sweden / Biology and Environmental Sciences; H. Nilsson, T. Backhaus, University of Gothenburg / Department of Biological and Environmental Sciences; A. Clarke, University of Gothenburg Sweden / Department of Biology and Environmental Sciences; N. Corcoll, University of Gothenburg, Sweden / Biological and Environmental Sciences

Abstract Herbicide pollution is a common problem in agricultural streams due to their extensive use and their unwanted effects on non-target species inhabiting these systems. *Selanastraceae* is a family of green algae that are particularly dominant in freshwater, making them a key component in the base of the food chain and an important part of the oxygen production. Therefore, it is crucial from a conservation point of view to accurately monitor the ecotoxicological impact of herbicides on this group of algae, not only on a short-term scale (e.g. days or weeks), but also in a long-term perspective (e.g. months and years). In this work, phenotypic and genotypic differences are studied between different strains of a population of *Kirchneriella* (Chlorophyceae, Selenastraceae) isolated from a stream polluted by herbicides over a 20-year period (Skivarpsån, SE Sweden). According to mixture toxicity modelling performed on data obtained from the Swedish pesticide monitoring program, the main drivers of algal toxicity in this river are the herbicides diflufenican (carotenoid synthesis inhibitor) and isoproturon (PSII inhibitor). Three strains of the isolated algae are examined in this study: two strains from the field that have been exposed to different levels of herbicides and one laboratory strain that has never been exposed to herbicide pollution. The taxonomy of this algae is investigated by light microscopy and DNA barcoding analyses (chloroplast 23S rRNA gene). Phenotypic differences between the strains are examined as impacts on growth rate, cell size, photosynthetic activity (chl fluorescence measurements), pigment content and sensitivity to the specific herbicides mentioned earlier (EC50s). Genotypic differences are studied as single nucleotide polymorphisms thought to be induced through exposure to diflufenican and isoproturon on pds and psbA genes via PCR amplification, cloning and sequencing. The results obtained from this project will contribute to a better understanding of genetic and phenotypic adaptations in green algae as a response to herbicide pollution (evolutionary toxicology) and their implications for ecological functions.

Can pesticide stress affect genomic patterns of freshwater invertebrate organisms? A pilot study in agriculture areas in Southern Sweden

P. Inostroza, University of Gothenburg / Department of Biological and Environmental Science; I. Vera-Escalona, Universidad Católica de la Santísima Concepción / Centro de Investigaciones en Biodiversidad y Ambientes Sustentables (CIBAS); A. López-Mangas, M. del Águila, University of Gothenburg / Department of Biological and Environmental Science; T. Backhaus, University of Gothenburg / Department of Biology and Environmental Sciences

The expansion and intensification of agricultural areas and the associated chemical pollution remains one of the most important stressors to aquatic ecosystems worldwide. Once chemicals from agricultural activities enter aquatic ecosystems, they may cause unwanted ecological consequences from the molecular to the ecosystem level, impacting the ecological health of aquatic ecosystems. Invertebrate communities represent one of the Biological Quality Elements according to the EU Water Framework Directive. They are therefore extensively used as biological indicators to assess water quality. However, a thorough understanding whether pollution from agriculture drives genome-level modifications of invertebrate freshwater organisms is still absent. We therefore used approaches from evolutionary ecotoxicology to address impacts of complex pesticide pollution on the genome of natural populations of the shredder invertebrate *Gammarus pulex*. The study was conducted in the southern part of Sweden, where the main agricultural activities take place. The area is therefore recognised as a hotspot for pesticide application and is part of Sweden's national pesticides monitoring. Three stream ecosystems were sampled and *G. pulex* was sequenced using 2bRAD technique. Our study informs on alterations of genomic regions and responses of aquatic invertebrates to complex pesticide pollution in distinct agricultural landscapes as well as gathering critical environmental information about mechanisms driving genomics changes in freshwater populations.

Complex Mixtures in the Environment: Monitoring, Fingerprinting and Assessment (P)

A Prospective Approach for Assessing Chemical Mixtures in River Catchments with Diverse Land Uses

S. Dyer, LeTourneau University / Biology and Kinesiology; L. Posthuma, RIVM / Centre for Sustainability, Environment and Health; C. Brown, University of York / Environment Department; D. De Zwart, Association of Retired Environmental Scientists ARES / Centre for Sustainability Environment and Health; J.M. Diamond, Tetra Tech, Inc.; C.M. Holmes, Applied Analysis Solutions, LLC; S. Marshall, Consultant; G. Burton, University of Michigan / School for Environment and Sustainability

Field-based ecological risk assessments incorporate risks from chemical mixtures and a myriad of stressors because ecosystems are continuously exposed to a wide-array of contaminants and nonchemical stressors. Considering the large numbers potential combinations of mixtures and stressors, this problem could seem insurmountable. We demonstrate that such combinations can be simplified by 3 land-use related chemical emission scenarios: agriculture, domestic, and urban. We applied a tiered methodology to assess the implications of each of the scenarios via a quantitative model. The results showed land use–dependent mixture exposures, clearly discriminating downstream effects of land uses, with unique chemical "signatures" regarding composition, concentration, and temporal patterns. Associated risks were characterized in relation to the land-use scenarios. Comparisons to measured environmental concentrations and predicted impacts showed relatively good similarity. The results suggest that the land uses imply exceedances of regulatory protective environmental quality standards, varying over time in relation to rain events and associated flow and dilution variation. Higher-tier analyses using ecotoxicological effect criteria confirmed that species assemblages may be affected by exposures exceeding no-effect levels and that mixture exposure could be associated with predicted species loss under certain situations. The model outcomes inform various types of prioritization to support risk management, including a ranking across land uses as a whole, a ranking on characteristics of exposure times and frequencies, and various rankings of the relative role of individual chemicals. Though all results are based on in silico assessments, our land use–based approach yields useful insights for simplifying and assessing potential ecological risks of chemical mixtures and can therefore be useful for catchment-management decisions. grossly confirmed by results of similar Europe-wide assessments made by the SOLUTIONS project and can, therefore, be useful for evaluating chemical safety assessment as well as catchment-management decisions.

Non-targeted analysis of xenobiotics in fish muscle

B. Gonzalez-Gaya, IMDEA Water (G84912732) / Environmental Chemistry; M. Musatadi-Larrucea, University of the Basque Country UPV/EHU; M. Olivares, University of the Basque Country UPV/EHU / Plentzia Marine Station (PiE-UPV/EHU) & Dep Analytical Chemistry; A. Prieto, University of the Basque

Country / Analytical Chemistry; O. Zuloaga, N. Etxebarria, University of the Basque Country UPV/EHU / Plentzia Marine Station (PiE-UPV/EHU) & Dep Analytical Chemistry

The complexity of the occurrence and toxicity of emerging contaminants in aquatic environments is remarkable. On the one hand, the identification and quantification of unknown pollutants in the media is a challenging work, due to the high amount of anthropogenic compounds released to the environment. Moreover, the different physicochemical properties of the compounds and thus, their degradation and bioaccumulation processes affecting aquatic organisms are often missing due to a lack of analytical procedures to measure emerging compounds in biota. The objective of this study was to optimize the extraction and purification steps to analyse xenobiotics in a biological tissue from a non-target or suspect analysis point of view. In this sense, the optimization was performed in fish muscle through liquid chromatography coupled with a high resolution mass spectrometer on a Thermo Scientific Dionex UltiMate 3000 UHPLC coupled to a Thermo Scientific™ Q Exactive™ HF hybrid quadrupole-Orbitrap equipped with a heated ESI source (Thermo, CA, USA). A selection of more than 200 compounds, including personal care products and pharmaceuticals, consumption products (additives, detergents), industrial compounds (perfluoroalkyl substances, plasticizers), and pesticides was used for method optimisation. For extraction, focused ultrasound solid-liquid extraction (FUSLE) and Precellys homogenization were tested using acidified acetonitrile and salting out effect. The clean-up of fish fillet extracts was done using different solid phase separation techniques as: (i) combination of normal phases as alumina, silica and Florisil; (ii) C18 and polymeric reverse phases; (iii) anionic and cationic exchange mixed-mode cartridges; and (iv) specific cartridges for proteins and lipids elimination. The best approach was chosen as the best consensus between the lowest matrix effect and the most efficient recovery of the larger mount of target compounds. Analysis of the extracts was performed in positive and negative mode in the Full scan data-dependent MS2 discovery acquisition mode. Apart from accuracy and precision of the method, limit of identification was calculated for the target compounds. Finally, the optimized method was applied to real samples from field samplings in the Biscay coast and commercial species acquired in local supermarkets, performing a full suspect analysis with a database of more than 40,000 compounds from the NORMAN list.

Assessment of Southwestern Atlantic pollution: POPs and Chlorpyrifos in seabirds from the south east of Argentine

A. Quadri Adrogue, Mar del Plata University / Marine Science; J. Seco Pon, M. Castano, G. García, S. Copello, Mar Del Plata National University; K.S. Miglioranza, University of Mar Del Plata / Laboratorio de Ecotoxicología y Contaminación Ambiental, Instituto de Investigaciones Marinas y Costeras

Persistent Organic Pollutants (POPs), such as Organochlorine pesticides (OCPs), polychlorinated biphenyls (PCBs) and polybrominated diphenyl ethers (PBDEs) are anthropogenic chemicals used for industrial and agricultural purpose; they were banned years ago and are regulated under the Stockholm Convention. POPs occurrence in the environment is of great concern due to their effects on organisms. Birds feathers constitute a useful non-destructive tool for POPs detection. There is scarce information about levels of these compounds in birds from the southern hemisphere. The aim of this work was to determine levels of POPs and chlorpyrifos in feathers of three seabirds wintering in Southwestern Atlantic, Olrog's gull (*Larus atlanticus*), Black-browed albatross (*Thalassarche melanophris*) and Cape petrel (*Daption capense*) and the relationship with sex and spatial distribution. POPs and chlorpyrifos were quantified by gas chromatography with electron capture detector (GC-ECD). All species showed a predominance of chlorpyrifos followed by OCPs, PCBs and PBDEs. This denotes the importance of agricultural activity in the region. Particularly, the Olrog gull presented the greatest contaminant levels (X=180,97ng/g), according to its distribution, being related to coastal areas, mainly associated to marshes. Regarding to sex differences on pollutants load, only females of Olrog gull showed lower levels than males (X=100,27; 288,56ng/g respectively), probably because of maternal transfer. Differences were also detected among pelagic species. Pollutants levels were higher in Cape petrel (X=151,63ng/g) than in Black-browed albatross (X=80,47ng/g) possibly as a consequence of higher lipid mobilization during migration. In all species, HCHs dominated OCPs composition, followed by endosulfans (α-/β->1). Among PCBs, tri-, tetra- and penta- CB were the most abundant congeners in feathers of Olrog gull and Black-browed albatross, while CB 156, CB 180 and CB 183 were the predominant PCBs in Cape petrel. The same PBDEs pattern was observed in both pelagic species, being BDE-47 and BDE-99 the predominant congeners followed by BDE-100; however, BDE-100 was the only PBDE detected in feathers of the Olrog gull. These results are similar to worldwide trends found in birds feathers. Therefore, the organic pollutants occurrence in birds from the southern hemisphere deserves more attention and long-term monitoring programs are suggested to reduce their incorporation to aquatic ecosystem.

TU163

Using targeted and non-targeted screening analyses to assess bioaccumulation and toxicity of produced water components on copepod populations in the North Sea

B. Hansen, SINTEF Materials and Chemistry / Environment and New Resources; L. Sørensen, T. Størseth, SINTEF Ocean / Environment and New Resources; D. Altin, BioTrix; J. Skancke, SINTEF / Monitoring and Modelling; T. Nordtug, SINTEF Ocean / Environment and New Resources

Produced water from the oil and gas industry represents the largest direct discharge of effluent into the marine environment worldwide, with total releases from activities on the Norwegian continental shelf alone contributing with > 30,000 tons of organic compounds of potential environmental concern. Due to rapid dilution and (bio)degradation, impacts on local populations of marine species is expected to be minimal. However, this hypothesis needs verification. In the current study, we developed and demonstrated a novel sample preparation technique that allows analysis of target and non-target body residue (GC-MS/MS, GCxGC-HRMS), metabolomics (NMR) and lipidomics (LC-qTOF-MS) profiling of the same sample material. This enables direct comparison and correlations between bioaccumulated produced water components and effects on biological systems. The method was applied to copepods sampled from four different locations in the vicinity of North Sea oil producing platforms which are continuously emitting produced water to the marine environment. From the methods used here, multivariate analysis of the PAH profile and of the lipidome data allowed for differentiation of the four copepod populations, whereas the metabolome data showed no differentiation.

TU164

Characterization of Bioavailable Environmental Pollutant Patterns in Marine, Estuarine and Freshwater Sediments

M. Muz, UFZ - Helmholtz Centre for Environmental Research / Effect Directed Analysis; B. Escher, Helmholtz Centre for Environmental Research GmbH - UFZ / Cell Toxicology; A. Jahnke, Helmholtz Centre for Environmental Research - UFZ GmbH / Cell Toxicology

Sediments are well known sinks for a wide range of hydrophobic organic contaminants and might act as a long-term source of pollution for aquatic ecosystems. Although the environmental relevance of sediments has been acknowledged, the assessment of their risk is often biased when applying exhaustive extraction methods and normalization to their fraction of organic carbon. This problem can be tackled by equilibrium passive sampling, which represents the bioavailable fraction of sediment contamination. Sediment samples collected in Sweden (n=4), the Saar river catchment (Germany) (n=10), the European Arctic (n=9) and Australia (n=4) were equilibrated with silicone-coated jars by horizontal rolling for three weeks. The toxicological characterization of the samples was established by reporter gene bioassays and revealed distinct patterns for a range of endpoints (Jahnke et al., Environ. Sci.: Processes Impacts 2018, DOI: 10.1039/c8em00401c). As the first step of the chemical characterization, the extracts were analyzed by a gas chromatography-high resolution mass spectrometry (GC-HRMS) instrument equipped with an electron ionization (EI) source (Q-Exactive GC, Thermo Scientific). The analysis focused on a target list of 160 compounds covering a wide spectrum of chemical classes. The preliminary results revealed specific contamination patterns. As an example, most of the PCBs were ubiquitous at all the sampling points. However, the site of Ålöfjärden (Sweden) was found to be a hot spot of PCB contamination, having concentrations three orders of magnitude higher than all the other sampling sites. Moreover, site-specific contaminants were found in Saar river samples, being the only ones containing the musk compound Phantolide, whereas other musk fragrance materials such as Galaxolide and Tonalide were detected at all sampling spots. As a next step, the extracts will be investigated for a comprehensive suspect list including recently discovered emerging contaminants, which will be followed by non-targeted approaches to identify site-specific compounds in addition to the ones that are ubiquitous, providing a basis of chemical characterization of marine, estuarine and freshwater sediments.

TU165

APEX - Systematic use of contaminant data from apex predators and their prey in chemicals management

J. Koschorreck, Umweltbundesamt; N. Alygizakis, Environmental Institute; A. Cincinelli, University of Florence / Department of Chemistry; R. Dekker, Naturalis; G. Duke, Environmental Change Institute; N. Glowacka, Environmental Institute; B. Knopf, IME Fraunhofer / Environmental Specimen Bank and Elemental Analysis; T. Martinelli, University of Florence; P. Movalli, Naturalis; M. Nika, National and Kapodistrian University of Athens; H. Ruedel, Fraunhofer IME - Institute for Molecular Biology and Applied Ecology / Department of Environmental Monitoring; R. Shore, Centre for Ecology & Hydrology; N.S. Thomaidis, National and Kapodistrian University of Athens / Department of Chemistry; G. Treu, German Environment Agency Umweltbundesamt / Chemicals; J. Slobodnik, Environmental Institute

How can environmental monitoring data support the safe use of substances and products in Europe? The aim of the EU funded LIFE APEX programme (2018-2022) is to improve systematic use of chemical monitoring data from apex predators and prey for protecting human health and the environment. More specifically, LIFE APEX responds to needs of regulators for specific regulatory applications in relation to REACH and the Biocidal Products Regulation.

Chemical monitoring data from apex predators (e.g. raptors, otters, seals) are of particular value; their position at the tops of food webs means they act as sentinels to reveal harmful substances, in terrestrial, freshwater and marine environments. When combined with data from selected prey (e.g. fish), apex predator data can deliver useful quantitative information on the persistence and bioaccumulation. LIFE APEX will make use of novel analytical methodologies that allow for screening of several thousands of chemical substances in each sample and prioritization of frequently occurring pollutants and their mixtures. LIFE APEX involves making better and more cost-effective use of chemical monitoring data from the large, valuable but under-used resource of environmental samples in Europe's Environmental Specimen Banks, Natural History Museums and other research collections. The objectives of LIFE APEX are: 1. To demonstrate four novel, regulatory applications of chemical monitoring data, specifically: a) to detect presence of chemical contaminants in the environment; b) to facilitate selection of most relevant substances for further hazard assessment; c) to assess impact and effectiveness of substance risk mitigation measures; d) to define predominant chemical mixtures in the environment. 2. To support and sustain regulatory take-up of these applications, specifically: a) to assess relevant resources and capacities for replication and transfer and engage key partners; b) to enhance quality assurance of sampling, processing, archiving and analysis of food web samples (and resulting data); c) to enhance availability and access to relevant apex predator and prey samples and related chemical monitoring data and the comparability and interoperability of this data. 3. To replicate and transfer LIFE APEX approaches and methods with partners across Europe. 4. To disseminate and communicate the LIFE APEX approaches and methods and in particular optimize uptake by regulators and industry.

TU166

Spatial and temporal trends in e-waste related organic pollutants in a developing economy - A pilot study

M. Nipen, University of Oslo; R.D. Vogt, University of Oslo / Department of Chemistry; K. Borga, Department of Biosciences, University of Oslo / Department of Biosciences; A. Haarr, University of Oslo; E.B. Mwakalapa, Norwegian University of Life Sciences / Department of Food Safety and Infectious Biology; M. Schlabach, NLU - Norwegian Institute for Air Research; P. Bohlin-Nizzetto, NILU - Norwegian Institute for Air Research / MILK - Environmental Chemistry Department; A.J. Mmochi, Institute of Marine Sciences; K. Breivik, NILU - Norwegian Institute for Air Research

A considerable amount of research has been carried out mapping the occurrence and levels of e-waste related pollutants in the environment in developing regions known as major recipients of e-waste from industrialized countries. However, little is known about levels and trends of such pollutants in emerging economies with increasing domestic consumption of electronic equipment, yet lacking adequate formal disposal and recycling systems. A pilot study was conducted in Tanzania to inform upcoming sampling strategies within a larger research project (AnthroTox). A goal of this project is to assess spatial and temporal trends of e-waste related legacy persistent organic pollutants, emerging organic contaminants, and selected metals in air, soil and dated sediment cores. The pilot study was conducted to assess the presence of e-waste related organic pollutants in soil samples collected at 12 sites suspected to be highly polluted and/or potentially connected to e-waste related activities. The samples were analyzed for 32 PCBs, 25 PBDEs, 13 new brominated flame retardants (nBFRs), 39 short and medium chain chlorinated paraffin (S/MCCP) homologue groups, and four Dechloranes. S/MCCPs were found in highest levels, with mean concentration of 480 ng/g dry weight (dw) for both SCCPs and MCCPs (range 18–1900 ng/g dw, and 4–2100 ng/g dw for SCCPs and MCCPs respectively). The highest level of SCCPs were found at an unofficial landfill, while the highest levels of MCCPs were found at an e-waste handling facility. nBFRs had mean concentration of 53 ng/g dw, with a range of 1–340 ng/g dw. The highest levels of nBFRs were found at an old landfill, followed by an e-waste handling facility (126 ng/g dw). Mean concentration of PBDEs was 50 ng/g dw (range 1.7–200 ng/g dw). The highest levels were found at an old landfill currently used as farmland, followed by an e-waste handling facility (72 ng/g dw). The mean concentration of PCBs was 25 ng/g dw (range 0.2–170 ng/g dw), with the highest levels found at an old landfill. Dechloranes had the lowest levels, with mean of 3.8 ng/g dw (range 0.1–10 ng/g dw). The highest levels were found in farmed soil adjacent to an old landfill. The levels of pollutants and the relative amount of compound groups were highly variable from site to site. At some locations, the levels found were comparable to heavily industrialized areas, and e-waste dumping sites in Asia, making Tanzania interesting for further research.

TU167

The evaluation and selection of techniques for non-directed analysis of xenobiotics in water using LC-HR-Q-Orbitrap/MS

B. Gonzalez-Gaya, IMDEA Water (G84912732) / Environmental Chemistry; A. Santamaria, I. Astigarraga, University of the Basque Country UPV/EHU; M. Olivares, University of the Basque Country UPV/EHU / Plentzia Marine Station (PiE-UPV/EHU) & Dep Analytical Chemistry; A. Prieto, University of the Basque Country / Analytical Chemistry; O. Zuloaga, N. Etxebarria, University of the Basque Country UPV/EHU / Plentzia Marine Station (PiE-UPV/EHU) & Dep Analytical Chemistry

New technological and operational approaches are needed to screen the most toxic contaminants in the environmental and to get insights about their sources, usages and effects on organisms, including human health. The transition from target analysis to non-target analysis through suspect analysis has become a rising field. Recent developments in data-independent/data-dependent acquisition (DIA/DDA) workflows in LC or GC-HRMS techniques allow the identification of hundreds of chemicals in a single injection maximizing information collected (i.e. molecular formula, isotopic profile, fragments, retention time). These approaches can be applied to screen many chemicals, providing information on the most relevant occurring ones that can be prioritized for further quantitative analysis, reducing the impact of a-priori taken decisions. Therefore, the objective was to implement a method for the suspect/non-target screening (NTS) of organic xenobiotcs in water, including wastewater treatment plant effluent, estuarine and riverine water. First, the extraction step (using a large volume solid-phase extraction (LVSPE50) device with a sorbent combination of 6 g Chromabond HR-X (Macherey-Nagel), 2 g Sepra ZT-WAX (Phenomenex) and 2 g Sepra ZT-WCX (Phenomenex) phases) was validated for 35L of water in terms of extraction efficiency, matrix effect and reproducibility of more than 200 compounds. Those include a wide set of known compounds including pharmaceuticals, personal care products, plasticizers, etc. which were analysed on positive or negative mode in the Full MS ddMS2 discovery acquisition mode in a Thermo Scientific Dionex UltiMate 3000 UHPLC coupled to a Thermo Scientific Q Exactive quadrupole-Orbitrap mass spectrometer (Thermo, CA, USA). This acquisition mode allows the fragmentation of peaks with the highest signals, without any previous list, thus, the most abundant. Matrix effect correction was evaluated using standard additions before and after extraction. Other quality control parameters such as the limit of identification were also calculated. The validated method was applied for the suspect screening of 40054 compounds included in the NORMAN suspect list and the NTS of halogenated compounds on effluent of Galindo WWTP at different periods of the year, estuarine water in the Nerbioi-Ibaizabal, and different rivers from the Biscay province (Basque Country, Spain). Both suspect and NTS workflows were run using the Compound Discoverer software (Thermo, Ca, USA).

Ultra-trace analysis of nitrosamines in drinking water using triple quadrupole GC-MS/MS advanced electron ionisation

A. Lamb, C. Cojocariu, Thermo Fisher Scientific; S. Insa, Institute for Water Research ICRA; J. Renpenning, Thermo Fisher Scientific; M. José Farré, Catalan Institute for Water Research (ICRA)

Nitrosamines are emerging drinking water contaminants linked to cancer by either ingestion or inhalation. Due to their high toxicity, nitrosamines are considered as priority pollutants and various countries around the world have already introduced maximum acceptable levels such as those highlighted in EPA 521 method for compounds such as NDMA, NDEA, NDPA, NDBA, NPYR and NPIP. Nitrosamines are considered toxic in drinking water at very low which meaning that method sensitivity is of highest importance. An additional challenge for nitrosamine analysis is selectivity in matrix as these compounds have low molecular weights, fragment easily and often cannot be quantitated from their molecular ion species. Poor selectivity and sensitivity can lead to false positive detection and inaccurate quantification of these compounds however gas chromatography (GC) coupled to triple quadrupole mass spectrometry (MS) provides extra selectivity and sensitivity compared to single quadrupole technologies. Current methods utilize SPE analyte concentration coupled with large volume injection (LVI) to achieve the required levels of sensitivity. However, LVI introduces more contamination into the GC-MS/MS system leading to increased frequency of GC consumable changes, instrument maintenance and source cleaning lowering productivity and increasing the cost per sample. Here the use of a novel AEI high performance electron ionization (EI) source in conjunction with a new triple quadrupole mass spectrometer provides the sensitivity and selectivity to analyze nitrosamines in drinking water at low part per trillion (ppt) levels with low liquid injection volumes. In this work the Thermo Scientific™ TSQ 9000™ GC with Advanced Electron Ionization Source mass spectrometer was evaluated for nitrosamines selectivity, sensitivity, recovery, repeatability and linearity of response.

TU169

Characterisation of pesticide mixtures and their effects on freshwater communities in the Aconcagua River, Chile

A. López-Mangas, University of Gothenburg / Department of Biological and Environmental Sciences; P. Inostroza, University of Gothenburg / Department of Biological and Environmental Science; A. Arrhenius, University of Gothenburg / Biological and Environmental Sciences; S. Elgueta, Instituto de Investigaciones Agropecuarias INIA / Department of Environment; T. Schulze, M. Krauss, W. Brack, Helmholtz Centre for Environmental Research UFZ / Effect-Directed Analysis; T. Backhaus, University of Gothenburg / Department of Biological and Environmental Sciences

Pesticides can affect non-target freshwater organisms and therefore alter the structure and/or function of aquatic ecosystems. In freshwater ecosystems, pesticides occur as complex chemical mixtures, whose effects have been shown greater than single compounds effects. Although pesticides are a well investigated group of chemicals, many uncertainties regarding mixture effects on aquatic ecosystems remain unknown. Here, we conducted a risk characterisation of pesticide mixtures and assessed their effects on freshwater communities in the Aconcagua River, Chile. Four specific objectives were established: (1) to assess the pesticide status of the Aconcagua River, (2) to characterise the biological status of freshwater communities, (3) to describe major correlations between pesticide and biological status, (4) to conduct predictive analysis using concentration addition and independent action approaches. Chile is one of the top food producers in South America and the Aconcagua River is one of the most important rivers in the country, which hosts mining activities, intensive agriculture and several wastewater treatment plants along its basin. Nine sampling sites were selected (three reference, three tributaries and three river sites) in order to characterise the river basin chemically and biologically. Two different analytical approaches were used to describe the pesticide status along the river: (i) grab surface water samples (2 L) were collected and analysed following the EPA method 508 by GC-MS, and (ii) 50 L were filtered *in situ* using large volume solid-phase extraction (LVSPE) and used for LC-HRMS analysis, also, further bioanalysis will be conducted. Bacteria from sediment, biofilm, macroinvertebrates and environmental DNA were collected in order to conduct diversity analyses and determine the biological status along the river.

TU170

Contribution of vegetation-related chemical fingerprints for the chemical composition of river waters

M. Nanusha, M. Krauss, T. Schulze, W. Brack, Helmholtz Centre for Environmental Research UFZ / Effect-Directed Analysis

River water contains large number of plant metabolites that possibly pose risk on human being, when the water is used for human consumption. Some of these metabolites are species-specific while others are common to all or most plant species. The majority of metabolites released by plant to river water are unknown. Several approaches have been implemented for the identification of chemical composition, mainly anthropogenic origin, of river waters. On the other hand, large number of chemical signals detected in river water was left unidentified. Some or most of these unidentified components might be contributed by natural or agricultural vegetation. Thus, an alternative approach has to be implemented to investigate the chemical contribution from vegetation. To address these, we analysed extracts from widespread natural plants (e.g *Allium ursinum*, *Fallopia japonica*) and agricultural crops (e.g. wheat, rapeseed, corn, potato) and water from adjacent rivers by non-target screening using liquid chromatography coupled to high resolution mass spectrometry (LC-HRMS). Among the detected nontarget peaks in plant extracts, we could discriminate peaks showing up in extracts from one plant (plant specific peaks) but not in the remaining plants and background reference river waters. For each plant, from several thousands of plant metabolites, specific peaks with intensity above 10^5 were distinguished, which were used for annotating peaks from water samples. Accordingly in river samples adjacent to the specific plant stocks, several dozens of such plant-specific peaks could be detected (e.g., 68 for *Allium ursinum* and 227 for rapeseed). The majority of these peaks elute at low retention times indicating high hydrophilicity. MS/MS spectra for most pairs of overlapping peaks confirmed that they were the same compounds. Thus, our study indicates that plants are the sources for the observed overlapping peaks in stream samples. Current activities focus on the identification of these compounds and evaluation of their potential toxicity.

TU171

An automated approach for the determination of gasoline range organics in water using gas chromatography coupled with static headspace sampling

G. Riccardino, J. Renpenning, C. Cojocariu, Thermo Fisher Scientific

Gasoline Range Organics refer to hydrocarbons with a carbon range from C6-C10 that have boiling points ranging from 60^0 to 170^0 Celsius. These chemicals are frequently present in the environment especially in soils and ground water and the source of contamination is usually human errors or accidents (such as oil spills) that occur when handling, storing or transporting oil and oil products. If GRO are detected in soils or water, the level of contamination needs to be determined by using quantitative analytical methods. Often the method of choice is head space sampling techniques coupled to gas chromatography and mass spectrometry and/or flame ionisation detectors. In this work, the Triplus Plus 500 valve-and-loop static headspace coupled with a Trace 1310 gas chromatograph and an ISQ 7000 mass spectrometer were employed to develop an automated method for quantitative assessment of GRO in water. Chromeleon chromatography data system was used to acquire, process and report data. The performance of the method was assessed and various analytical parameters investigated. The data presented in this study demonstrates the method performance and reliability in addition to automated data processing and reporting capabilities.

TU172

Profiling Environmental Mixtures in Water using GC/Q-TOF

S. Nieto, T. Anumol, Agilent Technologies Inc.; K. Chen, Agilent Technologies Inc. / Workflow Solutions; P. Wylie, Agilent Technologies Inc. / Market Development; C. Alaimo, University of California Davis; T.M. Young, University of California, Davis / Civil and Environmental Engineering

The traditional approach to monitoring organic contaminants involves analyzing a defined number of target compounds by mass spectrometry with the instrument operated in a selected data acquisition mode for targeted analytes. However, there is evidence that such an approach may significantly underestimate the exposure and risk of pollutants, compared to a more comprehensive broad-scope targeted and untargeted screen. With the plethora of chemical mixtures present in the environment, the ability to measure as many of them in an intargeted fashion is important. Recent advances in mass spectrometry allows an increased scope of analysis when using high resolution accurate mass instruments operated in full spectrum acquisition mode. Accurate mass information enhances the amount of detail in the information collected and allows for the determination of both targeted and non-targeted components using libraries, databases and fragment predictors. This study will present a workflow combining targeted quantitation, a broad scope suspect screen using curated databases and libraries as well as non-targeted screening using surface water samples collected in Sacramento-San Joaquin Delta in Northern California with a high-resolution accurate-mass GC-QTOF instrument. Untargeted screening was enhanced and facilitated with the use of a novel low energy EI mode that allowed greater molecular ion detection and hence easier identification in these water samples. The study detected several compounds not initially looked at during the targeted analysis that where present at high abundances in the samples.

TU173

Analysis of unknown Organic Compounds in Reservoir-Water by using Comprehensive Two-Dimensional Gas Chromatography/Time-of-Flight Mass Spectrometry

K. Li, China Institute of Water Resources and Hydropower Research; x. Wan, China Institute of Water Resources and Hydropower Research IWHR

A high throughout screening method, which used by comprehensive two-dimensional Gas Chromatography coupled to time-of-flight mass spectrometry, was applied to screening the unknown organic pollutants in eight sampling sites from a typical reservoir in China. A total of 288 organic contaminants were identified, of which 9 were detected at 100% sites of study reservoir including aniline?1,4-dichlorobenzene?nitro-benzene?o-nitraphenol?2,4-dimethylphenol?2,4-dichlorinephenol?1,3-dimethylnaphthalene?1,4-dimethylnaphthalene?diphenylamine in 2017. And compare to the testing results in 2018, only 66 organic contaminants were identified, of which none compound was detected at 100% sites. The large number of organic pollutants decreased in study area, which from 2017 to 2018, due to the cage-cleanup-activities in this reservoir.

TU174

Are complex mixtures of xenobiotics common in groundwater?

V. Kodes, Czech Hydrometeorological Institute / Section of water quality; J. Freisleben, Czech Hydrometeorological Institute

Although groundwater is considered relatively safe water resource being naturally protected by soil and rock layers, xenobiotics also occur in groundwater contaminated by agriculture, industrial sites, landfills, leaky sewers etc.. More than 200 man-made chemicals have been lately monitored in groundwater at almost 700 sites in the Czech Republic. The national groundwater monitoring network is set up the way that it does not monitor contaminated sites such as industrial areas, landfills etc. In spite of such setup, 120 chemicals were found in groundwater in various mixtures, up to 30 substances occurred in individual monitoring sites. In total 2715 samples were taken in years 2016-2017, thereof 528 (20%) samples were free of such compounds, 323 (12%) samples contained just one compound, 231 (8%) samples contained 2 compounds, 3 to 10 compounds were detected in 1255 (46%) samples and more than 11 up to 30 compounds were found in 378 (14%) samples. Prevailing contaminants were pesticides followed by VOCs (mainly chlorinated hydrocarbons) and PAHs. Also alkylphenols, pharmaceuticals, chelating agents, PCPs and benzotriazoles were detected in groundwater. The total concentration of xenobiotics in groundwater can exceed 100 and reach up to 551 μg/l. Monitoring results show that mixtures of various xenobiotics can be found in groundwater more often than one could suppose.

TU175

Identification of toxicants from a hydrocarbon contaminated sediment of a log pond

M. Dahl, S. Survo, University of Helsinki; P. Välitalo, Aalto University; G. Kabiersch, O. Alitalo, University of Helsinki; O. Penttinen, University of Helsinki / Faculty of Biological and Environmental Sciences; A. Rantalainen, University of Helsinki

Sediment from a log pond of plywood mill located in south Finland contained 15,000 to 50,000 mg/kg dw of C10–C40 hydrocarbons. It was unclear whether they originated from the hydraulic fluid of the log hoist or the wood extractives because biogenic organic compounds (BOCs) can interfere with chemical analysis of total petroleum hydrocarbons (TPH) by being extracted along with anthropogenic oil compounds. For risk assessment, additional information was needed on the nature of the hydrocarbons in the contaminated area, as TPH concentration often does not correlate with the results of toxicity tests. In the present study, methods of effect-directed analysis (EDA) were used for the identification of toxicants. The toxic potential was investigated using a biotest battery that included two in vivo acute toxicity tests, an estrogenicity test, and a genotoxicity test. A preparative fractionation of samples enhanced the potential to identify the key toxicants in BOCs and petroleum hydrocarbons. A combination of fractionation, biotesting and chemical analyses revealed that the key toxicant of log pond sediment was retene, a dialkyl-substituted phenanthrene derived from wood resin acids. Additionally, the most toxic fraction included three other wood-originated diterpenic compounds. Typical wood extractives such as sesquiterpenes and odd-carbon number alkanes in the range C21–C33 were identified in the fraction, which showed minor genotoxic potency. The most polar fraction contained triterpenes and showed estrogenic activity. No evidence for the presence of hydraulic fluid in sediment was found. The present study also indicated that in cases where the organic matter content of sediment or soil is high, using the results of standard mineral oil analysis in risk management can lead to incorrect actions, because standard methods do not differentiate petroleum hydrocarbons from naturally occurring hydrocarbons. However, sometimes environmental effects of BOCs can be larger than the impacts of petrogenic compounds if these compounds are concentrated at a particular location due to human activities. The present study showed that EDA can be applied in the identification of responsible toxicants to samples that are contaminated with different kinds of hydrocarbon.

TU176

How to measure time-weighted average concentrations with Diffusive Gradients in Thin films (DGT)?

J. Puy, A. Altier, M. Jiménez, Universitat de Lleida and AGROTECNIO / Dep Quimica; R. Uribe, Universidad del Tolima; C. Rey-Castro, Universitat de Lleida and AGROTECNIO / Dep Quimica; J. Galceran, Universitat de Lleida / Dep Quimica

Passive sampling can be a cost effective analytical approach to provide time-weighted average (TWA) concentrations of pollutants in natural waters. DGT differs from other passive samplers by incorporating a diffusion disc in between the accumulation element (binding phase) and the sample [1]. The DGT labile concentration is defined as $c_{DGT}= n_M$ [delta]^g / (D_M A t), where n_M is the accumulation, D_M the metal diffusion coefficient, [delta]^g the total thickness of the diffusive gel, filter and diffusive boundary layer, A the area of the device and t the deployment time. Solutions of Ni, Cd or NiNTA were used to compare c_{DGT} with the average total metal concentration for different deployment times and metal concentrations.When the accumulation in simple metal solutions approaches perfect sink conditions, c_{DGT} provides a good estimation of the TWA metal concentration. Transient effects following each concentration jump are mainly dependent on the pulse time as it will be presented.In presence of ligands, it is shown that c_{DGT} depends on the speciation, the mobility and the lability degree, [xi], of the complexes at each time interval [2]. Since [xi]≤ 1 and usually the diffusion coefficients of the complexes are smaller than that of the metal, c_{DGT} can underestimate the TWA total metal concentration as seen in many cases[3]. For only one strong complex and excess of ligand conditions, the free metal is negligible and the lability degree becomes independent of the time interval. Then, c_{DGT} reduces to $c_{DGT}(t)= D_{ML}$ [xi] $c_{T,M,Av}$/ D_M. Thus, a simple factor can allow c_{DGT} to improve the estimation of the TWA metal concentration in presence of a dominant complex as seen in the NiNTA system. Development of Stainless Steel Filter as a Novel Passive Sampler for Chlorinated Paraffins in Waters

C.L. Chen, South China Normal University / Environmental Research Institute; B. Yuan, Stockholm University / Department of Environmental Science and Analytical Chemistry (ACES)

Passive sampling has many advantages over active methods: providing time-weighted average (TWA) data, saving time and cost and can yield highly spatially resolved data. Of many passive samplers, the diffusion-based samplers have many advantages: such as the well-controlled sampling rate and a potential surrogate method for indicating mobility and bioavailability. The stainless steel filter (SSF) is used for solvent filtration before HPLC pumps, it has a well-defined wall thickness and pore size and it is inert to POPs. Therefore, we hypothesize that it might be possible to use it as a kinetic passive sampler by filling with the suitable sorbent. Chlorinated paraffins (CPs) is a mixture of polychlorinated n-alkanes of varying chain length (C10-C30) and degrees of chlorination (40 to 70% by weight). The CPs are generally grouped as short-chain (SCCPs, C10-13), medium-chain (MCCPs, C14-17) and long-chain (LCCPs, ≥ C18). Analysing CPs in the environmental samples is challenging, a cutting-edge analytical method for determining CPs has been developed and validated recently. The combination of this updated CPs analytical method with the kinetic passive sampling technique for in situ sampling of SCCPs, MCCPs, and LCCPs in the aquatic environment is of great interest. Herein, we will report the development of this SSF passive sampler for CPs in waters. We have tested that XAD-2 could be the suitable sorbent and further testings such as the time dependence, diffusion coefficient and effects of some key water chemistry factors are undergoing and the results will be presented at the conference.

TU178

Passive sampling as a tool for determining total chemical discharge in waste waters

H. Ahkola, Finnish Environment Institute, SYKE; L. Äystö, Finnish Environment Institute, SYKE / Centre for Sustainable Consumption and Production; J. Mehtonen, Finnish Environment Institute SYKE; T. Nystén, Finnish Environment Institute; M.T. Leppänen, Finnish Environment Institute SYKE

Currently industrial operators monitor their discharges mainly through analyzing the concentrations of substances in grab samples. However, if the emissions vary with time, the results from grab samples may give misleading information on prevailing chemical concentrations and emissions. Therefore, to achieve representative results through grab sampling, timing of the sampling is essential. Increasing the representativeness of the results might require more frequent sampling, resulting in increased analysis and sampling costs. With passive sampling, a more representative result on the prevalent concentration and occurrence of a large number of chemicals may be achieved. As the samplers are deployed for a length of time, the substances are enriched into the sampler material. This often enables the detection and quantification of smaller ambient concentrations than would be possible when using conventional grab sampling. Different matrices and varying conditions may affect the sampling procedure. The characteristics of waste waters vary dramatically depending on the field of industry. It may include e.g. a high concentration of suspended solids or solvents which attract the chemicals away from the dissolved form and make them unavailable for passive samplers. While grab samples are usually used in analyzing the total concentration of a chemical, passive samplers collect only the freely dissolved chemical fraction. The average dissolved concentration of the studied chemical in the matrix during the deployment can be calculated if the sampling rate is known. As operators are mainly required to monitor their total discharges, the results from passive samplers would either need to be converted into total concentrations by using substance- and matrix-specific conversion factors, or by limiting the use of passive samplers to only water soluble chemicals. The advantage of this technique is that a single chemical analysis may result in a temporally representative estimate of the ambient concentration of the studied chemicals. Thus, emission estimates would be more reliable than emission estimates based on few conventional grab samples. However, the results might not highlight e.g. transient high concentrations, which could have an impact in the receiving waste water treatment plant. To reach a comprehensive and reliable estimate on the emissions and range of chemical concentrations, it might be necessary to combine passive sampling with conventional grab sampling.

Analytical methodology for analysis of silicone materials in products

J.A. Durham, Dow Corning Corporation / Toxicology and Environmental Research Consulting; S. Lewis, Momentive; C. Mund, T. Böhmer, Evonik Nutrition & Care GmbH

With the January 2018 acceptance of a restriction of octamethycyclotetrasiloxane (D4) and decamethylcyclopentasiloxane (D5) by the European Union in wash-off personal care products and the future potential restrictions in leave-on personal care products and other consumer/professional products, the Silicone Industry has developed analytical methods for measurement of volatile methyl siloxanes (VMS) in silicone based materials. The methods currently available cover a range of silicone materials in the market place and take precautions to eliminate potential artefact formation of VMS during the analysis. This presentation details the following methods: 1) Quantification of residual amounts of VMS in fluid silicone polymers, which is applicable to silicone based sample matricesincluding hydroxyl-functional silicones ('siloxanols'), polydimethylsiloxane (PDMS) fluids, amino-functional silicones, polyether-grafted silicones (SiPE) and vinyl-functional siloxanes. 2) Quantification of residual amounts of cyclic volatile methyl siloxanes (cVMS) in silicone elastomers, which is broadly applicable to one-part and two-part pastes, sealants, heat cured elastomers, liquid silicone rubbers and room temperature vulcanized silicones in their cured and uncured states. 3) Determination of free cVMS in fully-formulated wash-off personal care products such as shampoos and conditioners. However, as the analysis of VMS is prone to false high findings depending on individual matrix interferences, users of these methods need to validate the methods in their own laboratory prior to analysis of unknown samples. Laboratories conducting the tests need a solid QA/QC program to ensure accurate results. Based on the current instrumentation recommendations, the methods are expected to work over a range of concentrations between 0.01%

and 0.5%.

TU180
Global monitoring of siloxanes in the environment: A commitment of industry in cooperation with governmental agencies and scientific community
J.A. Durham, Dow Corning Corporation / Toxicology and Environmental Research Consulting; C. Mund, T. Böhmer, Evonik Nutrition & Care GmbH; K. Plotzke, Dow Chemical Company / Consumer Solutions; R. mait, Bramlee Consulting LLC; R.M. Seston, Hyla Environmental Consulting, LLC / Toxicology, Environmental Research & Consulting; D. McNett, The Dow Chemical Company; T. Guerrero, ACC/SEHSC; J. Kim, The Dow Chemical Company / Toxicology and Environmental Research and Consulting; N. Meguriya, Shin-Etsu
The Silicones industry, through the Global Silicones Council, committed significant resources to better understand the environmental presence and behavior of siloxanes used to make silicones. These siloxanes are known as octamethylcyclotetrasiloxane (D4), decamethylcyclopentasiloxane (D5), and dodecamethylcyclohexasiloxane (D6). Industry -initiated environmental monitoring programs, which are coordinated with government agencies, employ methodologies and quality control measures that can accurately measure low part per billion levels in the environment, and which may allow for a scientifically sound risk assessment. The following programs are described in detail and show the working relationship the GSC has developed with government agencies across the globe. 1) United States Environmental Protection Agency (EPA) D4 monitoring program. 2) European Union Restrictions monitoring program. 3) Voluntary long-term monitoring of D4, D5 and D6 in aquatic environments in North America, Europe, and Asia.

TU181
TOXmini® relevance and sensitivity assessment
M. LOT, F. Mounède, T. Merzi, P. Baldoni-Andrey, TOTAL SA
In a regulatory context of ever increasing environmental responsibility (OSPAR convention, BREF CWW), there is a need to have biomonitoring tools to evaluate waste water quality at any time. To date, and for several decades, the standard toxicity testing tool used for rapid analysis of waste water has been Microtox®. However, this tool is too complicated to be used on production sites (off-shore and on-shore) by operators without prior knowledge. A new tool has become available called TOXmini®. This one is an equivalent of Microtox® but is portative (lighter weight) and easier-to-use. Main difference between tools is the calculation of an inhibition rate as endpoint for TOXmini® instead of an EC_{50} for Microtox® which lead to an easier usage (no dilution series). TOXmini® was compared to Microtox® test (reference test) on typical substances and chemical additives found in the oil industry. The effect of the effluent temperature was also assessed to mimic the same conditions as we can find in a production site (high and low temperature). Results show similar results between the two tools and no temperature effect on bacteria viability was observed. Tests on other marine organisms (algae and rotifers) were also realised in order to compare results on organisms of different trophic levels. It appears that there is no general rules about organism sensitivity. Hence, results show that TOXmini® may be used as a biomonitoring tool on production sites. However, in cases where bacteria would not be the most sensitive species, the use of this tool will not be self-sufficient and would require to be combined with additional bioassays.

TU182
USE OF EFFECT-BASED METHODS FOR WATER QUALITY ASSESSMENT OF TIBER RIVER IN ROME
W. Cristiano, Italian Institute of Health (ISS) / Department of Environment and Health; I. Lacchetti, M. Corti, K. Di Domenico, S. Caciolli, Italian Institute of Health ISS / Department of Environment and Health; H. Hollert, RWTH Aachen University / Institute for Environmental Research; L. Mancini, M. Carere, Italian Institute of Health ISS / Department of Environment and Health
The Tiber is the third-longest river in Italy and the main watercourse in Rome. As such, there has always been a historical and social relevance to the economic activities emerged along its banks. Indeed, the Tiber's river basin has been affected by different kinds of human pressure involving a number of potential sources of pollution, including pesticides, urban and industrial wastewater discharges, waste dumps and livestock waste products. It can be thus assumed the existence of thousands of chemical pollutants, also combined as mixtures, affecting its entire watercourse. Therefore, a monitoring strategy based on ecotoxicological bioassays has been elaborated through the analysis of organisms belonging to different trophic levels of a typical freshwater ecosystem, with a view to investigating the effects of such contaminants on aquatic biodiversity. A special focus has been placed on zebrafish at early life stages and their behaviour, as this model can provide fundamental data on the ongoing development of vertebrates exposed to toxic environmental samples. The goal of this study is to support the evaluation of the quality status of the urban section of the Tiber River in the city of Rome, which aims to implement the European legislation on waterbodies protection (Water Framework Directive). The results will help the scientific and administrative local communities in elaborating actions for reducing chemical pollution in one of the most populated areas of Italy and protecting both the ecosystem and human health.

TU183
Effect-directed monitoring tools as a toxicological fingerprint for ecological and human risk assessment of water bodies.
V. De Gussem, University of Utrecht / Environmental Sciences; L.M. Schuijt, Wageningen University; P. van den Brink, Wageningen University / Department of Aquatic Ecology and Water Quality Management; J. van Dijk, Copernicus Institute Utrecht University / Environmental Sciences; M. Jonker, N. Kramer, Utrecht University / Institute for Risk Assessment Sciences; A. van Wezel, University of Amsterdam IBED Institute
Classical analytical methods to monitor water quality have their limitations: i) not all chemicals of emerging concern can be measured at low enough concentrations in water, ii) they do not assess the presence and levels of all unknown chemicals (e.g. transformation products), and iii) they do not assess chemical mixture effects. For these reasons, the use of bioassays to assess the health risks associated with chemical contaminants in water has been promoted the past few years. We propose a battery of sensitive, 3R-based and practical bioassays, covering ecologically- and human-relevant toxicity pathways. These effect-directed monitoring (EDM) tools will assess the ecological and human health risks of chemicals in different types of water bodies, taking into account complex mixture of compounds. Endpoints of the bioassays were selected based on the modes of actions (MoA) or key events (KE) of human- or ecotoxically-relevant adverse outcome pathways (AOPs) reported for a compiled list of regulated environmental chemicals and prioritized chemicals of emerging concern (CECs). The selection of the bioassays was completed by technical and practical criteria, in order to facilitate the use of the EDM tools in the context of routine water quality assessment of surface water and drinking water. Using the assay battery, a toxicological "fingerprint" of a water sample can be obtained.

TU184
Mitochondrial toxicity of micropollutants in water samples measured by the oxygen consumption rate in cells
M.E. Müller, University of Tubingen; S. Vikstrom, Agilent Technologies; M. Koenig, R. Schlichting, Helmholtz Centre for Environmental Research GmbH - UFZ / Cell Toxicology; C. Zarfl, University of Tuebingen / Center for Applied Geoscience; C. Zwiener, Environmental Analytical Chemistry, Center for Applied Geoscience, University of Tuebingen / Geosciences; B. Escher, Helmholtz Centre for Environmental Research GmbH - UFZ / Cell Toxicology
Many anthropogenic chemicals enter the aquatic environment every day and some of them have the potency to impair mitochondrial functions. Due to the crucial importance of mitochondria as energy factories in all eukaryotic organisms, these chemicals may pose a risk to organisms and ecosystems. However, little is known how environmental pollutants interact in mixtures. The quantification of the oxygen consumption rate (OCR) of cells using the Agilent Seahorse XF^{e}96 Analyzer has the potential to differentiate the various modes of action of mitochondrial toxicity of single compounds, including inhibition of the electron transport chain or the ATP-synthase and uncoupling of oxidative phosphorylation by destroying the electrochemical proton gradient. Thus, the aim of our study was to analyse the applicability to measure the cellular OCR with the Agilent Seahorse XF^{e}96 Analyzer to identify and quantify mitochondrial toxicants in environmental samples. Using reference chemicals of known mechanism and potency, three experimental designs for the OCR measurements on HepG2 cells were developed to quantify and differentiate the effects on the main components of the mitochondrial respiration. Enriched river water and 4 selected environmental pollutants that are potentially occurring in river water were then tested with these bioassay designs. The herbicide bromoxynil exhibited a strong uncoupling effect and did not affect the electron transport chain, whereas the fungicide azoxystrobin was a potent inhibitor of the electron transport chain. The biocide tributyltin inhibited both the electron transport chain and the ATP synthase, but its uncoupling effect could not be quantified because it was masked by the inhibitory effects. Extracts of river water samples were tested at relative enrichment factors (REF) of up to 200 in comparison to the original water samples without apparent cytotoxicity during the duration of the experiment. Uncoupling or inhibitory effects could be detected in various extracts of river water while extraction blanks showed no or very low effects. These effects were then validated in binary mixture experiments confirming concentration addition of the water extracts and single chemicals of known mode of actions. In conclusion, the assay setup developed for OCR measurements in cells is capable of determining the effect of environmental samples quantitatively and precisely and allows conclusions on the mechanism of mitochondrial toxicity.

TU185
Design of bioluminescent enzyme biotests for analysis of the complex mixtures
E. Esimbekova, Institute of Biophysics SB RAS; V. Kalyabina, Siberian Federal University; V. Kratasyuk, Siberian Federal University / Biophysical
Complex in composition vital components of the natural environment, such as soil or food of plant origin, are prone to the accumulation of potentially hazardous substances, so the analysis of their safety is one of the priority tasks of

environmental toxicology. Rapid and simple biotesting techniques are needed to control safety and minimize health risks to consumers. The bioluminescent enzyme inhibition-based assay has a good potency for complex mixtures analysis. The purpose of the study was to develop a scheme for design of new enzyme biotests, suitable for assessing the safety of natural and artificial mixtures of complex composition. To assess the safety of complex mixtures potentially containing polluting chemicals, we used a coupled enzyme system of luminous bacteria NAD(P)H:FMN-oxidoreductase+luciferase (R + L). The bioluminescent method is based on the detection of the inhibitory effect of the analyzed sample on enzymatic reactions by registering changes in the intensity of the emitted light. At the first stage, the sensitivity of enzymes to the action of potential pollutants of a complex environment was established. It was shown that the coupled enzyme system R + L is sensitive to a number of heavy metals and pesticides at the level of their maximum allowable content in food. At the next stage, the effect of the food samples as a complex media on the coupled enzyme system R + L activity in the absence of pollutants was assessed. When components of the control (unpolluted) food samples inhibited or stimulated the R + L activity we modified the procedure of the sample preparation to decrease the effect. At the final stage model experiments were conducted to assess the sensitivity of the coupled enzyme system R + L to a complex mixture of the analyzed sample of food and toxic substances. Thus, it has been established that the basic principles for designing bioluminescent enzymatic tests for analyzing heterogeneous media are 1) to ensure maximum sensitivity to potentially toxic substances and 2) to select the procedure of sample preparation that guarantee the minimal effect of unpolluted complex media on the coupled enzyme system R + L for correct interpretation of results. The reported study was funded by the Russian Foundation for Basic Research, the Government of Krasnoyarsk region and the Krasnoyarsk Regional Fund of Science according to the research project no. 18-44-242003.

TU186
Sensitivity of epigean versus hypogean crustaceans: ecotoxicity and online biomonitoring
A. Gerhardt, LimCo International GmbH
Groundwater represents an important reservoir as drinking water resource in Europe, prone to pollution by agricultural chemicals and nutrients. Risk assessment is being based on toxicity data of surface water species, mostly Daphnia spp. However, groundwater invertebrate species are facing completely different abiotic and biotic factors, life cycles and lifetime duration; hence extrapolation of toxicity data from Daphnia spp. to groundwater crustaceans might not be appropriate and underestimate the toxic potential of pollutants. Moreover, groundwater as safe drinking water resource needs to be protected continuously, e.g. by online biomonitoring. Within GROUNDCARE (BMBF 2015-2019) we study the acute and chronic effects of nutrients (nitrate) and toxins (Cu, BPA) on surface and subsurface crustaceans. We also develop groundwater crustaceans as new biomonitor species in the Multispecies Freshwater Biomonitor (MFB) for permanent online biomonitoring of drinking water intakes. First results indicate *Proasellus slavus* as most sensitive species compared to *Gammarus fossarum* and *Niphargopsis casparyi* regarding acute and chronic exposures to Cu and BPA. Moreover, among the microcrustaceans, *Eucyclops serrulatus* proved to be more sensitive than *Daphnia magna*. Groundwater macrocrustaceans proved to be at least as sensitive as *Daphnia magna,* easier to handle, and with longer stand-alone times in continuous longterm biomonitoring of water quality, thus allowing for recording integrated effects of chronic low-dose chemical mixtures.

TU187
In situ assays to assess the impact of wildfires on reservoirs
N. Abrantes, University of Aveiro-CESAM / CESAM/DAO; A. Ré, University of Aveiro / Department of Biology and CESAM; I. Campos, University of Aveiro / Department of Environment and CESAM; J. Pereira, F.J. Gonçalves, University of Aveiro / department of Biology & CESAM; J.J. Keizer, University of Aveiro / Department of Environment and CESAM; M.J. Benoliel, Empresa Portuguesa das Águas Livres, S.A. EPAL / Direção Laboratórios e de Controlo da Qualidade de Água; J.M. Paiva, Empresa Portuguesa das Águas Livres, S.A. EPAL; V. Cardoso, EPAL- Empresa Portuguesa das Águas Livres, S.A. / Direção Laboratórios e de Controlo da Qualidade da Água; R. Barreto, EPAL- Empresa Portuguesa das Águas Livres, S.A.
Reservoirs are important and strategic water resources in Portugal, guaranteeing water for human supply and irrigation in a significant part of the territory. Hence, it is of fundamental importance to guarantee their water quality. Recently, wildfires have been pointed out as an important source of diffuse contamination to aquatic systems, affecting drastically their quality, namely through the production and subsequent exportation of deleterious pyrolytic substances, such as polycyclic aromatic hydrocarbons (PAHs), and through the input of metals associated to ash loads. Notwithstanding the recognition that wildfires can affect water quality, their potential toxic effects on aquatic ecosystems have been largely ignored. Hence, the main goal of this study was to assess the off-site effects of wildfire on a reservoir using *in situ* bioassays with key aquatic standard organisms. The bioassays were conducted in a recently burned area located in the Cabril catchment (central Portugal) just after the first post-fire rainfall events. Four sites were selected to perform the *in situ* assays: two in the main stream (ZD- downstream the burnt area and ZB – within the burnt area) and two in a tributary river (UB – within the burnt area and UU – upstream the burnt area (reference site)). The chemical composition of water was analysed, with specific focus on metal and PAHs. Three freshwater organisms, including the producer microalgae *Raphidocelis subcapitata*; the first consumer *Daphnia magna* and the benthic detritivore *Chironomus riparius*,were exposed in all four sites, using dedicated test chambers. For the microalgae the endpoint assessed was the growth rate inhibition, while for the other two species was the post exposure feeding inhibition. The chemical assessment proved the existing concern of wildfires impacts on aquatic systems, as a diffuse source of metals. The effects observed on the three species allowed discriminate unburnt and burnt sites. Thus, the *in situ* bioassays showed to be a suitable tool to assess the risks of wildfire to aquatic systems.

TU188
Biodegradation of Hydrocarbon Contents in a Crude-Oil Polluted Soil using Peroxidase from Fungal Di-Cultures (Rhizopus and Saccharomyces spp.)
P. Ferdinand, I.O. Onyeocha, Federal University of Technology, Owerri. / Biotechnology; E.U. Ezeji, Federal University of Technology / Biotechnology; H.E. Oparaji, UNIVERSITY OF NIGERIA, NSUKKA / Biochemistry
This study was carried out to evaluate the biodegradation of hydrocarbons in a crude oil polluted soil using peroxidase isolated from *Saccharomyces* and *Rhizopus* species. Crude oil polluted soil samples were collected from Bonny loading jetty site at Onne. Physicochemical analysis of the soil samples revealed that it was acidic (pH 5.02) with conductivity of 723. Dissolved mineral contents of the polluted soil revealed the presence of Cl, $P0_3$, Mg, K, Ca, $H(CO_3)_2$. Heavy metals identified in the polluted soil included Fe, Cd, As and Pb, while Cd, and Hg with higher values compared to the unpolluted soil. Hydrocarbon degrading peroxidase was produced from the fungal di-cultures isolated from the polluted soil using standard microbiological and biochemical techniques. Fourteen days pilot study carried out on the isolated fungi optimized for peroxidase production showed day eight (8) as the day of maximum enzyme production in the fermentation media. Optimum operational conditions for enzyme substrate reaction for peroxidase activity from the fungi were evaluated and observed at pH (4.5) and Temperature (50ºC). The degradation was carried out and evaluated using optimized gravimetric techniques. Peroxidase incubated with the crude oil in a basal mineral medium showed strength of utilization of the carbon catenation chains in all the optimized parameters. Peroxidase from the di-cultures showed optimal degradative ability at acidic ph range with the peak at 5.5 with the residual oil given as 15-20% v/v. Evaluation of biodegradation by the peroxidase showed that the total weight of degraded oil was 4.02g. The weight of oil degraded increased with increase in enzyme concentration. This study has shown that peroxidase has a great potential in the biodegradation of hydrocarbons present in crude oil polluted soil and is of high eco-toxicological relevance as regards to environmental remediationl. Keyword: Biodegradation, peroxidase, *Rhizopus* sp. *Saccaromyces* sp.

TU189
Effluent biodegradatibility evaluation using Whole Effluent Assessment
M. LOT, TOTAL SA; P. Thomas, C. Crouzy, CEHTRA; C. GELBER, P. Baldoni-Andrey, TOTAL SA
In its Risk-Based Approach (RBA) for the management of Produced Water discharges from offshore installations1, the Oslo and Paris Commission (OSPAR) Recommendation 2012/5 advocates the Whole Effluent Assessment (WEA) approach. WEA approach increases the understanding of the combined effects in complex mixtures like effluents. The advantage of WEA approach compared to WET approach (toxicity only) is that WEA approach gives more information about the future of the effluent with the characterization of P (Persistency) and B (Bioaccumulation) criteria. A WEA practical guidance2 document from OSPAR Commission indicates some available persistency tests but without giving any information about their interpretation. Moreover, the review of the persistency test highlights the inconvenience that they were developed to assess the biodegradability of mono substances and not complex mixtures such as produced waters. Hence, there is a need to identify the most appropriate methodologies (tests) to evaluate the biodegradation of produced waters taking into consideration the specificities of substances included inside (naturally occurring substances and additives).

TU190
Environmental compatibility of soils debris conditioned with foaming agents containing sodium lauryl ether sulphate in a tunnelling scenario
T. Pescatore, Italian National Research Council / Water Research Institute; L. Rolando, Water Research Institute - Italian National Research Council / Water Research Institute; A. Barra Caracciolo, National Research Council / Water Research Institute; P. Grenni, National Research Council of Italy (CNR) / Water Research Institute; F. Spataro, L. Mariani, Italian National Research Council / Water Research Institute; J. Rauseo, National Research Council / Institute of Water Research IRSA-CNR; n. ademollo, IRSA-CNR / Water Research Institute; G. Garbini, Italian National Research Council / Water Research Institute; D. Balducci, Italian National Research Council; E. Galli, IBAF - CNR / Earth system

science and environmental technologies; A. Finizio, University Milano - Bicocca / Department of Earth and Environmental Sciences; L. Patrolecco, Water Research Institute-National Research Council / Water Research Institute

The mechanized tunnelling industry by EPB-TBMs (Earth Pressure Balance-Tunnel Boring Machines) needs a wide use of foaming agents and polymers as lubricating products for soil conditioning. The anionic surfactant sodium lauryl ether sulphate (SLES) is the main components of foaming commercial products. Soil debris from excavation processes contain residual concentrations of SLES and their potential re-use for environmental purposes depends on its persistence that is influenced by site-specific conditions. The objective of this study was to evaluate the overall environmental compatibility of different soils from real excavation sites conditioned with foaming products containing SLES. For this purpose, three soils in different lithologies (S1 clay; S2 sandy-clay; S3 clay) were conditioned with one common commercial foaming agent (F, containing 5-10% SLES) in presence or absence of a polymer (P, containing 25-50% SLES); this latter is used in some excavation conditions to increase foam persistence. Several microcosms were set-up mixing 1,5 kg of each soil with water, foam and/or polymer and then incubated at room temperature for 28 days. Control microcosms consisting of un-conditioned soil were also considered. At selected times (0,7,14,21,28 days), soil sub-samples were collected from each microcosm to analyse SLES concentration and to produce aqueous elutriates on which different ecotoxicological tests were performed. Terrestrial and aquatic test organisms were considered: the luminescent bacteria *Vibrio fischeri*, the plant *Lepidium sativum*, the worm *Eisenia foetida*and the ostracod *Heterocypris incongruens*. Moreover, SLES residual concentrations were determined over time both in soil than in elutriate samples with Methylene Blue Active Substances (MBAS) spectrophotometric method, preceded by Pressurized Liquid Extraction(PLE) of SLES in the case of soil matrix. The results showed an initial (t=0d) SLES concentration in the different conditioned soils ranging from 54 to 105 mg/kg, with the higher value detected in the soils (S1 and S3) conditioned with both F and P. The overall ecotoxicity tests showed that already at the starting time SLES concentration in soils and elutriates did not exert any toxicity effect on the organisms tested. This study highlights the important role of the ecotoxicological approach in order to assess if soil debris can or not pose a potential risk for the terrestrial and water compartments in order to use this soil as a by-product.

TU191

Characterization of fine (PM2,5) and ultrafine (PM<0,3) atmospheric particles under industrial or traffic influence in the North of France

F. Cazier, ULCO - Centre Commun de Mesures / Centre Commun de Mesures; P. Genevray, D. Dewaele, C. Vandenbilcke, Université du Littoral Côte dOpale / Centre Commun de Mesures; A. Verdin, Université du Littoral Côte dOpale / Unité de Chimie Environnementale et Interactions sur le Vivant (UCEIV) EA 4492; L. Courcot, Université du Littoral Côte dOpale / 3Laboratoire dOcéanie et de Géosciences; D. Courcot, Université du Littoral Côte dOpale / Unité de Chimie Environnementale et Interactions sur le Vivant UCEIV EA4492; S. Achard, Universite Paris Descartes / Epidémiologie environnementale Impact sanitaire des pollutions

Airborne particulate matter (PM) is a complex mixture of particles from different origins. Compositions of PM strongly depend on the mechanism of formation, meteorology and mainly the nature of their emission sources. These latter are numerous, can be natural or anthropogenic and could be divided in stationnary (industrial sites, house heating …) or mobile sources (road traffic). As a result, the health impact of the atmospheric particles, especially on repiratory system, can change according to their origins. In this context, the objective of this work was to study the variation of composition of fine and ultrafine PM under industrial and road traffic influence before studying their impact on human epithelium. PM were collected at two different sites. First, Grande-Synthe, located on the French North-Sea coast. The sampling point was placed under the direct influence of Dunkerque port-industrial area. Secondly, in Roubaix, a city included in Lille metropolis, on a site located close to a high traffic road. PM were sampled from March to end of May 2017. Particles on plates and back-up filters collected with sierra 235 high volume cascade impactor were pooled to obtain average samples of fine and ultrafine particles. The PM were analysed for water-soluble ions, trace and major elements, n-alkanes and PAHs content. In addition, morphological characterization were realized by SEM-EDX. Average industrial and urban $PM_{2.5}$ concentration wer close with respectively 11.6 and 10.8 µg/m^3. Industrial samples show higher concentrations in SO_4^{2-} while NO^{3-} is the major soluble compound in urban PM. These compounds are linked with the sulfure emissions from industrial sintering plants and NOx emissions from road traffic. Regarding trace elements, Roubaix PM present high levels of Ba, Cu, Mo and Sn which are known tracers for vehicle metallic parts attrition. On the opposite, under industrial influence, Fe, Mn, Ni, V and Zn are the major elements, coming from the metallurgic plants in Dunkerque industrial area and heavy fuel oil combustion. PAH concentrations are two to sixteen times higher in industrial PM. If pyrogenic compounds are predominant on both site, they mainly come from vehicles for urban PM whereas they suggest coal combustion (coke oven) in industrial ones. In conclusion, particles sampled are clearly specific from industrial and traffic influence. So it will be relevant to study their respiratory impact of the PM and try to discriminate their toxicity.

TU192

Environmental leaching of steel shots

H. Tolvanen, Ramboll / Site Solutions; N. Lindroos, T. Suikkanen, K. Järvinen, Ramboll

EU commission has forbidden the use of lead in many commercial products. Also the use of lead shots in Ramsar wetlands and shooting ranges are under debate. The steel shots are very likely to replace the lead shots in future. Steel shots are usually made of recycled metal scarps and will also leach in acid wetlands and shooting ranges. Many times, shooting ranges in Nordics are in mineral soil areas where also groundwater is formed. The steel shot leaching affects to environmental fate of the alloy metals. The steel shot leaching was studied with two different leaching test methods: batch testing according to EN-SFS 12457-2 and alternating freezing-melting cycles in laboratory. Both tests were conducted in liquid solid -ratio 10. The test materials were mineral soil (as in groundwater areas) and wetland peats. Steel shots (Saga® Eurotrap steel) was added to both soil types as much as to cover approximately 20 years of steel shot shooting in common Finnish range. Among other rarer metals iron, chromium and nickel were leached in both test types and soils. In batch test metals were more readily leached than in freezing-melting cycles tests. The test method used affected to the results. The freezing-melting cycle test represents better the natural leaching of materials in the environment than the standard batch test. The steel shots were more readily leached in wetlands than in mineral soils resulting in higher concentrations for many metals. Also, different leaching pattern were observed for the soil types. In mineral soil the leaching behavior of metals was steadier than in wetland samples where the alternation in the metal concentration levels was common.

TU193

Industrial scale destruction of old chemical ammunition of the Great War on the western Front. Hundred-year-old forgotten contaminations?

H. Daniel, Bureau de recherches géologiques et minières (BRGM)

During WWI, ammunition had been used on an unprecedented scale. When hostilities ceased, huge ammunition dumps remained. Unexplosed ordnances were collected on former battlefields too. There was an urgent need to dispose million tons of hazardous ammunition. New methods for safely breaking down chemical shells were then developed.. After defusing, the rounds were emptied by perforation when the toxic contents were liquid, by steam or hot-water washing-out for TNT explosive shells and by open-burning for both chemical and explosive shells. These processes caused severe top soil contaminations especially on former burning-grounds of chemical shell. Recent research has been conducted on 9 burning-grounds in France and Belgium. To this day, no vegetation grows at some locations due to extreme high grade of heavy metal (Zn, Pb, Cd,…), ranging for Zn from 10 to 100 g/kg, chlorinated and /or brominated dioxin & furan (1 000 to 4 000 000 ng/kg), and arsenic (2 to 110 g/kg) when arsenical "*Blue Cross*" shells loaded with the sternutators diphenylchlorarsine and diphenylcyanoarsine were open-burned. Inorganic arsenical compounds are associated with organic by-products produced by the oxidation (diphenylarsinic acid) or thermal decomposition (triphenylarsine, As-PAH like phenylarsafluoren) of CLARKs. Brominated dioxin, energetic compounds (TNT, nitronaphtalin) and thianes (impurities of yperit) have been measured too. High resolution geomagnetic measurements had been conducted on a site where 1,5 million old chemical shells have been destroyed during the interwar period near Verdun, leading to severe top-soil contamination, crops and meat destructions and the sequestration of the ground. Open-detonation pits and systems of burning trenches have been recognized and carefully probed. Exposure to site-specific contaminants through the consumption of foodstuffs produced locally on the considered site was unlikely to be a health concern. However, as for inorganic arsenic, given the presence of highly contaminated zones, it was suggested that cereals should not be grown on certain spots. Spincourt is an example of the ignorance of soil contamination left behind by WWI in land-use planning. Further research is needed to assess these forgotten contaminations and sites and theirs related environmental risks.

TU194

Mixture of ligands influence on metal accumulation in Diffusive Gradients in Thin films (DGT). The interplay of labilities from concurrent complexes.

A. Altier, M. Jiménez, Universitat de Lleida and AGROTECNIO / Dep Quimica; R. Uribe, Universidad del Tolima; C. Rey-Castro, Universitat de Lleida and AGROTECNIO / Dep Quimica; J. Cecilia, Universitat de Lleida and AGROTECNIO / Departament de Matemàtiques; J. Galceran, Universitat de Lleida / Dep Quimica; J. Puy, Universitat de Lleida and AGROTECNIO / Dep Quimica

The interactions between a trace metal and ligands present in natural waters largely determine this metal availability to biota and plants. Natural waters contain mixtures of metal cations and ligands. After many efforts devoted to the study of simple systems with only one ligand [1-2], it is timely to enquiry whether the mixture entails specific non-additive effects, i.e. to what extent is it possible to predict the collective behaviour of the mixture from the values of the lability degrees of each single ligand system (SLS). Thus, a series of experiments with DGT (Diffusion Gradients in Thin films) devices [3] were carried out to measure

Ni accumulations in laboratory solutions comprising either Nitrilotriacetic acid (NTA), Ethylenediamine (EN) or mixtures of both ligands. It will be shown that NiEN and NiNTA can become more labile and inert (respectively) in the mixture than in the corresponding SLS. This "mixture effect" arises when one of the ligands (NTA, forming strong and partially labile complexes) is present at non-excess conditions. As variations in the lability degrees of NiNTA and NiEN arising in the mixture tend to cancel out, the summation of partial fluxes calculated from lability degrees obtained in SLS yields a reasonable estimate of the DGT performance in the mixture [4]. Numerical simulation will be used to justify this mixture behaviour. Daily behavior and removal of Rare Earth Elements in the wastewater treatment plant of Grand Nancy (France)

L. Pauline, LRGP-CNRS-UL; M. PONS, LRGP-CNRS-UL / Laboratoire Réactions et Génie des Procédés; D.A. Vignati, CNRS / LIEC UMR7360

Rare Earth Elements (REEs) have wide and growing applications in high efficiency electronics and energy technologies. These anthropogenic uses already disrupted the biological cycle of REEs and led to enrichments of La, Ce, Sm, and Gd in waters. Some REEs contained in sewage are not removed by conventional Wastewater Treatment Plants (WWTPs), notably anthropogenic Gd, which is particularly stable due to its organic complex form[1]. Furthermore, the concentration of some REEs measured close to a WWTP effluent discharge can be high enough to elicit effects on aquatic systems[2]. The presence of REE in sewage may also affect some aspects of treatment efficiency within WWTPs, particularly on the microbiological part[3]. Knowledge of the REE mixtures, abundances and distribution in WWTP influent and effluents is therefore necessary to evaluate REE removal efficiency and possible REE-related risks to living organisms within the WWTP and in the receiving waters. Presence of REEs in the influent and effluent of Grand Nancy's WWTP (350,000 population equivalent) was investigated. The Grand Nancy sewage network is mixed. The WWTP is of the activated sludge type with primary settling and chemical phosphorus precipitation. Twenty-four hours sample campaigns were conducted for each week day, in the aim to determine the REEs distribution and fate of a "typical week". REEs concentrations were measured in the total fraction after mineralization and in the dissolved fraction (< 0.45 μm). Results show that there is a Gd positive anomaly in influent wastewater, as well as in treated wastewater. The highest Gd concentration signal in influent appears mostly in late afternoon. Light REEs (from La to Eu) are preferentially removed from the influent wastewater during the treatment. References: [1] Möller, P.; Paces, T.; Dulski, P.; Morteani, G. Cocktail effect of nanoTiO2 mixtures with mercury to green alga Chlamydomonas reinhardtii

M. Li, University of Geneva; V. Slaveykova, University of Geneva / Département F.-A. Forel des sciences de lenvironnement et de leau

In aquatic environment nanoparticles are present as complex mixtures with other contaminants which can result in synergism, aditivity or antagonism of their combined action. Despite the fact that the toxicity and environmental risks of engineered nanomaterials have received extensive attention in recent years, their interactions with other contaminants and the subsequent effects to aquatic microorganisms are to explore. In such a context, the present study aims to examine the interactions and effects of cocktails containing nanoTiO_2 and mercury compounds, as a representative of priority hazardous substance, to *Chlamydomonas reinhardtii*, as a model phytoplankton specie. It was hypothesized that due to the its high reactivity nanoTiO_2 will adsorb Hg compounds and thus decrease its bioavailability and effects to alga, and that the effect will be more pronounced for cocktails containing nanoparticles of smaller primary size. The influence of nanoTiO_2 of different primary sizes, 5 nm (anatase, A5), 15 nm (anatase, A15) and 20 nm (anatase/rutile AR20) on inorganic Hg (IHg) and monomethyl Hg (CH_3Hg) effects to algae was studied. The effect of Hg, nanoTiO_2 and their mixture on the algal growth, generation of oxidative damage and membrane damage were determined by flow cytometry. In parallel, the stability of nanoTiO_2 in terms of hydrodynamic size and surface charge as well as Hg adsorptive capacity of nanoTiO_2 were determined. Results showed that the increasing concentrations of nanoTiO_2 with different primary size lead to a decrease of Hg-induced effects, due to the adsorption of Hg to nanoTiO_2. NanoTiO_2 had much higher adsorption capability to IHg than CH_3Hg.The results highlighted the need for improved understanding of the interactions of complex environmental settings containing mixtures of nanomaterials and other contaminants, central for sustainable development of nanotechnology. **Key word:** nanoTiO_2, mercury, phytoplanton, toxicity

A Safe by Design Nanobiostimulant Tested on Alfalfa (Medicago sativa) - Effectiveness, Mode of Action, and Social Acceptance

F. Schwab, Adolphe Merkle Institute / Materials Science; M. Maceroni, Adolphe Merkle Institute - University of Fribourg / BioNanoMaterials; F. Mauch, University of Fribourg; B. Rothen-Rutishauser, A. Petri-Fink, Adolphe Merkle Institute / BioNanomaterials Group

Safe by Design (SbD) nano-agrochemicals promise higher efficiency than conventional pesticides, and therefore have a high potential in reducing the pollution penalty of these products. However, before they can be implemented, much has to be learned about the gain of efficiency compared to conventional products, the economical and environmental costs of a large-scale production, the willingness of farmers to adopt their practice, and the risk of directly applying such new types of yield enhancers on agricultural soil. Here, we present the results of laboratory scale experiments to develop a bioinspired nanobiostimulant and compare its effects with conventional pesticide ingredients on the agricultural legume alfalfa (lucerne, *Medicago sativa*). As a reference substance for conventional pesticides, the broadband fungicide tebuconazole was tested. Seed germination and infection tests, and plant growth tests as well as biochemical tests with pathogens were conducted. The nanobiostimulant was quantified by inductively coupled plasma – optical emission spectroscopy (ICP-OES), and its interactions with the plant were visualized in view of potential uptake and translocation using transmission electron microscopy (TEM) and energy dispersive X-ray spectroscopy (EDS). In addition, interviews were conducted in Switzerland to evaluate the needs and willingness of farmers to adopt new agricultural strategies. The performance of the nanobiostimulant was found to be up to twice as high as for the conventional product. The evaluation of the results of the interviews is in progress and will be presented in detail at the conference. The use of nanobiostimulants promises to strongly reduce the organic pesticide burden of people and the environment.

TU198

Certification of field-operating personnel involved in environmental measurement and sampling improves the quality of environmental data in Finland

K. Björklöf, Finnish Environment Institute SYKE / Reference Laboratory; P. Punttila, Finnish Environment Institute SYKE / Ecosysttem Services

Representative environmental measurement and sampling are essential for reliable environmental research and monitoring, and high-quality nature inventories are elementary parts of well-prepared land-use planning. The results of field operations are used e.g. to monitor water and soil status. Based on the results of field work, big and economically significant decisions concerning e.g. waste water, soil refurbishment and land-use planning are often made. Error or negligence in field operations can easily be missed, but its effect may be great. The complexities of diverse natural environments can make truly representative sampling a tricky task, and incorrect sampling may greatly distort research findings. Sampling may therefore in many cases be a delicate process and the most demanding part of environmental measurements. This is mainly due to natural heterogeneity of the environment in space and time. In addition, the content of the field operations always depends on the nature and scope of the information that is needed. The competence and responsibility of the field operating personnel is therefore critical for representative environmental field operations. Field personnel need to have sufficient knowledge, skills and detailed information about the aim of the field work to assure the representative sampling, measurement or observations. The Finnish national environmental certification scheme for environmental sampling personnel is an independent system enabling environmental field operators to demonstrate their competence in different fields of environmental sampling. Certified field operators have systematic sampling, measurement and experience. In addition, they undertake to maintain and develop their skills and update their knowledge during the certification period. The Finnish national certification system is a widely acknowledged quality assurance procedure today. The field-work quality has improved both in governmental monitoring programs and in private companies. Education of field operators in Finland has improved significantly due to the certification system. More courses are available and the contents of the courses have improved. Certified field operators are also more motivated to take part in training courses regularly.

TU199

Development of sustainable surfactant-based formulations: studying the influence of ethylene oxide head groups on the toxicity of SLEnS-LAS micelles

S.M. Fernandes, ICBAS FCUP; V. Nogueira, Faculty of Sciences and CIIMAR - Porto University; I. Lopes, University of Aveiro / Department of Biology & CESAM, 3810-193 Aveiro; F.J. Antunes, University of Coimbra, Department of Chemistry / Department of Chemistry; R. Pereira, GreenUPorto & Faculty of Sciences, University of Porto / Dept Biology Faculty of Sciences of the University of Porto

Different formulations of surfactants (SF) are commonly added as active ingredients in biocides, industrial processes, cleaning agents, personal care and household products. Anionic SF are easily produced with lower cost associated, resulting in higher consumption levels worldwide. When in mixture, anionic surfactants like ether sulfate based (SLE_nS) and linear alkylbenzene sulfonic acid (LAS) form mixed micelles, acting as reservoirs for the cleaning process. SLE_nS with higher number of ethylene oxide (EO) units in the head groups present lower critical micellar concentration,reducing the quantity of chemicals needed to form the micelles therefore resulting in economic and environmental advantages. Despite its wide use in commercial products, the impacts of these micelles and their EO units' variations on soils are not available so far. Following this context, in this work were carried out ecotoxicological tests to assess collembolans reproduction (*Folsomia candida*), seed germination and plant growth *(Avena sativa, Hordeum vulgare*, *Lactuca sativa*, *Lycopersicum esculentum*) with main goal to assess the influence of the number of EO units in the sublethal toxicity of seven variants of SLEnS-LAS micelles. All the variants were tested in concentrations ranging from 247.5 to 1247.5 μg SLE_nS kg^{-1} of $soil_{dw}$. The majority of the significant ($p< 0.05$) inhibitory effects on plants growth are observed at the highest concentrations of almost all the substances tested with no apparent correlation with the EO units. Regarding collembolans reproduction, the formulations with less EO units (0 to 11) significantly inhibited the average number of juveniles produced with observed effects at the lowest concentrations tested and resulted in EC_{50} values ranging from 924.18 to 1025.04 μg SLE_nS kg^{-1} of $soil_{dw}$ while no significant results were obtained for the micelles with higher number of EO units (50 and 30).The results of this work contribute to the confirmation that a different design of chemical compounds may result in different responses to terrestrial organisms of different trophic levels. In this way, this research proves that the upstream use of standardized ecotoxicological assays, prior to their manufacture and marketing, may support an efficient precautionary attitude concerning the rising demand for new and more effective surfactants formulations, promoting the search for sustainable alternatives without detracting the required functions.

TU200

Further examination of the Hansen Solubility Parameters for prediction of hazard and exposure properties

J. Kuhlmann, PFA-Brussels; P.R. Fisk, PETER FISK ASSOCIATES LTD; W. Gebbink, PFA Brussels; B. Barnes, Peter Fisk Associates Limited

Hansen Solubility Parameters (HSP) – parameters predicted based on the molecular structure of a chemical - were developed originally to give information about solubility parameters of solvents and assisting in the choice of the appropriate solvent. This study explores the further use of HSP to not only predict solubility parameters, but to give information on hazardous effects of solvents as well as exposure properties. Comparing these properties can assist in sustainable solvent choice. An initial investigation of the use of HSP for description of certain hazardous properties of substances such as bioaccumulation potential and toxicity to aquatic organisms has been undertaken. These parameters are of significant regulatory interest, for example, in the identification of substances with persistent, bioaccumulative and toxic (PBT) or very persistent and very bioaccumulative (vPvB) properties. This work has been extended to examination of adsorption of substances to soil and sediment. The present work explores the predictability of these properties using HSP and discusses the successes and limitations identified, and potential for future development. Challenges in respect of QSAR are being identified, as the HSP are of clear value but do not often follow linear relationships with the desired end point.

TU201

Learning from the past to design better chemicals

E. Papa, University of Insubria / Department of Theoretical and Applied Sciences; A. Sangion, University of Insubria / Department of Theoretical and Applied Sciences (DiSTA); N. Chirico, P. Gramatica, University of Insubria

Green chemistry based approaches are focused on the maximizing the generation and use of substances and processes that have limited/no impact on humans and the environment. Among the 12 green chemistry principles, particularly principle 4 "Design benign chemicals" and principle 10 "design for degradation" are useful to prevent hazardous substances, such as those characterized by PBT properties (Persistent, Bioaccumulative, Toxic) from being developed and entering the environment, as well as to generate safer alternatives to existing hazardous chemicals. Modelling approaches based on Quantitative Structure-Activity Relationships (QSARs) rely on the assumption that biological activities/properties of chemicals are intrinsically dependent on the molecular structure. QSARs can be applied, also in combination with data mining (data exploration) techniques, for the rational design of chemicals before their synthesis (i.e. Safe by Design – SbD approach) or after, to detect safer alternatives to undesired chemicals. Endpoints like toxicities, physico-chemical properties as well as biotic and abiotic degradations can be predicted starting from models based on molecular descriptors of the chemical structure. These models are available from the literature, regulatory tools, or are developed ad hoc for a specific endpoint. In this poster, we show the different steps necessary for a correct development, validation and application of QSAR models taking into account regulatory requirements, as defined by OECD and ECHA. In addition, we provide examples of how these models in combination with multivariate explorative analysis (MVA), are applicable to distinguish between desirable/safe and undesirable/unsafe compounds on the basis of different endpoints such as toxicities/activities, bioaccumulation and biotransformation properties, and environmental degradations. These examples show how *in silico* based screening of chemicals, before and after the chemical synthesis, can provide concrete opportunities to identify benign chemicals and alternatives for undesired chemicals by maximizing the existing knowledge through lessons learnt from the past.

TU202

Risk profiler at work - comparing environmental risk profiles of insecticides

T. Frische, Federal Environment Agency (UBA) / Section Plant Protection Products; A. Höllrigl-Rosta, S. Bär, German Environment Agency UBA / Section Plant Protection Products; P. Kotschik, Umweltbundesamt / Federal Agency of Environment / Risk assessment for plant protection products; C. Ullrich, German Environment Agency UBA / Section Plant Protection Products

The environmental risk assessment for authorisation of pesticides is targeted at individual compounds in individual uses and serves the purpose of limiting the risk from each single pesticide to an acceptable level. Additional concepts in risk assessment now also aim at classifying and comparing levels of risk between pesticides. One is the substitution concept according to Article 50 of the pesticide regulation (EC) 1107/2009. Comparison of risk levels is also required for identifying pesticides with a more environmentally favourable risk profile than others, or for risk benchmarking, where the risks arising from the use of one pesticide are set in relation to the risk levels of other pesticides authorised for similar uses. A major challenge when comparing environmental risks from pesticide use is the diversity of environmental compartments, organisms and endpoints to be considered if a holistic assessment is intended. Moreover, acceptability of risks may either be demonstrated using standardised data and procedures (so-called "tier 1") or might require a specifically refined assessment (higher tier). While tier-1 risk indicators for the same endpoints can be compared directly, this is not necessarily the case for the results of higher-tier assessments. In order to facilitate the comparative assessment of pesticides, the German UBA has developed an approach using tier-1 risk profiles. These profiles are generated with an Excel tool and consist of tier-1 risk indicators for all assessment areas based on a small set of basic data for the pesticides, in combination with automatically assigned exposure scenarios for the relevant target crops. By comparison of corresponding risk indicators, conclusions can be drawn on possible critical risk levels for each pesticide and the magnitude of risk differences between pesticides, respectively. The results of a case study comparing the risk profiles of several insecticides from different mode-of-action classes will be presented. The outcome is discussed with regard to (i) the possible added value of comparing risk profiles in pesticide risk assessments and (ii) the predictive power of standardised pesticide risk indicators (i.e. tier 1 versus higher tier).

TU203

Sustainability assessment implementing the Safe by Design concept for innovative nano-enabled products in the field of cultural heritage conservation

E. Semenzin, University Cà Foscari Venice / Department of Environmental Sciences Informatics and Statistics; E. Giubilato, University Ca Foscari of Venice / Department of Environmental Sciences Informatics and Statistics; E. Badetti, University Ca Foscari of Venice / Environmental Sciences, Informatics and Statistics; M. Picone, University Ca Foscari of Venice / Department of Environmental Sciences Informatics and Statistics; A. Volpi Ghirardini, University Cà Foscari Venice / Department of Environmental Sciences Informatics and Statistics; D. Hristozov, Ca Foscari University of Venice; A. Brunelli, V. Cazzagon, University Ca Foscari of Venice; A. Marcomini, University Ca Foscari of Venice / Department of Environmental Sciences Informatics and Statistics

Nanotechnology provides innovative and promising solutions for the conservation of cultural heritage, but the development and application of new nano-enabled products pose concerns regarding their human health and environmental risks. To address these issues, we propose a sustainability framework implementing the

Safe by Design concept to support product's developers in the early steps of product development, with the aim to provide safer nano-formulations for conservation, while retaining their functionality. In addition, this framework can support the assessment of sustainability of new products in comparison to their conventional chemical counterparts. The goal is to promote the selection and use of safer and more sustainable nano-based products, along their life cycle, in different conservation contexts. The application of the proposed framework is illustrated through a hypothetical case which provides a realistic example of the methodological steps to be followed, tailored and iterated along the decision-making process. The proposed framework should not be considered as restricted to cultural heritage science and to nano-based formulations but can be extended to the development of innovative chemical products across various application domains, regardless of whether they occur as individual substances or in mixtures.

TU204
The regulatory counterpart of Safe-by-Design: Regulatory Preparedness for nanomaterials and other innovations
A.K. Jantunen, European Commission - Joint Research Centre / Directorate F Health, Consumers and Reference Materials; A. Mech, K. Rasmussen, Joint Research Centre / Nanobiosciences Unit; J. Riego Sintes, European Commission - Joint Research Centre; S. Gottardo, European Commission JRC; C. Noorlander, L. Soeteman-Hernandez, National Institute for Public Health and the Environment RIVM; A.J. Sips, RIVM / VSP; M. Groenewold, S. Dekkers, National Institute for Public Health and the Environment RIVM
While industry is adopting the Safe by Design concept for developing innovative materials, technologies and products that meet requirements for the protection of human health and the environment, regulators for their part need of their own concept for staying up-to-date on emerging innovations and preparing to assess and ensure their safety. Such preparedness can both enhance the safety of innovative products entering the market and avoid unnecessary delays in market introduction. At the NanoReg2 Workshop on Regulatory Preparedness for Innovation in Nanotechnology (October 2017), Regulatory Preparedness was defined as the regulators' timely awareness of innovations and actions to check whether present legislation covers all safety aspects of each innovation, including initiating revision of the legislation as appropriate. Together, Regulatory Preparedness and Safe-by-Design constitute the NanoReg2 Safe Innovation Approach for developing innovative products based on nanotechnology. However, while the focus is on innovations in nanotechnology, the workshop outcomes are relevant for regulatory approaches to the safety of innovative technologies in general. The workshop participants (ca. 60 regulators, industry representatives and other stakeholders) presented views on and identified current practices in regulatory work on the safety of innovations, tools that are already in use or would be needed, and potential difficulties in implementing Regulatory Preparedness in the European Union. Regulatory Preparedness was seen to require from regulators a combination of continuous and interconnected anticipatory activities (e.g. horizon scanning), together with appropriate resources. Since industry has a corresponding need to be aware of regulatory requirements concerning their innovations and how these requirements are likely develop, communication between regulators and innovators is of key importance. However, mutual trust must be ensured for the useful exchange of information that can involve valuable intellectual property.

Life Cycle Impact Assessment (P)

TU205
Development of Air Pollution Characterization Factors for African countries
S. Karkour, Tokyo City University; L. Tang, NARO; N. Itsubo, Tokyo City University
The 2017 United Nations previsions predict that the African population composed of 1.2 billion people nowadays might reach 2.5 billion by 2050, with more than 400 million people, Nigeria is projected to be the 3rd world population by 2050. From an economic perspective, according to a PWC report published in 2017, three African countries will be among the thirty strongest economies in 2050: Nigeria(14th), Egypt (15th) and South Africa (27th). This population and economic growth will for sure have an impact on the environment in Africa, the continent is already experiencing several environmental issues including Air Pollution, Water scarcity, Human Toxicity or Land Use degradation as highlighted by the 2013 UNEP report: African Environment Outlook (AEO-3). Additionally, according to the WHO (2018), more than 500,000 deaths occurred in Africa due to ambient air pollution in 2016. From the viewpoint of LCA, the number of groups focusing on LCA in Africa is still very limited compared to other regions of the world (Bjorn et al 2013). Even if regionalization has been getting a trend in LCA, nothing has been really made for the African continent. Specific LCI databases and LCIA methods have not been developed yet. For example, for the damage of air pollution, the current global LCIA methods RECIPE2016 and LIME3 divide the continent and its 54 countries into only respectively six and two parts. Therefore, this study aims at bridging the research gaps by providing specific characterization factors for African countries concerning Air Pollution. Our goal is also to evaluate the future environmental burden by establishing some projections for the characterization factors. In order to develop these factors expressed in DALYs per unit of pollutant, four relevant substances were chosen in accordance with the previous studies: Primary PM2.5, NOx, SO2 and NH3. Using a global Chemical Transport Model (CTM), the increase of concentration of PM2.5 in each country/region was evaluated following a rise in the emissions of precursors. Later, the latest global health estimates provided by the WHO were used in order to evaluate the possible effects and damages on the African population.

TU206
Habitat quality across the Scandinavian boreal forest from remote sensing and citizen science observations
J. Borgelt, Norwegian University of Science and Technology (NTNU) / Department of Energy and Process Engineering; I. Steinsland, J. Rød, NTNU; F. Verones, NTNU / Department of Energy and Process Engineering
The increasing human population and associated growing pressures on ecosystems have already resulted in a significant loss of natural habitat and biodiversity. One of the strategic goals of the Aichi biodiversity targets is to halt this development by decreasing the human impacts. Therefore, biodiversity monitoring and decision-making processes have to be more effective. A tool for assessing environmental impacts is Life Cycle Assessment (LCA). In LCA, impacts on ecosystem quality are calculated by linking declining habitats to species loss following an ecological concept called species-area relationship. However, this does not account for variability in species richness within regions or within land use types. The massive amount of species observations by members of the general public, i.e. citizen science observations, may help to tackle those shortcomings by improving our knowledge on the distribution of biodiversity, by filling data gaps and by reducing time-consuming field campaigns. Hence, a potentially efficient way of advancing in biodiversity conservation is the implementation of citizen science observations into biodiversity monitoring. In this case study, we want to predict habitat quality across the Scandinavian boreal forest by combining citizen science observations of selected forest bird taxa and spectral information from satellite imagery as well as other remote sensing derived variables. Taxa are selected based on ecology and habitat requirements. We aim to illustrate the importance of citizen science efforts for decision-making processes. This feedback to citizens is likely to improve data collection and thereby prediction accuracy in the near future. The developed framework is expected to be applicable in other regions and ecosystems. Furthermore, the products can be integrated into decision-making processes and environmental impact assessments, such as (LCA).

TU207
Comparison of USEtox and an H-based approach for eco-toxicity based ranking of chemical emissions from an industrial cluster
M.H. Lindström, University of Gothenburg; T. Rydberg, IVL Swedish Environmental Research Institute
Impact assessment methods developed in an LCA context have shown useful as tools for ranking and priority setting also in other contexts, such as for national chemicals release inventories. The study presented here is a case study to prioritise eco-toxic risks based on emissions from a group of industries (a "cluster") in Stenungsund in Western Sweden. In additon to applying USEtox™ ecotoxicity characterization factors (v 2.0) for this purpose, a novel approach based on H-phrases for ecotoxicity was developed as a rapid way to include all relevant substances, inspired by the approach by which ProScale™ was designed for human toxicity potential assessments. The total amount of each substance emitted during 2000-2016 (in kg) has been calculated for the cluster, then multiplied with USEtox CFs to obtain the potential toxicity of the different substances. Some of the emitted substances were not specified, in these cases a CF was chosen from a representative chemical of the group. H-phrases were gathered from PubChem and formulated into two different ranking methods. The ranking methods uses environmental H-phrases (H4-phrases) to evaluate the toxicity of substances. The first method (version 1) uses the different variations of H-phrases within the list of substances to create eight different ranking levels. The second method (version 2) only uses the most severe H-phrase in its ranking and consists of seven levels. The two different H-phrase ranking methods was also compared to the CFs of substances emitted to water. For both the H-phrase approach and USEtox, the metal pollution turned out to be responsible for the highest toxic potential along with some of the non-specified chemicals. Halogenated organic compounds (AOX), chlorides and non-methane-volatile-organic-compounds (NMVOC) also have a high toxic potential. This might be because of the high toxicity of the representing chemicals for the groups. Chemicals with high CFs were chosen to avoid underestimation of the toxicity of these group, but this could possibly result in an unrealistically high toxic potential. In the comparison of the CFs of substances emitted to water and the H-phrase rankings there was much variation. This is realistic since the variables have different structure, CFs contains a fate-factor while H-phrases do not. To continue developing the H-phrase approach, a calibration with effect-based hazard factors, such as EC50 or HC50, would be relevant

TU208
Regionalized quantification of the loss of aquatic insect species due to river

transformation into reservoir
G. Trottier, CIRAIG - cole Polytechnique de Montral / Département de génie chimique; K. Turgeon, ISFORT Université du Québec en Outaouais; D. Boisclair, Universite de Montreal / Biological Sciences; F. Verones, NTNU / Department of Energy and Process Engineering; C. Bulle, UQAM, Ecole des sciences de la gestion; A. Boulay, CIRAIG - École Polytechnique de Montréal / Chemical engineering department; M. Margni, CIRAIG - cole Polytechnique de Montral / Mathematical and Industrial engineering
Freshwater biodiversity, is critically threatened by flow alteration and habitat degradation, which are commonly associated with hydropower. The first and only attempt to assess potential impacts from water stream use and management in life cycle assessment (LCA) on aquatic biodiversity, is an unpublished exploratory work focusing solely on fish species. As a consequence, this impact pathway has yet to be characterized in LCA. This project aims to develop LCA characterization model and factors to assess the impacts of hydropower production on freshwater biodiversity, focusing on aquatic insects and based on strong empirical natural science. In this paper, we focused on the occupation impact pathway (similar to a “land occupation” impact pathway which is leading to impacts of transforming and occupying the original bed of a river that was transformed into a reservoir following impoundment) and developped a characterization model and factors that quantifies the impacts of hydropower occupation within LCA (i.e., the transformation of a river bed into a reservoir due to an impoundment). We used two datasets from the US Environmental Protection Agency, one pertaining to lakes and reservoirs and the other, to rivers. We calculated a mean PDF for the overall US and accounted for regionalization by calculating a specific PDF for nine ecoregions in the US. We also calculated an impact score by multiplying the characterization factor (PDF) with the mean surface of river occupied (i.e., original riverbed) and assuming a lifetime of 100 years for each of the reservoirs. Preliminary results showed an overall loss of aquatic insect species across the US, as well as in five out of nine ecoregions. Two ecoregions showed a marginally significant loss of species, one ecoregion showed a non-significant gain of species and one last ecoregion showed a significant gain of species. Overall, our results show that the transformation of a river into a reservoir does lead to a loss of aquatic insect species. Regionalization also seems to be playing a relatively important role considering the different levels of significance regarding loss, and gain, of species. Further analyses still needs to be conducted to identify and understand what are the underlying mechanisms that rule the similarities/differences among ecoregions. Eventually, these results could help better our understanding of the environmental cost associated with the use of hydropower.

TU209
Water footprint and regionalization: the case study of Walloon corn
S. Gerbinet, Université de Liège / Chemical Engineering; F. Van Stappen, CRAW Walloon Agricultural Research Centre; A. Leonard, University of Liege
Corn is an important cereal with a lot of applications in the feed and food industries (e.g. starch production). To evaluate properly the environmental impact of its applications, for example in the growing context of biobased products, a better understanding of the impact of its production is needed, using Life Cycle Analysis (LCA). The studied system is the production of corn in Wallonia (South of Belgium), whose the primary data are taken from Van Stappen et al (2018. Sensitive parameters in local agricultural life cycle assessments: the illustrative case of cereal production in Wallonia, Belgium. Int J Life Cycle Assess 23 2: 225–250). The functional unit is 1 hectare of corn crop in Wallonia. The LCI data are based on actual agricultural practices recorded in farms’ accounting data. The system has been modelled in GaBi 8 using GaBi datasets. The ILCD recommended method has been used. To have a better understanding of water depletion, some other methodologies have been tested for this specific impact categorie such as ReCiPe and the AWARE model. The part of water resources depletion using ILCD recommended method that is not due to the fertilizers (20 %) production is mostly related to the electricity used for maize drying and storage (70 %), especially associated with nuclear electricity (cooling needs). This is not the case if another method is used for assess the water depletion. When AWARE method is used, most of the impact is coming from fertilizers production and from mechanization (due to the use of on unspecified flow for water consumption), whereas, using ReCiPe, most of the impact is from fertilizers production only. A study of the water origin has been realized using AWARE and ILCD recommended method and underlines the large variety of results. The share of nuclear electricity in water depletion is really high when using ILCD recommended method, therefore special attention has been put on this process.: we have compared the GaBi dataset with the Ecoinvent dataset. For the Ecoinvent dataset the calculations have been realized in GaBi but also in Simapro. This comparison is realized for the three methods investigated and underlines large differences between softwares. Therefore, this contribution allows to underline the difference between methods for water depletion calculation but also the differences induced by regionalized or not regionalized datasets. Finally, it highlights the problem of results that are dependant of the software.

TU210
Green water scarcity under climate change: a life cycle impact assessment method applied to Portugal
P. Quinteiro, University of Aveiro / Centre for Environmental and Marine Studies (CESAM) - Department of Environment and Planning; S. Rafael, CESAM University of Aveiro / CESAM Department of Environment; B. Vicente, CESAM Department of Environment and Planning University of Aveiro / Centre for Environmental and Marine Studies CESAM Department of Environment and Planning; M. Marta-Almeida, Swedish Meteorological and Hydrological Institute (SMHI) / Swedish Meteorological and Hydrological Institute (SMHI); A. Rocha, University of Aveiro CESAM / University of Aveiro CESAM; L. Arroja, University of Aveiro / Department of Environment and Planning; A.C. Dias, University of Aveiro / Centre for Environmental and Marine Studies (CESAM) - Department of Environment and Planning
Climate change is one of the greatest challenges today. The debate now is not about the human contribution to climate change, but how to deal with the impacts of future climate change, namely regardingthe risks of water stress and fresh water scarcity, with consequences on food production, energy and other economic sectors, human health and ecosystems. The impacts related with water use, and mainly the impact of green water flows, are particularly relevant for agricultural and agro-forestry based products, depending on local land-use and land cover changes. Green water flows refer to the portions of green water (from rain) used by vegetation that is evaporated or transpired. This is an on-going research issue in Life Cycle Impact Assessment (LCIA), since the environmental mechanisms of green water consumption are not yet well understood. This study is devoted to develop green water scarcity characterisation factors (CFs) at mid-point level for Portugal, considering a high spatial resolution (9 x 9 km) both for reference climate (period 1986-2005) and future climate (period 2046 to 2065). These CFs were calculated considering two different interfaces: (1) interface green water – soil (ws), in which the relation between the changes on green water flows and the surface blue water production is considered, and; (2) green water – atmosphere (wa) interface, in which the relation between the evapotranspiration recycled to the atmosphere and the precipitation levels at the same catchment level is considered. Considering the reference climate conditions, it was noticed that some regions of Portugal are currently suffering of pressure on green water resources (mainly in Central littoral and coastal areas). Under future climate conditions, a global increase of CF_{wa} at the country level was observed. For the ws interface, the CF_{ws} mainly increases in the South coastal and Central interior areas, whereas in coastal areas (Northern and Centre) the CF_{ws} decreases comparatively to those for the reference climate. This CF_{ws} decrease means that the availability of green water required to produce blue water is ensured. These CFs contribute to the operationalization of the green water scarcity footprint methodology for decision support of agricultural and agro-forestry producers and policy makers. Furthermore, the approach used in this study can be, with a reasonable amount of effort, fully applied to other countries.

TU211
Quantitative Evaluation of Rice Production Considering the Impact of Light Pollution
Y. Kurahara, N. Itsubo, Tokyo City University
In recent years, it became clear that the brightness of artificial light at night has been increasing year by year, and its scale is expanding. According to Science Advances, it is reported that from 2012 to 2016, the artificially illuminated outdoor area increases by 2.2% per year and the annual radioactivity total radiance increases by 1.8%. Light pollution is described as the situation in which these lights are obstructing or having damages through their leaks, a common example is the outdoor lighting. Light pollution has various effects on human activities, wild animals, plants, agricultural crops and livestock. Rice is also one of the crops affected by light. Rice is a short day plant where flower buds begin to form when the light exposure becomes longer than the critical dark period, which is the minimum requirement time needed for flowering. However, today road and sign lightings are increasing with the countryside urbanization. Therefore, the influence of light pollution on rice is expected to increase due to the increase in artificial light at night. Although the influence for each region and each type of rice must be considered, the evaluation in Japan as a whole has not been done. Growth of rice is hindered by night lighting, and light pollution has become a problem as a type of pollution causing heading delay. There are no examples of investigations on light hazards in LCA research. There is also no light pollution in the item of impact category of the LIME method. In this research, we aim to conduct a quantitative evaluation of rice production considering the impact of light pollution, using existing research related to light pollution.

TU212
Health impact evaluation of PM 2.5 in two Korean cities by using LCIA method
S. Jeong, Kunsan National University / Department of Environmental Engineering
This study evaluated health impacts of PM2.5 in two Korean cities, J and I by using life cycle impact assessment method. Site-specific intake fractions were obtained by multiplying the human inhalation exposure factor and fate factor. Effect factor was obtained by multiplying severity factor and dose-response factor. Finally, the characterization factor ($DALY/kg_{emitted}$) was calculated by using the intake fraction and the effect factor. Emission inventory (year 2015) of PM2.5,

NO_x, SO_x, and NH_3 was also used to find relative PM2.5 contribution of emission source to human health. Human health impact of J and I cities due to inhalation of PM2.5 was quantified as 2,606 and 683 DALY, respectively. The prominent PM2.5 emission source contributing to human health in J city was PM2.5 generated from non-point sources (road dust, construction sites etc.) and the next was NH_3 generated from agriculture (livestock manure, fertilizer etc.). However, contributors of I city showed that NH_3 of agriculture was the prominent contributor and PM2.5 of non-point sources was followed. This study implies that the prominent PM2.5 emission sources should be monitored and well managed to reduce human health impacts due to primary and secondary PM2.5. (This work was funded by the Jeonbuk Green Environment Institute, Korea)

TU213

Improving the life cycle impact assessment of metals in slags: importance of chromium speciation, water chemistry, and metal release

J. Hedberg, Surface and Corrosion Science, KTH Royal Institute of Technology / School of Engineering Sciences in Chemistry, Biotechnology, and Health, Dep. Chemistry, Div. Surface and Corrosion Science; K. Fransson, RISE Research Institute of Sweden; S. Prideaux, KTH royal Institute of Technology; S. Roos, RISE Research Institute of Sweden / Energy and Environment; C. Jönsson, RISE Research Institute of Sweden; I. Odnevall Wallinder, KTH royal Institute of Technology

The investigations of metal ecotoxicity in life cycle assessment (LCA) and life cycle impact assessment (LCIA) are becoming important tools for evaluating the environmental impact of a product or a process. There is however improvement needed for the LCIA of metal ecotoxicity in order to make this assessment more relevant and robust. In this work three issues within LCIA of metal ecotoxicity are investigated, mainly focusing on topics related to stainless steel manufacturing. The first issue is the importance of considering regional water chemistry when constructing the characterization factor (CF) in LCIA. A model freshwater of relevance for stainless steel manufacturing in a region of Sweden was created having water chemistry different from available options. The second issue is related to the lack of consideration of changes in speciation of Cr(VI) in freshwater for a given emission, as Cr(VI) to some extent will be reduced to Cr(III). Two new options were suggested based on general steady-state relationships between Cr(VI)/total Cr as a way to improve the relevancy of LCIA for Cr(VI) in freshwaters. The last issue discusses how to treat metal release from slags in LCIA. Metal release from slags was shown to vary significantly between different ways of modelling slag emissions (total metal content, slag leaching tests, estimated emissions to groundwater). The results show the importance of metal release from slags as it significantly influences the resulting estimated ecotoxicological impact with respect to different CFs that consider Cr(VI) reduction.

TU214

Spatially-explicit characterization of the exposure and health burden of fine particulate matter in the US

K. Stylianou, University of Michigan / Environmental Health Sciences; O. Jolliet, University of Michigan / Department of Environmental Health Sciences, School of Public Health

The growing literature on regionalized life cycle impact assessments (LCIA) has highlighted the need to develop spatial estimates to characterize exposure and health damage from pollutants. In this paper, we develop spatially-explicit intake fraction (iF- fraction of the emission taken in by population) and characterization factors (CF – impact per kg precursor emitted) for fine particulate matter (PM2.5) from ground level emissions of $PM_{2.5}$, NH_3, SO_2, and NO_x in the US. We calculate iFs for 43,304 locations in the contiguous US using a reduced-form chemical transport model, the Intervention Model for Air Pollution (InMAP), with high spatial resolution in urban settings and large spatial domain. For each source location, we integrate iFs multiplied by a non-linear exposure-response function and region-specific burden estimates at each receptor location to derive cumulative location-specific CF estimates. The emission-weighted national average CFs using an average slope of the exposure-response are 209 µDALYs/kg for primary $PM_{2.5}$, 94 µDALYs/kg for NH_3, 75 µDALYs/kg for SO_2, and 38 µDALYs/kg for NO_x, with the estimates highly correlated with iF estimates. The US location-specific estimates show considerable variability of about three orders of magnitude. Urban emissions result in higher iF and consequently CF estimates and have a spatial extent about a factor 10 lower than rural emissions. We also report CF estimates for four distinct sectors (agriculture, fuel combustion, industrial processes, and mobile) that account for the spatial distribution of the corresponding emissions, in order to provide exposure and health damage characterizations that are more accurate for processes in life cycle assessment (LCA) studies. Sector-specific estimates for $PM_{2.5}$ and NH_3 vary by about a factor of three with the agricultural sector inducing the lowest and the mobile sector the highest health impacts per kg emitted. This difference is driven by the proximity of emissions to populations. For SO_2 and NO_x, sector-estimates show negligible differences. The sector emission release height also influences CF estimates. This work informs LCIA, helping quantify sector-specific health damages from $PM_{2.5}$–related emissions, using the current state of knowledge for $PM_{2.5}$ exposure and health effect.

TU215

Testing land use biodiversity indicators in organic and conventional beef production systems

E. Montemayor, S. Martí, Institute of Agrifood Research and Technology - IRTA; A. Assumpcio, IRTA / GIRO-Integral Organic Waste Management Program

Biodiversity loss has become a major environmental concern closely linked to land use impacts and unsustainable production and consumption patterns. FAO-LEAP TAG on biodiversity indicators aims to provide guidelines and recommendations of which indicators could be suitable to account for the effects of livestock activity on biodiversity. The UNEP-SETAC life cycle initiative has preliminarily recommended the Potential Species Loss, PSL, approach. Following requirements of the UNEP-SETAC life cycle initiative, the method has been improved to include three intensity levels (minimal, light and intense use), as well as reducing characterization factor uncertainty. Both the FAO-LEAP and UNEP-SETAC initiatives ask for case studies to test the performance of indicators with the final aim to show how biodiversity indicators will behave. The goal of the current study is to test applicability and resolution of biodiversity indicators in case studies comparing organic and conventional beef production in Catalonia, Northeast Spain, Europe. We have chosen two extremely different systems, organic and conventional beef production in order to judge information reported by indicators but also feasibility of their application. Total Impact score for the production of 1kg carcass beef are 7.5·10-13 PDF and 2.33·10-12 PDF for conventional and organic production system, respectively. Although, with a very different way of management, the total surface of area used is quite similar per calf, 2834 m2 and 2800 m2 for conventional and organic, respectively. In the organic farm the higher contributors are pastures, mainly because the surface area is larger, but also because of a higher CFs for the ecoregion. In the conventional farm, the most important contributors to biodiversity loss are quantity of soil required to apply manure and area used by the palm feed component. Application of PSLglo biodiversity indicator allowed us to conclude some aspects in relation how the production systems affect biodiversity. However, several aspects still remain not clear enough. Organic farms could have some other biodiversity benefits that are not well represented within the current indicator. The inclusion of other biodiversity taxa more related with soil quality and/or invertebrates could help to improve assessment and might give lower impact values for organic farms. Some of the local biodiversity indicators commented in the coming FAO-LEAP guidelines could contribute to improve the assessment. \n

Bio-Based Industries: Sustainability Benefits of Technological Innovation and Closed Loop Approaches across Supply Chains (P)

ARE FOREST PRODUCTS CARBON NEUTRAL? BIOGENIC GLOBAL WARMING POTENTIAL (GWPbio) PUT INTO PRACTICE

S. Gmuender, J. Barrera, M. Zollinger, L. Iten, Quantis; A. Ernstoff, Quantis / Quantitative Sustainability Assessment

Biogenic carbon is widely accepted to be carbon neutral in LCA standards and directives. Carbon lost from forests during wood harvesting is assumed to be recaptured during forest regrowth, and thus the impact of carbon emissions is considered to be zero. Furthermore, the timespan between loss through removal and gain by regrowth is considered negligible with regards to climate change. This assumption has to be reconsidered as the excess of CO_2 residing in the atmosphere does indeed cause radiative forcing effects and hence evidence suggests that this contribution to global warming cannot be excluded. In this work, the radiative forcing resulting from temporary carbon release is quantified. To do this we combined the methodology as used in the calculation of the GWP for a 100-year horizon (CO_2 impulse response function described by the Bern cycle model) with a forest growth curve. This allows to assess the global warming potential from biogenic carbon emissions (GWPbio) of bioenergy produced from existing forests. The GWPbio takes into account several carbon pools such as the soil organic carbon (SOC), the carbon stored in living biomass and natural dead wood. In addition, the natural dynamics of forest stands are considered as well as the potential benefits from delaying the emissions by temporally storing carbon in wood products are considered. Here the carbon footprint results from three case studies are presented: i) bioenergy from forest biomass, ii) kraft paper and iii) construction timber used for housing. These results indicate a significant influence of the temporal increase of the CO_2 concentration in the atmosphere on the carbon footprint results. Nevertheless, the GWPbio factors show a dependency on the sourcing strategy. The values range from almost minus one (thus permanent removal of CO_2 from the atmosphere) for efficient sourcing from fast-growing forests to higher than one for sourcing from slow-growing forests with poor management strategy. This worst-case scenario includes leaving a share of harvest residues left to decay, immediate carbon release through for example burning and the inclusion of foregone carbon sequestration of forests.

TU217

Novel Wood LCA and Environmental Product Declarations

D. Jones, Ecquate Pty Ltd / The Evah Institute; M. Vlieg, The Evah Intitute / Vlieg LCA; O. Biaz, N. Bortsie-Aryee, Global GreenTag
This work discusses six wood building product CASE studies employing transformational Life Cycle Analysis (LCA) methods. Issues and solutions for modeling spatial variability in land use change, forest form, biodiversity and tropical sources are highlighted. Impact and benefit potentials are compared considering fire-history, fuel type, durability and fate at end of life. Government, Carbon Trusts, NGOs, competing industries and leading economists do have carbon accounting systems that include sequestration. LCA, however, seldom attributes carbon sequestration consistently because of habitat and biodiversity loss. With approaching climate change tipping points, critical time factors demand consistent accounting not only for mitigation but also for carbon drawdown and storage outcomes that include climate braking. Typically the three prior rotations to secure forest product centennial carbon uptake must consider: Previous land use models tropical and sub-tropical deforestation displacing higher value vegetation as well as three prior rotations to compensate for any land use change. Fire and re-growth history to factor carbon loss from soil, detritus and logs. Fuel and scrap use in debarking, saw-milling and wood processing. Fate after wood service life includes reuse and renovation (5-75%), with remaining 90% for recovery and 10% to landfill as incineration is very rare in Australia. Australian and US landfill wood carbon loss and methane generation is much lower than the IPCC base case The range included wood framing, cladding, paneling, paper and board used for 60 years in buildings and 20 years in interior fitout. Results were compared for three building and three fitout products. Ongoing rainforest and fire loss for Brazilian and Malaysian wood cancelled out carbon uptake. Other products had full to minor CO_{2e} uptake, varying with fire loss and biofuel used to debark, sawmill and process logs.

TU218

Biomass waste-to-energy: from residue to resource

Y. Torreiro, L. Perez, EnergyLab; P. Villanueva-Rey, EnergyLab / Industry and Sustainable buildings; A. Rodríguez-Abalde, EnergyLab
In order to reduce the climate change effects, the final gross consumption of energy in the EU must proceed at least 20% of renewable energies in 2020. Among renewable energies biomass stands out mainly due to its role in the fight against climate change. It has a lower environmental impact and it contributes to improving competitiveness, employment and regional development. In addition, the large number of abandoned forests and the existence of typologies of biomass that are currently not being used make the use of residual biomass as essential to the development of a circular economy. Biomasses that can be valued are those coming from the pruning of vineyards and kiwifruit. They count on a great potential both from the energy and the economic point of view and also high availability. Nowadays, the combustion of biomass in boilers is the most widely used valorization option for thermal applications. However, there are also other forms of exploitation not so widely used, such as cogeneration. This has proven to be an efficient and clean way of simultaneous production of electricity and useful heat in the place of consumption. This technique allows the consequent saving of primary energy (up to 40%) and emissions to the atmosphere. The generation of electrical energy from biomass combustion is based on generating work from heat through steam production on behalf the thermodinamic procces known as Rankine cycle. There is an alternative to the cycle described above, the organic Rankine cycle (ORC). This cycle is similar to the previous one but instead of water it operates with a high molecular weight organic fluid whose boiling point is below 100ºC. The traditional process is considerably simplified in terms of complexity and cost. These advantages make the use of this cycle especially attractive for the use of low quality heat. In this work the viability of the use of microcogeneration (60 kWt boiler-ORC) as a system of energy recovery from vine and kiwi pruning was studied. The results obtained allow to conclude that the temperature differences between the hot and the cold focus influence in a significant way in the efficiency of the employed system. Furthermore, in the conditions used (hot focus temperatures up to 98ºC) cogeneration yields close to 97% (9% of net electrical efficiency and 88% of thermal efficiency) were obtained. Because of this, this method could be postulated as ideal for the energy recovery of the selected residual biomasses.

TU219

Gap analysis of circularity measurements for biological cycles

K. Navare, KU Leuven / Department of Material Engineering; K. Van Acker, KU Leuven / Materials Engineering; K. Vrancken, University of Antwerp, Dept. Bio-engineering
The circular economy aims at maintaining material and resources in the economy at their highest utility and value for as long as possible, in order to reduce waste, the material input and the environmental impact associated with it. In many circular economy reports and frameworks, a distinction is made between technical and biological material cycles. The technical cycle involves the management of stocks of non-renewable materials typically extracted from ores, whereas the biological cycle involves the flows of renewable materials, such as wood. However, the existing circularity indicators, focusing on measuring *resource use efficiency* and *recycling rates, are* typically developed for the technical cycle. These indicators seem less relevant to assess the circularity of biological cycles. Technical materials could be restored, refurbished and recycled to their original quality level. In the biological cycle, materials degrade in quality with every subsequent use and hence are cascaded down with every application. Additionally, the biological materials are supposed to return as nutrients to the biosphere, which is not the case with technical materials. Currently, it is assumed that the biomass going back to biosphere contributes to closing the loop. However, this is true only if it maintains the regenerative capacity of the ecosystem. An assessment of a system's capability to foster and sustain ecological cycles is lacking in the context of circularity measurement. There is clearly a gap in the current evaluation of circularity for biological cycles. This study intends to highlight that gap. It focuses on woody biomass, in which case the most often used measure of the cascading use is the *cascading factor*, which quantifies how often the resource is used in a value chain. However, even this measure overlooks factors that are crucial for enabling circularity of biological materials, most importantly the product lifetime and reuse of material. This study aims to assess the characteristics of circularity in wood-value chain, analyze the parameters needed to quantify them and then systematically validate if these parameters are included in the existing circularity measurement tools and indicators. The study also aims to conduct a bibliometric analysis to investigate the different tools and indicators being focused on in the current literature. This gap analysis can then serve as a guideline for designing a thorough framework for circularity assessment.

TU220

Environmental Footprint of bio-refineries feeding with olive biomass residues and wastes

C. Lago, CIEMAT / Energy Dpt Energy Systems Analysis Unit; I. Herrera, CIEMAT / Energy; D. Garrain, Y. Lechón, CIEMAT / Energy Dpt Energy Systems Analysis Unit
The bio-economy and circular economy EU strategies promote the use of renewable biological resources with special emphasis to close the loop of wastes. In this new context, sustainability assessment of the bio-refineries using biomass resources, such as those from olive industry, is crucial to select the supply chains that generate the lowest environmental impacts. The aim of this work is to determine the environmental impacts using biomass residues, such as olive tree pruning and wastes residues from olive oil production mill, to produce several co-products in a modern bio-refineries, substituting reference and/or conventional goods, by means of the Environmental Footprint. Two different bio-refineries have been evaluated. One of them uses olive tree pruning as feedstock, while the other one consumes olive pomace residue after extraction of residual oil with hexane in the olive mill. The most relevant results are related to the GHG emissions savings into the global warming impact category, obtaining a range of 51 to 95% when compared to their conventional counterparts. Saving from the land use change effects of removing biomass residues from soil are of the most important contributor to those savings. Nevertheless, due to the application of fertilizers, pesticides and other chemicals in the farming stage, other impact categories such as photochemical ozone formation, acidification, terrestrial and marine eutrophication, present worst environmental behaviour.

TU221

Pros and Cons of the valorisation of fish canning wastewater through biopolymers production

A. Hospido, Universidad de Santiago de Compostela / Chemical Engineering; V. Benedetti, Universidade de Santiago de Compostela; S. Longo, A. Fra-Vázquez, A. Val del Río, Universidade de Santiago de Compostela / Chemical Engineering; A. Mosquera-Corral, Universidade de Santiago de Compostela / Department of Chemical Engineering Institute of Technology Universidade de Santiago de Compostela Santiago de Compostela Spain
Fish-canning industries are essential for the local economy in Galicia (NW of Spain) and, at the same time, they generate significant amounts of wastewater with different compositions, which treatment often represents a challenging issue. In this context, the nationally funded projects FISHPOL and TREASURE aim at extracting valuable by-products (i.e. polyhydroxyalkanoates (PHAs)) identified as a promising sustainable alternative to petrochemical plastics (Dietrich et al. 2017)), while treating the wastewater in a sufficient degree to guarantee its safe release to the environment. In parallel, in the recently adopted Plastic Strategy (EC, 2018) the search for alternative feedstocks for plastic production, including bio-based feedstocks, is recommended as long as it is demonstrated that they result in genuine environmental benefits compared to the non-renewable alternatives in a lifecycle perspective. With this perspective the FISHPOL process was developed, which comprises four sequential stages: i) an acidification stage to produce volatile fatty acids (VFAs), ii) an enrichment unit designed to select PHA accumulating microorganisms through a feast-famine regime, iii) an accumulation unit to maximize PHA content inside the bacterial cells and iv) a final extraction process. Therefore, the objective of this study is to evaluate the environmental performance of the FISHPOL process to valorise the fish canning effluents and to compare it with the treatments applied at present: conventional activated sludge and anaerobic digestion completed with an aerobic/anoxic post-treatment. The preliminary Life Cycle Assessment results show a significant impact for the valorisation scenario when compared to the actual scenarios, being the environmental bottleneck the extraction with Dichloroethaneof the biopolymer

from the biomass. An alternative solvent extraction based Dimethyl Carbonate was simulated, resulting in a much lower environmental impact compared to the option applied during lab essays within the FISHPOL project, which positioned the valorisation scenario as a competitive alternative from the environmental point of view. In any case, the evaluation performed has also pointed out the lack of suitable impact categories to consider the effect of plastic littering on water bodies, which is a strong limit of the study, as it leads to the underestimation of the environmental benefit of the biopolymers when compared to their conventional alternative.

TU222

Environmental assessment for fully bio-based self-reinforced polymer composites

D. Spinelli, Next Technology Tecnotessile; P. Chhantyal, Steinbeis Advanced Risk Technologies; L. Van der Schueren, G. Buyle, Centexbel Textile Research Center; B. Bizubova, CHEMOSVIT-FIBROCHEM s.s.; E. Muks, TECNARO GmbH; H. Knudsen, COMFIL ApS

An eco-friendly industry based on green materials, sustainable technologies, and optimal processes with a low environmental impact is today's demand but this remains a considerable challenge to achieve the most appropriate manufacturing methodology. As a fundamental step, there is a need to develop bio-based, sustainable polymeric materials with high stiffness, high impact and high durability without impairing recyclability. The BIO4SELF project within the framework of EU H2020 aims to investigate bio-based Self-Reinforced Polymer Composites (SRPCs). In this work, the environmental assessment of the BIO4SELF project is carried out by applying the Life Cycle Assessment methodology, standardized by the series ISO 14040. The main objective was to analyse the environmental impact of the current production process using bio-based polymers and provide advice on sustainable development of 'hot spots'. As a part of the assessment, the environmental performances of current materials available in the market were compared and the polylactic acid (PLA) that has least energy demand in comparison to other bio-based polymers was chosen. The information provided included the main inputs and outputs, considering energy consumption, materials and generated wastes in the whole life cycle of the production chain of bio-based products. The analysis shows that the highest impact was demonstrated for the PLA granule production, spinning and thermoforming processes due to their higher energy usage. Minor impacts have been observed for commingling, weaving and consolidation processes. The obtained results are in agreement with other bio-polymer based materials (i.e packaging containers). At the end of the project, the achieved results will be updated with the industrial scale production, as the increase in production capacity will lead to the reduction of total energy demand and carbon dioxide emissions. This investigation is expected to open up the path for using PLA materials in a broad range of textile and composite applications. *Acknowledgement* This project has received funding by the H2020 Seventh Framework Programme of the European Union under grant agreement n° 685614.

TU223

Environmental benefits of the green-chemistry based design of Pro-Xylane

P. Martz, LOréal Research & Innovation / LOREAL; N. Maurice, M. Philippe, LOréal Research & Innovation; L. Leseurre, F. Point, J. Schoonjans, Chimex; J. L'Haridon, LOréal Research & Innovation

Pro-Xylane is a cosmetic ingredient used mainly as an anti-ageing agent in skin creams. Produced by Chimex, its chemical structure is derived from the xylose, a natural component of glycosaminoglycans, a component of cellulose and an antibacterial and antifungal agent. Pro-Xylane is produced in a two-steps process: 1) The reaction of xylose and acetylacetone in water, then 2) the hydrogenation of the intermediate. The first process developed in 2009 has then been redesign to lower its impacts, following the green chemistry principles, resulting for example in an improved yield, a lower consumption of chemicals, and a change in the catalyst. A life cycle analysis (LCA) has been conducted to compare the first and improved processes. Taking into account all steps of the chemical production, an LCA allows to quantify the environmental impacts, such as air and water pollution, energy use or water consumption. The LCA outcome, based on detailed data collected in Chimex's factory, shows that the eco-design of the process has lead to a large decrease of impacts in main environmental areas of concern, such as the emission of greenhouse gazes. Detailed results will be described during the congress. According to this work, LCA can be used as an useful tool to ecodesign chemical processes, especially when combined with the green chemistry thinking: 1) it helps to understand where the main environmental impacts occur and in consequence, where to focus improvement work, 2) it quantifies the environmental benefits associated with the use of the green chemistry principles.

TU224

Self-healing maintenance road techniques for improving circular economy: Preliminary results of the Environmental Footprint

A.M. Rodríguez-Alloza, Universidad Politecnica de Madrid / Department of Civil Engineering Construction, Infrastructure and Transport; D. Garrain, CIEMAT / Energy Dpt Energy Systems Analysis Unit; J. Gallego, Universidad Politecnica de Madrid / Department of Civil Engineering Transport and Territory

Self-healing roads are a new generation of pavements whose materials are capable of recovering their original properties after having suffered breakages or failures. This innovative technology aims to reduce the consumption of natural resources and non-renewable energy in the whole life-cycle of roads, due to the potential achievement of increasing their lifespan compared to traditional maintenance operations. Several previous tests have demonstrated the possibility of achieving new asphalt mixtures by means of the addition of microcapsules that dispense rejuvenating products (that could have bio-oils as components) after heating with microwave or induction energy. Therefore, an ideal scenario would be the self-healing treatment with microwaves or induction when the pavement reaches a certain degree of deterioration, so the traditional maintenance technique could be postponed. Moreover, these new materials could reduce the acquisition of extra abiotic materials for rehabilitations. Thence, it could be a novel technique in line with the redesign and reduction thinking for improving the circular economy. Due to the lack of rigorous environmental and economic studies, the objective of this study is the quantification of the advantages and shortcomings of this novel technique, since it is currently one of the priority research lines for paving materials nowadays. Analyses have been done by the application of the Environmental Footprint (EF) methodology. Preliminary results show that there is a clear influence in the comparative EF for maintenance techniques when rejuvenators are activated by means of microwave-healing technology.

Life Cycle Assessment of winery by-products valorisation for alcohol and calcium tartrate production: a case study of a real biorefinery in Italy

F. Fabbri, L. Vogli, Università di Bologna / Centro Interdipartimentale di Ricerca sulle Scienze Ambientali; D. Marazza, University of Bologna / Department of Physics and Astronomy; R. Prati, G. Marani, Caviro Extra S.p.A.; S. Righi, University of Bologna / Department of Physics and Astronomy

The exploitation of winery waste and by-products to produce alcohol and other goods is a step towards wine sector's sustainability in a circular economy framework, although the measure of related environmental impacts is poorly developed. Aim of this study, which is part of the Emilia-Romagna region VALSOVIT project financed by 2014-2020 European Regional Development Fund programme, is to perform a Life Cycle Assessment (LCA) over primary data at commercial scale in a large biorefinery located in Faenza (Italy) to evaluate the impacts produced by treating one tonne of winery by-products (grape marc and wine lees) to produce alcohol and calcium tartrate (CaT), and to compare the results to those of two alternative treatment scenarios (composting and anaerobic digestion). The analysed processes include: 1) grape marc and wine lees handling and distillation; 2) alcohol and CaT production; 3) process residues treatment and valorisation for energy production. The electric and thermal energy used are self-produced by the company via A) the combustion of biogas produced by anaerobic digestion of process residues, and B) the combustion of exhausted grape marc. The excess energy is used in the LCA model to gain credits. Both digestate and aerobic sludge from WWTP are used for agricultural application, gaining credits from avoided production of synthetic fertilizers. The scenarios for comparison have been modelled using secondary data (Ecoinvent and Thinkstep datasets). LCA is conducted using GaBi 8.7 software. The ILCD recommended impact assessment methods and the related characterization factors, along with Primary Energy Demand indicator, have been used for calculating the environmental impacts. The results obtained show that the valorisation of winery by-products is more environmentally performing than both composting and anaerobic digestion, as it is the best option in 8 categories out of the 16 considered in the analysis. For many indicators, such as GWP, Resource Depletion, Water Depletion, Land Use and Primary Energy Demand, environmental benefits are obtained, mostly due to credits from excess energy production. The life cycle phases generating the highest environmental impacts are the grape marc and wine lees processing residues treatment, and the CaT production.

Environmental Risk Assessment of Amphibians and Reptiles: Advancing Knowledge and Reducing Uncertainty (P)

TU226

Effects of pesticides and antibiotics on the early development of the model amphibian organism: Xenopus laevis

L. Boualit, University of Lausanne / Faculty of Geosciences and Environment; H. Cayuela, Universite Laval / Institut de Biologie Intégrative et des Systèmes; R. Santos, HEPIA; N. Chèvre, University of Lausanne / Faculty of Geosciences and Environment

According to the International Union for Conservation of Nature (IUCN), amphibians are suffering a massive decline. With more than 40% of endangered species, they represent one of the most threatened group among vertebrates. Amphibian decline is multicausal and pollution is usually considered as one of major factors involved in population decrease and local extinction. Especially, the use of pesticides and antibiotics in the context of farming activities is suspected to degrade the quality of breeding sites (e.g. lac, swamp, and ponds). Indeed, these molecules are carried by surface and sub-surface runoff as well as drainage into aquatic systems and can be found in high concentrations in surface waters.

Freshwater ecosystems are of crucial importance for amphibians' life cycle. In pond-breeding amphibians, embryonic and larval development takes place in aquatic habitats. Environmental conditions experienced over aquatic development are critical since they affect growth (rate and timing) and survival until metamorphosis. They also have far-reaching consequences for postmetamorphic performances as they influence size and body condition at metamorphosis, two factors directly related to fitness components (survival, growth, and reproduction) at terrestrial stage. Therefore, exposure to chemicals during aquatic development may have a strong detrimental impact on amphibians' population dynamics. To date, the impacts of pesticides and antibiotics on amphibians' populations are still poorly understood. To fill this gap, we investigated the effects on embryos of African clawed frog (*Xenopus laevis*) of nine pesticides and two antibiotics regularly detected in worldwide surface waters. The main objective of this project is to identify and develop sensitive markers for highlighting effect of pesticides and antibiotics at early stages of amphibians' life-cycle. We used the Frog Embryo Teratogenesis Assay-Xenopus (FETAX) as a basis. To improve individual monitoring, we adapted FETAX protocol relying on the Fish Embryo Acute Test (FET), primarily developed for zebrafish. Briefly, embryos are exposed to six concentrations of tested molecules over a 96h post fecundation (hpf) period and four apical observations (coagulation of embryos, lack of somite formation, non-detachment of the tail and lack of heartbeat) are recorded. On top of these observations, molecular biomarkers, embryos' activity, time of hatching and embryos' size at 96 hpf are recorded as well.

TU227

Development of a standardized toxicity test method using a native amphibian

L.A. Van der Vliet, Environment and Climate Change Canada / SCIENCE AND TECHNOLOGY BRANCH; B. Lo, Nautilus Environmental Company Inc; P. Jackman, Environment and Climate Change Canada / SCIENCE AND TECHNOLOGY BRANCH; R.P. Scroggins, Environment and Climate Change Canada / Biological Methods

Although there is growing evidence of the sensitivity of amphibians to contaminants, and thus a growing demand for their use in regulatory frameworks, amphibian toxicity data are currently under-represented in risk assessments. Few standardized methods are available, which in part contributes to this under-representation. In addition, none of the available aquatic methods pair whole-organism chronic endpoints with species that are relevant to Canadian environments. To address this gap, Environment and Climate Change Canada has invested in developing a standardized test method for assessing contaminants with a native amphibian species (*Lithobates pipiens*, Northern leopard frog). We will discuss some lessons learned from laboratory research and data from recent inter-laboratory testing rounds to validate the new test method. For the inter-lab project, we used sodium chloride, thyroxine and perchlorate as model compounds in this multi-laboratory experiment. Environment and Climate Change Canada's amphibian test method will continue along the usual path for standardization of a toxicity test method, including development of quality control criteria, improvement of methodology text, and peer review. The result will be the first Canadian standardized toxicity test method using a native amphibian species.

TU228

Telemetry study on the common toad (Bufo bufo) during postbreeding migration through cereal fields in Germany

G. Montinaro, T. Grimm, Rifcon GmbH; J. Ludwigs, Rifcon GmbH / Business Development; J. Erni-Lindenborn, M. Erni, Rifcon GmbH

The Scientific Opinion on the state of the science on pesticide risk assessment for amphibians and reptiles, recently published from The European Food Safety Authority, points out the need to collect more data on the ecology of these animals to reduce uncertainties when assessing the potential risks associated with exposure to pesticides. Amphibians represent a group of vertebrates endangered at European level but there is still a general lack of knowledge of the ecology of many species, particularly related to their terrestrial life stages. Only a few telemetry studies are available on anurans in Europe and data on their occurrence in different agricultural crops is sparse. Technical developments have now led to reduction of tag weights and an increase in battery life. These developments can now facilitate the undertaking of field studies on amphibian species aimed at providing data to determine relevant PT values (i.e. the portion of time individuals spend active in treated crops) for risk assessment purposes. We will present data for the common toad (*Bufo bufo*), obtained from individuals equipped with state-of-the-art radio tags in order to follow the animals in the post breeding season. The methods used and results obtained will be presented and discussed.

TU229

Telemetry of sand lizards (Lacerta agilis) in vineyards - do methods established for terrestrial vertebrate risk assessment to record higher tier data work for reptiles?

G. Montinaro, M. Erni, J. Erni-Lindenborn, M. Münderle, Rifcon GmbH; J. Ludwigs, Rifcon GmbH / Business Development

The scientific opinion on the state of the science on pesticide risk assessment for amphibians and reptiles, published in 2017 by the European Food Safety Authority, highlights a gap in our knowledge of the ecology of the reptiles to be used for higher tier risk assessment. The sand lizard (*Lacerta agilis*) was proposed as a focal species to represent other lacertids utilizing agricultural land. *L. agilis* is commonly distributed in vineyards, a permanent crop to which pesticide applications are frequently made. For sand lizards, vineyards represent what can be considered to be a secondary habitat. *L. agilis* occurs predominantly at the edges of these areas, particularly if bordered by abandoned gardens. A study site with these characteristics was selected, as these habitats represent areas from which the animals can move into the surrounding vineyards. Several sand lizards were caught and individually marked. Continuous radio-tracking was performed in summer 2018 and confirmed the use of vineyards and other habitats by *L. agilis*. The applicability of refinement factors recommended in the scientific opinion on the state of the science on pesticide risk assessment for amphibians and reptiles could be therefore demonstrated. These refinement factors included the portion of time active animals spend in treated areas, as commonly applied to other terrestrial vertebrates. In addition to data on the use of vineyards by sand lizards we also present the tagging methodology used and other technical aspects of the telemetric process.

TU230

Examining Mercury Transfer in the American Alligator (Alligator mississippiensis)

F. Nilsen, US EPA / ORISE Fellow / National Exposure Research Lab; T.R. Rainwater, Clemson University; A. Brunell, Florida Fish and Wildlife Conservation Commission; J. Bowden, University of Florida; L. Guillette, Medical University of South Carolina; S.E. Long, T. Schock, National Institute of Standards and Technology / Analytical Chemistry Division

Prenatal exposure to environmental contaminants is a cause of developmental issues in humans and wildlife. Mercury (Hg) and other environmental contaminants are particularly detrimental to the developmental phases, often impairing the organization and development of important organ systems by causing irreparable damage. Wildlife species that are environmentally exposed to elevated Hg concentrations can be useful in modeling human exposure. The transfer of Hg in the American alligator (*Alligator mississippiensis*), a common sentinel for contaminant exposure, was examined in a series of experiments. To determine the presence of Hg within the eggs, total Hg (THg) was measured by atomic absorption spectroscopy in alligator egg yolk samples from three locations, Yawkey Wildlife Center, SC, Lake Apopka, FL, and Lake Woodruff, FL. The mean THg concentrations observed at each site were 26.3 ng/g ± 11.0 ng/g, 8.8 ng/g ± 5.1 ng/g, 22.6 ng/g ± 6.3 ng/g, respectively. After the presence of Hg in alligator egg yolk was confirmed at different locations, maternal transfer was examined by measuring THg in nesting female blood samples, corresponding egg yolk, and embryo samples across three years from a single location, Yawkey Wildlife Center, SC. We observed that ~12 % of the maternal THg is found in their egg yolk, and a highly significant correlation was observed which explained 66% of the overall variation between the two samples ($rho = 0.66$; $p < 0.0001$). The correlation equation derived by this analysis ($y = 0.138x – 2.5534$) was the used to extrapolate maternal transfer in alligator populations at other locations based on the nesting female's blood THg, and further evaluate alligators a developmental model for embryonic Hg exposure. To assess environmental Hg transfer the developmental compartmentalization of topically applied THg was examined using alligator eggs collected from a low Hg site, Lake Woodruff, FL. Through this analysis, we observed that environmental Hg transfer is unlikely after calcification. The observed nest-specific THg concentrations that persisted through the dosing experiment further indicate that maternal transfer is occurring. This study details new life history information for the American alligator, which can improve biomonitoring efforts and inform population management programs in areas of high Hg contamination, as well as identifying this species as a candidate model organism for maternal transfer of environmental Hg exposure.

In vitro modulation of transcriptional activity of nuclear receptors of fin and blue whales by environmental pollutants

K. Luhmann, Norwegian Polar Institute / Ecotoxicology; R. Lille-Langøy, L. Øygarden, University of Bergen / Department of Biological Sciences; K.M. Kovacs, C. Lydersen, Norwegian Polar Institute; A. Goksøyr, University of Bergen / Department of Biology; H. Routti, Norwegian Polar Institute

Baleen whales, such as fin whales (*Balaenoptera physalus)* and blue whales (*B. musculus*), are impacted by multiple stressors, including exposure to pollutant mixtures. Both of these species are listed in threatened categories in the IUCN Red List of Threatened Species. Despite their conservation status, there is little information available regarding persistent organic pollutant (POP) concentrations in their blubber, or the potential toxicological effects of pollutants on these species. One critical mode of action of POPs is endocrine disruption, but this aspect of toxicology has been studied very little in wildlife. The health of marine mammals depends on the normal functioning of energy metabolism, the immune system and reproduction. These processes are regulated by nuclear receptors, such as thyroid hormone receptor beta (THRB), glucocorticoid receptor (GR) and the peroxisome proliferator-activated receptor gamma (PPARG). To study the transcriptional activity of THRB, GR and PPARG when exposed to legacy POPs that are abundant in whale blubber, GAL4-UAS based *in vitro* luciferase reporter gene assays were performed. PCB52, PCB118 and *o,p´*-DDT increased the transcriptional activity of GR. The transcriptional activity of PPARG was increased by PCB congeners 101, 118, 138, 153 and *o,p´*-DDD, *trans*-nonachlor, oxychlordane and the POP mixture. THRB transcriptional activity was increased by PCB153 and antagonistic effects were detected for *trans*-nonachlor, PCB52, oxychlordane, PCB101, PCB138, *o,p´*-DDE and HCB. These results are also representative for other mammalian species, because the ligand binding domain (LBD) of THRB has been shown to be identical in killer whales, white whales and humans; PPARG-LBD is the same in killer whales, white whales, polar bears and humans and the LBD of GR is the same in killer whales and minke whales. The findings of the study contribute to a better understanding of an endocrine disruptive mode of action of POPs on whales and other mammals. Due to remaining knowledge gaps, additional studies will be needed that focus on the effects of POPs on endocrine disruption.

TU233

Field study in apple orchards to assess exposure and effects of a fungicide on the European Rabbit (Oryctolagus cuniculus)

O. Fuelling, Tier3 Solutions GmbH / Field study; A. Cervencl, B. Giessing, Tier3 Solutions GmbH; S. Norman, RidgewayEco

The EU requires a risk assessment for non-target wild mammals to register a Plant Protection Product for the European market. Here we present a realistic field study on populations of the European rabbit (*Oryctolagus cuniculus*) to monitor for potential effects after sprays of a fungicide in apple orchards. The aims were to elucidate: (i) the presence of rabbits in the apple orchards, (ii) their exposure to the fungicide by grazing on the grassy understorey and (iii) any effects on reproduction by comparing test-item-treated orchards with reference orchards. The study was conducted in six apple orchards in Herefordshire, UK. It ran from March to August (2018) which is the period of rabbit reproduction in the UK. The cropped area of three orchards was treated with 10 applications of a fungicide. The other three orchards were not treated with the test-item and hence served as reference sites. The analysis of the vegetation samples found residues of the test-item in the grasslayer between the tree rows after the applications. Thus, grazing rabbits were exposed to the test item. To document the presence and behaviour of rabbits thermal-imaging devices were used during ‘Transect Counts’ inside the orchards. In each orchard 13 transect counts of approx. three hours length each were conducted. Rabbits could be observed during all transect count sessions and in all six orchards the abundance and behaviour of observed rabbits showed no significant difference. Spatial data from 15 adult females tagged with a GPS-collar continuously recorded location data between two to eight days per individual. The data revealed that their warrens were located in the margin of the orchards. Moreover, the data showed that all tagged rabbits spent a considerable amount of time within the test item orchards. From these results it could be concluded that the rabbits inhabiting these warrens used the orchards for foraging and were, therefore, exposed to the test item. In order to identify the proportion of juvenile rabbits in the local population, as an indicator for reproduction, ten automatic ‘Wildlife Cameras’ were placed in each orchard. 39,576 video footages showing at least one rabbit were analysed for the number of juveniles and adults visible. There were no statistically significant differences in juvenile proportions between ‘test item orchards’ and ‘reference orchards’. Hence, there was no indication that rabbit reproduction was affected by the test item application.

TU234

Validation of dynamic energy budget physiological models for small mammals

A. Gergs, Bayer AG - Crop Science Division / Department of Environmental, Social and Spatial Change; K. Rakel, Research Institute gaiac / gaiac- Research Institute for Ecosystem Analysis und Assessment; V. Ducrot, Bayer Ag / Environmental Safety Ecotoxicology

In the prospective environmental risk assessment for pesticides, toxicokinetic-toxicodynamic (TK-TD) models are useful tools for the evaluation of potential risks and may help to reduce animal testing. Dynamic energy budget (DEB) models are particularly suitable to analyses chemical effects on life-history traits related to growth and reproduction. DEB models for chemical effects consist of two modules, a ‘physiological’ module that describes the energy acquisition and use for growth and reproduction, and a TK-TD module that accounts for the chemical effect. While the TK-TD module is always specific for a given chemical, the general idea of the physiological module is that the same DEB model can applied to the different species, and species only differ in their parameter values. Model validation is key to reliable applications within the prospective environmental risk assessment. We will showcase a validation of the physiological DEB model for two laboratory species, the Wistar strain of the brown rat and the New Zealand White strain of the European rabbit. Both model parametrizations are publically available from the add-my-pet collection which generally hosts underlying code, parameter estimates and data for a broad range of species.

TU235

Determining the effects of 3 nonsteroidal anti-inflammatory drugs (NSAIDS) on the african clawed frog Xenopus laevis

A. Sobrino-Figueroa, Universidad Autonoma Metropolitana, Iztapalapa / Hidrobiology; S. Nava-Serrano, UAM-Iztapalapa; S. Alvarez-Hernandez, Universidad Autónoma Metropolitana-Iztapalapa / Applied Ficology Laboratory. Department of Hidrobiology

NSAIDs are drugs most consumed worldwide because used to remedy the pain of mild to medium grade and they are over-the-counter. These drugs are present in hospitals effluents. and has been demonstrated that these drugs do not degrade in water treatment systems, for this reason have been detected in surface water at concentrations of 6.5 ng L^{-1} to 100 ug L^{-1}. Because the effects of these drugs on aquatic organisms are not known in this work, the oxidative, neurotoxic and genotoxic effects of 3 analgesics: Naproxen, Paracetamol and Acetylsalicylic Acid was evaluated in the African frog *Xenopus laevis*. X. laevis specimens were obtained by donation. They were grown in the laboratory under the following conditions: Temperature 23 ° C, Photoperiod: 16 hours Light/8 hours Darkness. Water hardness: 160 mg. With juveniles of 3 cm in length, bioassays were performed where 6 organisms were exposed to a sublethal concentration of the drugs (CL_1) for 15 days. Skin samples were taken for the determination of lipoperoxidation (Tbars), brain to determine the activity of the enzyme acetylcholinesterase (AchE) and blood for the evaluation of micronuclei frequency. A "t" test was carried out between the control and the exposed organisms to detect the differences in the responses to the drugs. In the results obtained, significant differences were observed between the control and the organisms exposed to NSAIDs. The analgesic with the highest oxidant effect (12.6 nM Tbars mg^{-1}) was paracetamol (control = 0.94 nM Tbars mg^{-1}). A decrease in AchE activity of more than 20% was observed in the Naproxen tests. The 3 drugs had genotoxic effects. The highest frequency of micronuclei was obtained in the tests with paracetamol (4.2%) and the lowest frequency in the tests with acetylsalicylic acid (2.5%). The results indicated that in sublethal concentrations tested NSAIDs have deleterious effects on frogs. It is important to study the effect of these compounds in aquatic systems, to determine the degree of risk in which organisms are chronically exposed to these drugs.

TU236

Virus infections are augmented by exposure to environmental pollutants in vertebrates

C. Waugh, Norwegian University of Science & Technology; V. Jaspers, Norwegian University of Science & Technology / Biology

During the last few decades we bear witness to the emergence/re-emergence of virulent pathogens that threaten human and wildlife health. Despite advances in biomedical research and improvements in therapeutics, virus infections still cause significant morbidity, mortality and socioeconomic loss. Among the most cited and recognised drivers of pathogen emergence are climate change and habitat destruction, with other clear factors including viral subtype, host genetics and age. Yet, these factors do not completely explain the variation among responses within an infected population. Other exogenous factors thereby must play a role. Here we review how legacy pollutants, that are known to modulate immune function of vertebrate hosts, affect the emergence/re-emergence of virus infections and may thereby drive outbreaks and the evolution of disease severity. The immunomodulating properties of such chemicals have led to postulations as early as the 1960s that they are involved in viral outbreaks in humans and marine mammals, as well as increasing the severity of virus infections in a number of animal models. Despite these presumptions, a clear link between pollutants and virus infection severity has yet to be determined. Thus, we reviewed the literature on the effects of legacy pollutants on virus infections in vertebrate hosts. Here we present the results of this review which provide the first review and meta analysis on the effects of legacy pollutants on virus infections in vertebrates. We show that pollutants augment mortality and virus titre in infected mammals, fish, and birds.

TU237

Immunotoxicology of persistent organic pollutants and mercury in northern Norwegian White-tailed eagle (Haliaeetus albicilla) nestlings

E. Hansen, UiT - The Arctic University of Norway; S. Bourgeon, University of Tromsø / Department of Arctic Marine Biology; J.O. Bustnes, Norwegian Institute for Nature Research / Fram Centre; B. Bårdsen, Norwegian Institute for Nature Research NINA / FRAM Centre Tromso; I. Eulaers, Aarhus University (AU), Arctic Research Centre / bioscience; N. Huber, University of Veterinary Medicine, Vienna / Department of Integrative Biology and Evolution

The marine environment functions as a sink and transport route for contaminants, and marine top predators are characterised by relatively high levels of organohalogenated contaminants (OHCs) and mercury. As such, they represent good biological models to assess the impact of such environmentally persistent pollutants (EPPs) on ecosystem health. Here we propose a project that will use a sentinel top predator in the Norwegian marine fauna: the white-tailed eagle (WTE: *Haliaeetus albicilla*) for developing new methods to understand how EPPs affect biomarkers of immunotoxicity, i.e., leukocyte coping capacity (LCC). LCC assesses the capacity of circulating leukocytes to produce a respiratory burst *in vitro* in response to a secondary challenge by phorbol myristate acetate (PMA). This measurement was performed in the field on WTE nestlings in three different areas of northern Norway and represents an *in vitro* assessment of the bird's current physiological status and its ability to cope with stressors. Individuals with a higher LCC have a greater potential to produce a respiratory burst, and physiologically, are better able to respond to challenges after stress. In the context of immunotoxicity, we predict both inter-individual and inter-population differences. First, we predict that WTE nestlings with a higher load of contaminants will have a reduced LCC (i.e., lower immune defense and higher susceptibility to stressors) compared to less contaminated nestlings. Second, we predict that there will be regional differences in LCC-profiles, considering that environmental quality (e.g. habitat quality and food resource) influence the level of contaminants and stressors in the chicks. Preliminary results show evident differences in LCC profiles among WTE nestlings, and these differences will be further investigated in relation to level of OHCs in blood plasma and mercury in feathers, in addition to analysis of stable isotopes in feathers to include effect of diet. Final results from this study will be ready by early May 2019.

TU238

More than one can bear: Exposure to persistent organic pollutants alters the adipose tissue transcriptome in polar bear mother-cub pairs from Svalbard, Norway.

P. Herst, Universite Laval / Department of Animal Science; C. Joly Beauparlant, A. Droit, Laval University / Computational Biology Laboratory Research Centre; J. Aars, The Norwegian Polar Institute; M. Dalvai, Laval University / Department of Animal Science; H. Routti, Norwegian Polar Institute; J. Bailey, Laval University / Department of Animal Science

Being on top of the food chain, polar bears (*Ursus maritimus*) are highly contaminated with persistent organic pollutants (POPs). Females nurse their offspring with contaminated milk – consequently, even young cubs have higher POP concentrations than their mothers. Recent studies suggest that POPs may affect lipid metabolism in female polar bears, however, the mechanisms and impact on her offspring remain unknown. We hypothesize that (1) increasing exposure to POPs in polar bear mothers disrupts adipose tissue transcriptomes of adult female polar bears and their offspring and (2) POP-related transcriptomic dysregulation in adipose tissue is sex-specific and differs between male and female polar bear cub pairs.Adipose tissue biopsies were collected from adult female polar bears and their cubs in Svalbard, Norway, spring 2011-2013 (PCB plasma concentration: 10.46 - 248.62 ng/g wet weight). Total RNA extracted from biopsies from adult females (n=13) and cub pairs (?-?n=5 | ?-?n=4 | ?-?n=4) were subjected to next-generation sequencing to assess RNA presence and quantity.The expression of the top 50 most correlated genes with POPs exposure are altered differently due to low, medium and high exposure in mothers. Several cubs from low exposed mothers had a gene expression profile resembling medium exposed cubs. Male and female cub pairs responded differently to POPs. DISCUSSION & PERSPECTIVES: POPs alter the adipose transcriptome of polar bear mothers and cubs, which may be linked to metabolic dysfunction. Male and female cubs demonstrated remarkably different adipose transcriptome profiles.We will elucidate coping mechanisms polar bears utilize to adapt to their changing environment. This is also a unique opportunity to observe sex-specific coping between cub pairs. This study will broaden our understanding of POPs and their impact on lipid metabolism and physiology in apex predators and offspring.

TU239

Large-scale monitoring of the exposure to per- and polyfluoroalkyl substances and mercury in the white-tailed eagle (Haliaeetus albicilla): clinical-chemical effects and the role of diet

I. Eulaers, Aarhus University AU Arctic Research Centre / Department of Bioscience; C. Sonne, Aarhus University AU Arctic Research Centre; P. Ambus, Copenhagen University / Department of Geosciences and Natural Resource management; R. Bossi, Aarhus University / Dept of Environmental Science; R. Sun, University of Antwerp / Department of Biology; J. Søndergaard, Aarhus University AU Arctic Research Centre; J.O. Bustnes, Norwegian Institute for Nature Research NINA; K. Skarphedinsson, Icelandic Institute of Natural History

Although bird of prey nestlings are considered valuable sentinels of local environmental contamination, an effort to evaluate their extended suitability for large-scale monitoring was yet to be endeavoured. We have therefore sampled blood and body feathers from white-tailed eagle (*Haliaeetus albicilla*) nestlings along the Swedish, Finnish, Estonian, German, Danish, Norwegian and Icelandic coasts. This large-scale effort represents the anticipated exposure spectrum and has documented individual traits (age, crop content, foraging habitat and trophic level) that may confound contaminant exposure and effects. Body feathers and blood plasma were analysed for mercury (Hg) and per- and polyfluoroalkyl substances (PFASs), respectively, and a range of blood clinical-chemical parameters (BCCPs) was quantified as well. Finally, stable carbon (foraging habitat) and nitrogen (trophic level) isotopes were analysed in the same body feathers. Our first results confirm elevated exposure to Hg and PFASs in Baltic nestlings and lower exposure in Norway and Iceland. Notable Hg hotspots are located along the Swedish coast and in Finnish Lapland, while only the central Swedish and Finnish Baltic seem to be hotspots for PFASs. We did not observe a significant overall relationship between trophic level and contaminant exposure, which supports the notion of locally elevated environmental background levels. Multiple regression models investigating the simultaneous effects of individual contaminant exposure, age, short-term food ingestion, foraging habitat and trophic level indicate that the latter two stable isotope based dietary descriptors also show relationships with BCCPs indicative for liver, kidney and blood metabolism. Moreover, short-term diet ingestion (recorded crop content) as well as an individual's age influences these same BCCPs as well as a range of elements. Finally, the models show the potential effect of Hg and PFAS exposure on clinical health as significant relationships where found between the contaminant levels and BCCPs indicative of liver and kidney functioning. We will present a more thorough data analysis of this expanding dataset in order to show the feasibility and importance of large-scale monitoring, which allows evaluating the efficiency of dedicated contaminant Conventions as well as the impact of increasing environmental change.

TU240

Blood clotting assays enhance assessment of anticoagulant rodenticide exposure and effects in free-ranging birds of prey

S. Hindmarch, Fraser Valley Conservancy; B.A. Rattner, U.S. Geological Survey / Patuxent Wildlife Research Center; J.E. Elliott, Environment and Climate Change Canada / Science and Technology Branch Ecotoxicology and Wildlife Health Division

Non-target wildlife, particularly birds of prey, are widely exposed to and acutely poisoned by anticoagulant rodenticides (ARs). An unresolved issue surrounding such exposure, however, is the potential for sublethal effects. In particular, the consequences of AR exposure and resulting coagulopathy on health and survival of unintentionally exposed animals, which often encounter a multitude of anthropogenic stressors, are understudied. In a wildlife rehabilitation setting, AR intoxication may be masked by more obvious injuries related to collision with vehicles or electrocution, thereby obfuscating proximate from ultimate cause of mortality , although the two make also act cumulatively to cause death. An assessment of coagulation function of admitted wildlife may provide a means of establishing the proportion of animals exhibiting sublethal coagulopathy, and ultimately ensuring provision of appropriate and swift treatment. In conjunction with routine diagnostics for injury and disease, we performed two blood clotting assays (prothrombin time, Russell's viper venom time) affected by vitamin K-dependent coagulopathy of samples from live raptors admitted to a rehabilitation facility. We also measured clotting time in pre-fledge barn owl chicks from 10 nest sites in Lower Mainland Canada. Prolonged clotting time or failure to form a clot altogether was observed in 23% of 61 sampled raptors admitted to the rehabilitation facility. This is a biologically significant proportion of individuals given the fortuitous and biased nature by which raptors are found and admitted to rehabilitation facilities. In contrast, there was no evidence of coagulopathy in any of the pre-fledgling barn owl chicks. The utility of avian coagulation tests for diagnosing AR exposure is promising, yet there remains a need to establish species specific reference values and standardize and streamline[assay methodologies among test facilities.

TU241

In vitro cell proliferative effect induced by organochlorine pesticides and their binary mixtures detected in raptors from Southeastern Spain

M.J. Aldeguer, E. Martínez-López, University of Murcia / Health Sciences Department - IMIB-Arrixaca - Veterinary Faculty; A. García-Fernández, University of Murcia / Toxicology and Risk Assessment Group/IMIB-Arrixaca

The effects related to the exposure to organochlorine pesticides (OC) have been widely studied in many species, including human and wildlife, around the world. Over the past three decades, studies on their effects have been focused on endocrine alterations in living beings, for example, estrogenic effects. Wild birds, especially raptors, have been widely used as sentinel of both environmental exposure to OC, and their acute and chronic effects. However, there is still a great uncertainly about the exposure to OC mixtures. In this study we have used a rapid and sensitive in vitro test to evaluate cell proliferation in MCF7 cell line after exposure to increasing concentrations of four OC pesticides (p,p'-DDT, p,p'-DDE, endosulfan αβ, HCH-technique) and four binary mixtures (two of them at 1:1, DDT:DDE and endosulfan:HCH; and the other ones at 3:1, endosulfan:DDT and endosulfan:DDE). Mixtures were designed following patterns of exposure to OC in raptors species from the southeastern Spain. MCF7 cells were exposed to 7 sublethal concentrations of each pesticide and each mixture, using the 6-day E-Screen assay. 17β-estradiol was used as positive control, and DMSO as vehicle. The range of assessed concentrations was 1,0E-5M to 1,0E-11M for individual compounds, and diluted until 1,0E-13M for mixtures. Relative Proliferative Effect (RPE) referred to the positive control allowed us classify each compound and mixture as weakly (RPE< 25%), partially (25-75%) or highly (>75%) estrogenic. All single OC were classified as highly estrogenic, at least, in one of the concentrations assessed, although the intensity on their responses varied along the concentrations. RPE obtained for the mixtures were lower than those for single compounds, except for the endosulfan:HCH mixture, which was classified as highly estrogenic. Moreover, the highest effect was observed at the lower concentration. Half of the binary mixtures were weakly estrogenic, and the rest showed partial or high cell proliferative effect. Finally, we suggested that difference on affinity of each compound with each estrogenic receptor seems to be more relevant than its relative presence in the mixture. Keywords: Estrogenic, proliferation, organochlorine, mixture, in vitro, MCF7, raptor.

TU242
Eggshell index, declining fertility and embryonic death could be related to the presence of DDE and dieldrin in unhatched eggs of Montagu's harrier (Circus pygargus)
I. Navas, University of Murcia / Health Science Department - IMIB-Arrixaca - Veterinary Faculty; E. Martínez-López, P. Gómez-Ramírez, University of Murcia / Health Sciences Department - IMIB-Arrixaca - Veterinary Faculty; S. Espín, University of Murcia / Toxicology and Risk Assessment Group/IMIB-Arrixaca; P. María-Mojica, University of Murcia / Health Sciences Department - Toxicology Area - Veterinary Faculty; A. García-Fernández, University of Murcia / Toxicology and Risk Assessment Group/IMIB-Arrixaca
Unhatched eggs have been widely used to assess exposure and effects induced by environmental endocrine disruptors, especially organochlorine compounds in raptors. Data on exposure estimates of the mother, body burden of contaminants in nestlings and reproductive success, among others, could be easily obtained from this type of sample. However, eggs also have some disadvantages, like the scarce number of available samples to be analysed. On the other hand, the effects of DDE on the reproductive success in birds of prey have been well reported. From the beginning of this century, Montagu's harrier (Circus pygargus) population dramatically declined in Southern Spain. To try to relate it to exposure to organochlorine pesticides, 15 compounds were analysed in the contents of 55 Montagu's harrier unhatched eggs sampled in Southern Spain between 2003-2006. The pesticide concentrations were studied in relation to different parameters of fertility, embryonic death and reproductive success. Threshold effect levels related to reproductive success were also estimated for DDE and dieldrin. Eggshell thickness (ET; mm) was measured and Eggshell Index (EI; g/ mm2) calculated in all eggs. P,p'-DDE showed the highest mean concentration (14.4 mg/g lipid; median 8.56 mg/g lipid) and was also the most frequently detected (in all fertilized eggs, and in 97% of unfertilized eggs). Lindane, heptachlor and its epoxide, endosulfan I, and dieldrin were also detected but at lower concentrations. Fertilized eggs showed higher concentrations of pesticides, especially of p,p'-DDE and lindane, than unfertilized eggs, with the exception of dieldrin which showed a mean concentration ten times higher in unfertilized than in fertilized eggs. No relationships between pesticide concentrations and ET nor EI were found, except for p,p'-DDE and EI (r=-0.530; p=0.006). Eggshell index could be a better biomarker of hatching failure than ET. Finally, two eggs showed p,p'-DDE concentrations above the threshold level related to reproductive effects proposed by other authors. After comparison with other studies, we propose 3000 ng/g (wet weight) of p,p'-DDE as NOAEC in Montagu's harrier. Regarding dieldrin, the highest concentration was 136 ng/g (wet weight), 3-6 times lower than the threshold values proposed by others, but a relationship between dieldrin exposure and fertility should not be discarded. **Acknowledgments**: EGMASA-Junta de Andalucía, ERBFacility-Cost Action.

Monitoring long term effects of a crop protection product on birds: a case study in citrus orchards in Italy
F. Sotti, RIFCON GmbH Goldbeckstr Hirschberg Germany; A. Sharples, FMC / Global Regulatory Sciences; S. Laucht, Rifcon GmbH; B. Sharma, FMC Agricultural Solutions / Global Regulatory Sciences; J. Ludwigs, Rifcon GmbH / Business Development
According to the Guidance Document on Risk Assessment of Birds and Mammals (EFSA 2009) potential adverse effects of pesticides on wild vertebrates should be assessed. One higher tier refinement option for wildlife is to conduct field effect studies to monitor potential acute and long-term effects on birds. In the past, it was not questioned to move application timings (intended according to the GAP in summer or autumn) into spring: It was commonly agreed between applicant, regulator and other parties involved in study planning, that applications (i.e. exposure of birds) were set to the onset of breeding, and that this would be a worst-case scenario to explore potential long-term (i.e. reproductive) effects of exposed individuals. However, within the last few years a regulatory concern of this design becomes more common that short-term exposure at any time of the year could have long-term effects on reproduction. The current study aimed to investigate potential long-term reproductive effects on exposed birds after insecticide use against Mediterranean fruit flies (*Ceratitis capitata*) and to cope with the logistic difficulties to follow exposed birds between breeding seasons. The study was conducted based on member state requested design in 2016 and 2017 in Sicily, the most representative region for citrus in Italy. The product is usually sprayed when the fruits grow, thus in late summer when the breeding season of birds ends. We focussed on the most representative species such as sparrows (*Passer sp.*), blackbird (*Turdus merula*), goldfinch (*Carduelis carduelis*), great tit (*Parus major*), Sardinian warbler (*Sylvia melanocephala*), utilizing such citrus orchard, and covering all diet guilds of birds using orchards. We applied bird trapping, nest searching, monitoring and telemetry as field methods. There was no evidence for any long-term effects such as reduced breeding success or mortality of young reared by exposed individuals of the previous season in treated citrus orchards. This study and its results can be considered an example how registration relevant reproductive data can be recorded even for birds exposed late in the season, when the breeding period is already completed.

TU244
Effect of exposure duration on the magnitude of body weight effects in mammalian toxicology studies
A. Guckland, WSC Scientific GmbH; M. Wang, WSC Scientific GmbH / Dept Efate Modelling; R. Murfitt, Syngenta Ltd / Environmental Safety; M. Ebeling, Bayer AG Crop Science Division / Ecotoxicology - Terrestrial Vertebrates Expert Team; M. Foudoulakis, Corteva Agriscience, The Agriculture Division of DowDuPont / CPRS; S. Haaf, ADAMA Deutschland GmbH
The time-dependence of effects on female body weight observed in dietary toxicity studies conducted with rats was evaluated using Benchmark Dose calculations (BMD_{10}, i.e. an effect level of 10% was considered). A total of 37 long-term toxicity studies conducted with 13 different active substances used as pesticides were evaluated. These active substances belong to different use classes (i.e. herbicides, insecticides and fungicides). Time-dependent changes of BMD_{10} were evaluated for each active substance using female body weights after 14, 21, 28, 42 and 70 days of exposure. The greatest body weight effects were observed at the end of toxicity studies (after longest exposure). BMD_{10} values declined continuously with exposure duration for all use classes and substances. After 70 days of exposure the BMD_{10} levels were about half of the BMD_{10} after 14 exposure days, indicating that animals respond to pesticide exposure in an exposure-time-dependent way, i.e. effects on body weight of the animals are less pronounced when the duration of exposure is short. Based on these findings, the realism of the current wild mammal risk assessment for plant protection products is discussed and how it could be improved by considering an appropriate time period for the selection of endpoints in chronic toxicity studies, which reflects the exposure time of free ranging animals in the field.

TU245
Essential and non-essential chemical elements in the muscles and liver of harbour porpoises (Phocoena phocoena) from the Norwegian coastal waters
T. Ciesielski, Norwegian University of Science and Technology / Biology; J. Kropidłowska, T. Bączek, Medical University of Gdansk; U. Lindstrøm, Institute of Marine Research; B. Jenssen, Norwegian University of Science and Technology / Biology
Anthropogenic activity and the associated industrialization have been often accompanied with pollution of marine environment. Heavy metals and other potentially toxic elements may contribute to adverse health effects of marine mammals. Moreover, concentration of elements in organs and tissues of top marine predators may integrate information about general pollution status of marine waters. The aim of this study was to examine the influence of biological and environmental (seasonal variation) factors and spatial distribution in relation to potential source on the accumulation of elements in liver and muscles of harbour porpoise. Therefore, in 2016 and 2017, 134 by-caught specimens of harbour porpoises (*Phocoena phocoena*) were collected along Norwegian coast. Concentrations of 47 chemical elements were quantified by ICP-MS. In comparison to other areas, relatively low concentrations of hazardous elements were found in the muscles and livers of Norwegian porpoises. Increasing levels of Cd and As determined in populations from northern part of Norway could be related to their distinct feeding preferences. For Hg concentrations, there were significant relationships with Ag and Li in hepatic and muscle tissue, whereas Se was strongly correlated ($p < 0.001$) with most of toxic elements such as Ag, Cd, Hg, Pb, Sn. For Cu, statistically significant negative relationships with Ag and Cd were probably related to competitive binding to metallothionein. The body length was found to be significantly ($p < 0.001$) related to Ag, Au, Bi, Cd, Ce, Co, Cs, Hg, Mo, Nd, Pb, Pr, Sb, Se, Sm, Sn, V, Zr, whereas Ca and Cu revealed negative significant relations to body length. Au, Ag, As, Cu Ba, Cs in liver and Ti, Cu, Sb, Rb in muscle was higher in females than males, whereas males had higher content

of Se and Ni in liver and Sn in muscle. Hepatic tissue generally had higher elemental concentration than muscle, with exceptions for Al, Cr, Cs, K, Mg and Ni. The results on spatial differences indicate northward increasing abundance of Cd and As in harbour porpoises along the coast of Norway. For several elements there were also seasonal differences between spring and autumn, however the reason for this is yet to be explained.

DNA double strand breaks and chemical elements in incubating female common eiders (Somateria mollissima) in Christiansø, Denmark

B. Noori, NTNU The Norwegian University of Science and Technology / Biology; C. Sonne, Aarhus University AU Arctic Research Centre / Department of Bioscience; S. Garbus, Aarhus University AU Arctic Research Centre / bioscience; P. Lyng, Aarhus University AU Arctic Research Centre / Biosciences; A. Krokje, NTNU The Norwegian University of Science and Technology / Biology

Genotoxic agents are ubiquitous in the Baltic Sea and may cause effects not only at a molecular level but at an individual and population level as well. Fasting during reproduction may lead to a state of oxidative stress and enhance the genotoxicity of non-essential elements due to low levels of essential elements and nutrients. Therefore genotoxic agents pose a threat to fasting species. The present study aimed to assess DNA double strand breaks (DNA DSBs) in relation to body mass and non-essential elements in blood of female common eiders (Somateria mollissima) in the Southern Baltic Sea (Christiansø, Denmark) at the beginning (day 5) and end (day 25) of incubation. Furthermore, the present study aimed to investigate the relationships between non-essential and essential elements in whole blood of female common eiders (*Somateria mollissima*) on day 5 and day 25 of incubation. This was a unique study because each incubating eider was sampled twice and therefore acted as its own control. The present study analyzed DNA DSBs using gel electrophoresis to quantify DNA-fraction, of total DNA, that migrated into the gel (DNA-FTM). During incubation DNA-FTM increased significantly throughout incubation (0.4 -70 %). Body mass decreased significantly (17 - 44 %) throughout incubation. Significantly increasing levels of Cd were associated with decreasing levels of Ca and Zn and increasing levels of Cu, which may demonstrate an increase in absorption of Cd from day 5 to day 25 of incubation. Increasing levels of Pb were significantly correlated with decreasing levels of Ca, which may indicate Pb was released from medullary bone during incubation. As and Hg were not found to significantly increase. Hg was found to be positively and significantly correlated with Se, suggesting a protective effect of Se on Hg. DNA-FTM was found to be negatively and significantly correlated to body mass and positively correlated to Hg (not significantly). Given the high levels of DNA DSBs in the current study compared to previous studies in Baltic Sea eiders, there may be other factors at play, apart from non-essential elements, causing DNA DSBs. However, the high levels of DNA DSBs and body mass loss may reflect the overall health of this endangered population, which is exposed to multiple stressors.

TU247

Toxic metals and rare earth elements in blood of red-necked nightjars (Caprimulgus ruficollis) inhabiting differently polluted environments

S. Espín, University of Murcia / Toxicology and Risk Assessment Group/IMIB-Arrixaca; P. Sánchez Virosta, University of Murcia / Toxicology and Risk Assessment Group, Department of Health Sciences, IMIB-Arrixaca, Faculty of Veterinary; J. Zamora Marín, University of Murcia / Department of Zoology and Physical Anthropology, Faculty of Biology; M. León Ortega, University of Murcia / Department of Ecology and Hydrology, Faculty of Biology; P. Jiménez, University of Murcia / Toxicology and Risk Assessment Group, Department of Health Sciences, IMIB-Arrixaca, Faculty of Veterinary; A. Zamora López, University of Murcia / Department of Zoology and Physical Anthropology, Faculty of Biology; M. Camacho, M. Zumbado, O.P. Luzardo, University of Las Palmas de Gran Canaria / Toxicology Unit, Research Institute of Biomedical and Health Sciences; A.J. García-Fernández, University of Murcia / Toxicology and Risk Assessment Group, Department of Health Sciences, IMIB-Arrixaca, Faculty of Veterinary

Toxic metals have been widely reported in avian tissues due to their well-known accumulation capacity and the adverse effects they cause in vertebrates. However, further research evaluating metal exposure is required to assess spatial and temporal trends and fill the knowledge gap for some species such as the red-necked nightjar (*Caprimulgus ruficollis*), from which, to the best of our knowledge, no data exist. In addition, rare earth elements (REE) and other minor elements (ME) are becoming increasingly important due to their use in modern technology, but data on exposure and effects have been rarely reported, with no studies in wildlife. This study reports concentrations of 50 elements (i.e. trace elements, ATSDR's list toxic elements, REE and ME measured by ICP-MS) in whole blood of red-necked nightjars inhabiting three different scenarios of contaminant exposure (agricultural/urban area, n=15; ancient mine site, n=17; and control area, n=16; in south-eastern Spain). Levels of the essential elements Se and Mo were higher in nightjars inhabiting the control and the agricultural-urban areas compared to the ancient mine site. However, birds inhabiting the mining area showed higher concentrations of the toxic elements As, Pb and Cd, and lower hematocrit level. Decreased Se levels in the mining area may be related to its protective role against metal toxicity. Several essential elements (Fe, Zn, Cu, Se, Mn, Mo, Cr, Co, Ni) were positively correlated with different toxic metals (e.g. As, Cd, Hg, Pb, Ba, Sr, V), REE (e.g. Ce, Ga, La, Nd, Y) and ME (e.g. Ti). Hematocrit was negatively correlated with Pb, Cd and Sr; moreover, Pb and Cd concentrations were similar to or higher than levels reported as causing adverse effects on the antioxidant system in other avian species, suggesting that nightjars in the ancient mine site may be suffering from biochemical effects related to toxic metal exposure. Even though most REE and ME concentrations were close to the LOQ, some of these emerging contaminants may trigger sub-lethal effects that, together with the ATSDR's list toxic elements, will be evaluated in a future study.

TU248

Blood concentrations of toxic metals and rare earth elements from E-waste in nestling Eagle owls

P. Sánchez Virosta, University of Turku / Biology; M. León Ortega, University of Murcia / Department of Ecology and Hydrology, Faculty of Biology; M. Camacho, M. Zumbado, University of Las Palmas de Gran Canaria / Toxicology Unit, Research Institute of Biomedical and Health Sciences; J.F. Calvo, University of Murcia / Department of Ecology and Hydrology, Faculty of Biology; O.P. Luzardo, University of Las Palmas de Gran Canaria / Toxicology Unit, Research Institute of Biomedical and Health Sciences; A.J. García-Fernández, S. Espin, University of Murcia / Toxicology and Risk Assessment Group, Department of Health Sciences, IMIB-Arrixaca, Faculty of Veterinary

Toxic metals accumulate in the organism and their adverse effects in vertebrates are well documented. However, rare earth elements (REE) and other minor elements (ME) increasingly used in technological and electronic devices have been rarely reported, with no studies in wildlife. This study reports for the first time blood concentrations of 50 elements, including essential trace elements (Fe, Zn, Cu, Se, Mn, Mo, Cr, Co, Ni), ATSDR's list toxic elements (Ag, Al, As, Ba, Be, Cd, Hg, Pb, Pd, Sb, Sn, Sr, Th, Tl, U, V), REE (Ce, Dy, Er, Eu, Ga, Gd, Ho, In, La, Lu, Nb, Nd, Pr, Sm, Ta, Tb, Tm, Y, Yb) and ME (Au, Bi, Os, Pt, Ru, Ti) measured by ICP-MS in nestling Eagle owls (*Bubo bubo*) inhabiting three different scenarios of contaminant exposure (agricultural/rural area, n=50; industrial area, n=14 and ancient mine site, n=23; SE Spain). Some essential element concentrations (Zn, Se, Mn, Co, Ni) were higher in nestlings inhabiting the agricultural/rural area. Nestlings showed higher concentrations for some ATSDR's list toxic metal (As, Hg, Pb, Th, Tl), REE and ME (Ta, Os) in the ancient mine site. Hg and Pb are known to alter the metabolism and function of essential elements, which could explain the negative correlations found (Hg-Fe, Hg-Mn, Hg-hematocrit and Pb-Co) in the mining area. A previous study showed that Pb, Cd and Hg at similar exposure level disrupted antioxidant molecules in this species. This study shows that, in addition to the classical toxic elements, Eagle owls are exposed to other ATSDR's list elements, ME and REE, the latter included as new and emerging contaminants by international organizations. Toxic effects of long-term exposure to environmentally relevant levels of such substances are poorly documented and should be evaluated in future studies.

TU249

Bird feces as indicators of metal pollution

T. Eeva, University of Turku / Department of Biology; N. Raivikko, University of Eastern Finland; S. Espín, University of Murcia / Toxicology and Risk Assessment Group/IMIB-Arrixaca; P. Sánchez Virosta, University of Turku / Biology; M. Rainio, University of Turku / Department of Biology; J. Sorvari, University of Eastern Finland

Non-invasive sampling methods are urgently needed for ecotoxicological field studies. Birds have turned out to be good biomonitors and bird feces have been used as a proxy for measuring dietary metal exposure levels in wild populations. Collecting and analyzing feces from nestlings is an easy and cost-effective way of getting information on individual dietary exposure. However, what can be concluded on fecal levels is not always clear and there are several potential methodological pitfalls. We have started a series of studies aiming to improve the reliability and repeatability of fecal metal measurements. One of our aims is to reveal the most important levels of variation: temporal variation within individual, among-siblings within brood, among broods/spatial variation. One source of variation is dual composition of bird droppings, which consist of white uric acid and darker feces. We collected fresh fecal samples from pied flycatcher (*Ficedula hypoleuca*) nestlings living in a metal polluted area and separated uric acid from feces in order to explore how metal levels (As, Cd, Co, Cu, Ni, Pb) vary between the two matrices. We found that, for all the metals, the levels (d.w.) in the fecal part was more than double of that in the uric acid, more than 2/3 of the total metal load being found in the fecal part. Since the mass proportion of uric acid in the bird droppings varied a lot among samples (mean±SD: 39%±16.9; d.w.), standardizing sampling e.g. by collecting only the fecal part would markedly reduce the variation due to composition. Alternatively, uric acid part can be used as a biomonitor of internally circulated bioavailable metal.

TU250
Lead exposure in Common shelduck (Tadorna tadorna): tracking the success of the Pb shot ban for hunting in wetlands
I. Valverde, Universidad de Murcia / Health Sciences Department - Veterinary Faculty; S. Espín, University of Murcia / Toxicology and Risk Assessment Group, Department of Health Sciences, IMIB-Arrixaca, Faculty of Veterinary; I. Navas, University of Murcia / Health Science Department - IMIB-Arrixaca - Veterinary Faculty; P. María-Mojica, University of Murcia / Health Sciences Department - Toxicology Area - Veterinary Faculty; J. Gil, La-Granja Wildlife Rehabilitation Center / Conselleria de Agricultura, Medio Ambiente, Cambio Climático y Desarrollo Rural; A. Garcia-Fernandez, University of Murcia / Health Sciences Department - IMIB-Arrixaca - Veterinary Faculty
Wetlands have accumulated lead (Pb) shot pellets for years due to hunting activities. Lead poisoning in waterfowl due to ingestion of those shot pellets has been well documented worldwide, which led to the ban of Pb ammunition in Ramsar sites and other protected wetlands in Spain in 2001 (Real Decreto 581/2001). However, these Pb shots may persist in the environment for 30-300 years depending on the soil properties and use, remaining available to water birds for long periods of time. Although some studies have evaluated the incidence of Pb shot ingestion in Common shelducks (*Tadorna tadorna*) by exploring the presence of Pb pellets in the gizzard, to the best of our knowledge, no studies have reported Pb concentrations in tissues of this species inhabiting wetlands affected by intense Pb shot hunting in the past.Our main objective was to assess Pb exposure in Common shelducks fourteen years after the implementation of the Real Decreto 581/2001. For this purpose, this study evaluates the Pb shot ingestion in 25 Common shelducks found dead due to a botulism outbreak in La Albufera Natural Park (Valencia, Spain) in 2015, and reports Pb concentrations in internal tissues. Necropsies revealed the presence of steel pellets in the gizzard of five Common shelducks, but no Pb shots were found. The Pb distribution pattern in tissues was bone > kidney > liver > brain > muscle, with Pb concentrations of 778.96±998.64, 122.40±89.18, 92.08±57.65, 17.33±16.46 and 13.32±12.16 ng/g (wet weight), respectively. This study reports for the first time Pb concentrations in internal tissues of Common shelducks in wetlands affected by Pb shot hunting. These concentrations were below those reported in different water bird species inhabiting La Albufera de Valencia before the Pb shot ban. In addition, Pb levels detected were low and below concentrations related to adverse effects in birds.These results suggest that the ban on the use of Pb ammunition over wetlands of international importance has been effective in La Albufera Natural Park. **Acknowledgements**: This study was financed by Fundación Séneca (MASCA-Project 19481/PI/14 and 20031/SF/16).

Modulatory effects of lead (Pb) in chicken macrophages (HD-11) and B-lymphocytes (DT40) in vitro
B. Han, Wageningen University & Research / Dept of Toxicology; D. García-Mendoza, Wageningen University & Research / Toxicology; H.H. van den Berg, N. van den Brink, Wageningen University / Dept of Toxicology
Elevated levels of lead have been found in the environment due to human activities, especially in soil and sediment of historic hunting areas where lead shots were used. Wild birds may ingest spent lead shots by mistake, and after ingestion, lead pellets may dissolve in the intestinal tract and could cause both mortality and various sub-lethal effects, including immunomodulatory effects, for which mechanisms are largely unknown. Once the functions of their immune systems are disturbed by lead exposure, the susceptibility of birds to infections might increase, including avian influenza, which could pose risks not only to birds but also to human populations. To assess the mechanisms leading to immunomodulatory effects of lead, we used two chicken cell lines, chicken macrophage (HD-11) and B-lymphocyte (DT40), as *in vitro* models for different cells of the innate and adaptive immune system in birds respectively. Effects of lead on cell viability were quantified, together with cell membrane integrity, oxidative stress, and several functional endpoints, in both non-activated and activated cells. Cells were activated by poly IC to mimic virus infections, and nitric oxide (NO) production from macrophage, antibody production from B-lymphocytes, proliferation, and expression (qPCR) and secretion of cytokines (ELISA) were the functional endpoints included. Our results indicated that lead was toxic to both cell lines, macrophages being more sensitive. Lead depleted glutathione (GSH) when its *de novo* synthesis by the cells was inhibited, which resulted in increased oxidative stress. NO production in activated macrophages was also increased by lead exposure in a concentration-dependent manner, however, this increase was neutralized by inhibiting the *de novo* synthesis of GSH. The proliferation of both cell lines was also inhibited by lead, especially in non-activated cells. Finally, lead modified the expression of functional immune genes including anti-viral interferons (IFN-α and IFN-β), cytokines (IL-8 and IL-18, etc.) and viral infection related toll-like receptors (TLR3 and TLR7). These results suggest that the adverse effects of lead on the immune system of birds are probably closely related to depletion of GSH, inhibition of proliferation and disruption of cytokines and receptors expressions. However, as the immune system is complex, *in vivo* study will be continued to investigate the long-term and systematic effects of lead exposure on the avian immune system.

Revision of the EFSA Guidance Document on Birds and Mammals (P)

Challenges in selecting avian reproduction endpoints and options for data interpretation and analyses
M. Foudoulakis, Corteva Agriscience, The Agriculture Division of DowDuPont / CPRS; T.B. Fredricks, Bayer CropScience / Global Regulatory Sciences; T. Carro, FMC Agricultural Solutions / Environmental Safety Assessment; J.D. Maul, Syngenta Crop Protection Inc. / Environmental Safety; R. Barfknecht, Bayer AG, Crop Science Division; S. Plautz, BASF / The institute of environmental and human health; P. Valverde-Garcia, Corteva Agriscience The Agriculture Division of DowDuPont; J.R. Wheeler, Shell International; J.W. Green, JohnWGreen-ecostats.com / Data Science and Informatics
Avian reproduction studies are required to assess the risks to wild birds from potential exposure to plant protection products in many regions (e.g. EU, USA). Avian reproduction studies evaluate the reproductive effects of dietary exposure of adult birds [usually bobwhite quail (*Colinus virginianus*) or mallard duck (*Anas platyrhynchos*)]) to a test substance over a twenty week period, usually performed to OECD (1984) and/or OCSPP (2012). All data and calculated indices of the response variables are analysed to determine statistically significant differences amongst treatment groups. While these animal and resource intensive studies have been routinely performed since the late 1970s, due to the complexity of these studies (high number and nature of response parameters), the limited number of treatment levels (typically three), low number of replicates (12-18 pairs), and high number and nature of the variables assessed, careful data interpretation is required. Statistical differences between the concurrent control and treated groups can arise by chance alone, and can appear to be treatment-related. The aim of this research is to illustrate how different approaches can be used to improve the interpretation of standard laboratory studies by providing further context in the data assessment. The concurrent control should be the most relevant group for comparisons to derive effect levels. However, the historical control data (HCD) from the same (and sometimes multiple) laboratory can also be used to assist in the data analysis. This research examines the interpretation of appropriate statistical analysis for avian studies (which statistical tests for which circumstances), the inherent power of comparisons to determine an effect, the importance of the biological relevance (in relation to the magnitude of effect), and how findings can be applied to the overall reproductive performance of a study in a methodical, comprehensive approach that eliminates the reliance on individual parameters.

TU253
Small mammal male body weight and home range
M. Wang, WSC Scientific GmbH / Dept Efate Modelling; J. Hahne, Bayer AG Crop Science Division; M. Ebeling, Bayer AG Crop Science Division / Ecotoxicology - Terrestrial Vertebrates Expert Team
Longterm risk assessments for wild mammals for plant protection products are usually based on the findings in the laboratory rodent studies conducted for toxicological purposes. Often, it is challenging to identify which of the findings would be relevant for the wild mammal population level. For this purpose, the relevant EFSA guidance includes a schematic view on typical phases of the reproductive cycle, which starts with the establishment of a breeding site and mating. In the EFSA scheme, effects on body weight that are observed in e.g. the rat reproduction study are considered potentially relevant for adverse effects on wild mammals in that phase. As this EFSA guidance is currently under revision, we aimed to evaluate the possible relation between male body weight and home range size for male common voles and wood mice, two species which are typically part of the worst case agricultural risk assessment scenarios. Furthermore, the activity range of both species is very different, so that potentially contrasting results could be expected. Our hypothesis was that larger males might be able to establish a larger activity range and then potentially encounter more females for mating. Since there is no pair bonding between males and females in these species, and both sexes mate promiscuously leading often to mixed paternity litters, a larger female encounter rate might be a key factor for male reproductive success. Thus, if the male activity range were positively correlated with male body weight, then effects on male body weight could be more relevant for the population level risk assessment than if there is no correlation. To our knowledge there is no reference on any European rodent species in which a relation of adult male body weight and home range size has been described or from which such a relation could be concluded. We therefore employed data from 5 yet unpublished field radiotracking studies where individual body weight measurements of common voles or wood mice are available as well as home range measurements were described. These studies were conducted in cereal fields in Germany, either during drilling in spring, drilling in autumn, or in developed fields in late spring. On our poster we present the outcome of this analysis, comparing the home range size against the body weight of male common voles and wood mice. Overall, we found no support for the hypothesis that larger males would have larger activity ranges.

TU254
Revised fruit residue per unit dose (RUD) values for use in wildlife risk assessments of plant protection products
J. Hahne, Bayer AG Crop Science Division; J. Schabacker, Rifcon GmbH; M. Foudoulakis, Corteva Agrisciences / RSRA ERS; J. Ludwigs, Rifcon GmbH; R. Murfitt, Syngenta Ltd / Environmental Safety; K. Ristau, BASF SE
The EFSA Guidance Document on the Risk Assessment for Birds and Mammals [EFSA GD, 2009] provides default 'Residue-per-Unit-Dose' (RUD) values, expressed as mg a.s./kg fresh weight, for bird and mammal food items to be used in wildlife risk assessments. Some of these default RUDs e.g. monocot and dicot foliage, are based on large numbers of residue studies provided by the industry. However, the RUDs for other diet items, like fruits, were taken from published literature and comprise only small numbers of trials of unclear relevance for regulatory purposes and current EU agricultural conditions. Therefore, many available industry fruit residue studies conducted for regulatory purposes have been evaluated. For this data compilation, the selection of relevant studies providing fruit residue data was based upon the following criteria: GLP-studies conducted in EU during the last 20 years Trials that have been evaluated and accepted as valid by EU member state authorities Trials with one or more applications are considered For the fruit groups 'grapes' & 'large fruits from orchards' (e.g. apple, pear, citrus): Only trials with 1 application are considered For the fruit groups 'other berries' (e.g. currant, raspberry) & 'gourds' (e.g. cucumber, melon)': Studies with one or more than one application are considered and the residue values after the last application taken for the evaluation. Regarding the residue level, this represents a conservative approach (and otherwise values would be based on only a limited number of field trials for these fruit groups) The residue dataset was analysed in terms of the relationship between residue level and application rate. In order to successfully apply the RUD concept given in the current EFSA GD, there should be a linear relationship between the application rate and the resulting residues. The database was then analysed in terms of other 'residue groups' to identify possible differences in residue levels (e.g. depending on fruit size, shape) or differences between regulatory zones. The large dataset of ≥100 residue trials per 'fruit group' revealed significantly lower RUDs compared to the default RUDs given in the current EFSA GD. The authors will present a new proposed default RUD data set for fruits, including some alternative fruit groupings, as diet for birds and mammals that should be considered in the ongoing revision of the EFSA GD. \n

TU255
Comparison of approaches and tool for the determination of time weighted average concentrations using the moving time window approach
A. Guckland, WSC Scientific GmbH; M. Wang, WSC Scientific GmbH / Dept Efate Modelling
The long-term risk assessment for birds and mammals can be refined considering the substance specific foliar degradation (DT_{50}) and thus, a refined time-weighted average residue concentration. For multiple applications EFSA (2009) proposed to apply the moving time window approach to identify an appropriate MAF × TWA factor. This approach is described in detail in Appendix H of the bird and mammal guidance (EFSA, 2009). Recently, several tools have been developed to facilitate the calculation of the MAF × TWA factor using the moving time window approach. However, existing tools differ regarding their results. In order to facilitate a uniform risk assessment for birds and mammals, differences in the way of calculation and possible deviations from the guidance are identified and an alternative calculation is proposed.

TU256
TREC: Refinement of ecotoxicological risk assessment with a moving time window TWA calculator
A. Weyers, Bayer AG - Crop Science Division / EnSa. Ecotoxicology; M. Ebeling, Bayer AG Crop Science Division / Ecotoxicology - Terrestrial Vertebrates Expert Team; P. Neumann, Bayer Ag; L. Vrbka, Bayer AG Crop Science Division
Risk assessment for bird and wild mammals is an integral component of the registration process for plant protection products. In the relevant EFSA guidance document (2009), default values are provided for two parameters relevant for the assessment: MAF (multiple application factor, to account for residue build-up from repeated applications); and 21 day (21-d) f_{TWA} (time weighted average factor, to account for residue dissipation over 3 weeks as default averaging interval). These default MAF and 21-d f_{TWA} values are based on a conservative default DT_{50} values (e.g. 10 days for leaves). The EFSA GD also allows refined calculations of MAF and 21-d f_{TWA} based on more specific DT_{50} values, *e.g.*, from residue dissipation trials. These refined calculations must employ a moving time window approach for 21-d f_{TWA} values. This poster describes the mathematical background and methodology of TREC, the time-weighted average residue calculator developed by the Crop Science division of Bayer for the refinement of risk assessment. Even though the main area of use of TREC is the bird and wild mammal risk assessment, it can be used in any other area of risk assessment requiring calculation of peak exposure or TWA values based on supported kinetic models. The main features of the TWA calculator TREC (implemented as macro-enabled Excel spreadsheet) are: - Full flexibility in definition of the application sequence (e.g. varying application rates and intervals) - Flexibility in the definition of assessment settings (e.g. duration of TWA interval) - Support for various kinetic models - single first order (SFO), hockey stick (HS), double first order in parallel (DFOP), and first order multiple compartments (FOMC) - Possibility to explicitly describe formation of a metabolite from parent - Batch mode for evaluation of multiple trials at once

Fate and Effects of Metals: Advances in Metals Risk Assessment and Regulatory Guidance (P)

Free indium concentration measured with AGNES: speciation in solution, lability of complexes and dissolution of nanoparticles
J. Galceran, Universitat de Lleida / Dep Quimica; P. Pla-Vilanova, M. Heidarkhan Tehrani, A. Dago, E. Companys, J. Puy, Universitat de Lleida and AGROTECNIO / Dep Quimica; E. Rotureau, CNRS UMR 7360 / Laboratoire interdisciplinaire des environnements continentaux LIEC CNRS UMR; J.P. Pinheiro, Universite de Lorraine / LIECENSG UMR CNRS
Free metal ion concentrations play a key role in ecotoxicological paradigms such as the Free Ion Activity Model (FIAM) or the Biotic Ligand Model (BLM). Free concentrations of Zn, Cd and Pb have been determined with the electroanalytical technique AGNES (Absence of Gradients and Nernstian Equilibrium Stripping)[1-2] in a wide variety of matrices ranging from river water to wine or soil extracts. Other amalgamating elements with negative standard redox potential (such as In, Sb, Sn, Cu, Ga or Tl) are candidates to be analyzed with the same technique. A new AGNES methodology has been implemented for the measurement of free indium, for both, the traditional Hanging Mercury Electrode [3] and the Thin Mercury Film/Rotating Disk Electrode [4]. Speciation of indium in solutions with oxalate and nitrilotriacetic acid indicates that current stability constants in NIST database are not very accurate. The determination of the lability degree of complexes with an ancillary electroanalytical technique allows to optimize the deposition times. AGNES can also be applied to dispersions without any previous separation of the solid or colloidal phases, so it is suitable for providing relevant information about the behaviour of nanoparticles and other colloidal matter, avoiding usual artefacts that can impact on other analytical techniques. The complexation of indium to humic acid has also been studied. The analysis of dispersions of In_2O_3 nanoparticles in background electrolyte and in synthetic seawater will be compared with bulk speciation in contact with solid $In(OH)_3$. The characteristics of the slow dissolution will be discussed. References: 1. Galceran, J., *et al.*, AGNES: a new electroanalytical technique for measuring free metal ion concentration. TU258
Zn availability measured by different analytical techniques
J. Galceran, Universitat de Lleida / Dep Quimica; E. Companys, J. Puy, M. Sedo, Universitat de Lleida and AGROTECNIO / Dep Quimica; R. Vera, University of Girona / Chemistry; E. Antico, C. Fontas, University of Girona / Department of Chemistry
There is a growing interest in the knowledge of how different chemical species impact on the availability of a given metal. The key role of the free metal concentration is usually highlighted, but the dissociation from complexes (e.g. complexes with particulate matter such as humic acids) or their direct internalization into the roots can also contribute to the uptake from soil. To assess metal speciation, many analytical techniques have been developed, such as those based on passive sampling. The aim of the present work is to apply and compare four techniques to the same Hoagland growth hydroponic media at different concentrations of ligand (EDTA or humic acid) to measure Zn availability. The determination of the free fraction has been performed with AGNES (Absence of Gradients and Nernstian Equilibrium Stripping) [1] and PIM (Polymer Inclusion Membranes) [2] techniques. Labile fractions have been followed with DGT (Diffusive Gradients in Thin films) [3] and LASV (Anodic Stripping Voltammetry with Linear stripping) [4]. PIM and DGT are passive sampling techniques. The information provided by the different techniques will be presented as well as the correlations between the obtained results. A methodology developed for DGT [5], based on the splitting of the flux into a contribution from the free metal ion and another contribution from the complexes, has been applied to interpret fluxes from dynamic techniques, allowing also the determination of the lability degree of the complexes [5]. HBM (Human Biomonitoring): a tool of environmental toxicology for public health
J. Gonzalez, ISCIII / CNSA; M.G. Motas, CNSA ISCIII / CNSA; E. Prieto, M. Lucena, J. Ramos, A. Castaño, ISCIII / CNSA; S. Pedraza – Díaz, ISCIII; M. Rosado, S. Gomez, ISCIII / CNSA; S. Gónzalez, ISCIII; C. Grande, H. Garcia, M. Esteban, ISCIII / CNSA
Human Biomonitoring is a proven useful tool to assess the exposure to environmental pollutants in general population and a valuable support for improving the development of environmental and health policies to improve the quality of life and the health of citizens. Furthermore, HBM can be apply in the study and follow up at individual level when high exposures are detected. The Spanish Ministry for Food, Agriculture and the Environment funded an HBM program to enhance the understanding of the distribution of priority environmental pollutants in Spain in order to establish reference values for selected heavy metals, persistent organic pollutants and cotinine in the first stage (2007–2010). In order to broaden the knowledge in adolescent population, in 2015 was launched the study BEA (Biomonitoring in adolescents). This is a cross sectional study nationwide in high schools of 10 urban locations. Samples of urine, blood and hair were collected from 500 volunteers of 14-16y. An epidemiological questionnaire to collect basic data, socioeconomic, diet and lifestyles information were completed by the time of sampling. The study was carried out in parallel with that developed by other European countries in the framework of the european project HBM4EU. The work presented is focused on two cases from Huelva and Albacete (7.05 and 13.9 μg/L respectively) that had urinary mercury concentrations above the HBM I-II values defined the German HBM Commission (7 μg/L). Volunteers showing hair mercury levels above the national average were also contacted. The total mercury level of these cases ranged from 5.26 to 7.9 μg Hg/g hair and 71% of them were from Huelva. After the reanalysis of these samples, volunteers were contacted to arrange a new sampling to follow up the levels.A fieldwork team visit the home of the adolescents and collected a new batch of samples including samples from members of the family and performed an exhaustive interview to identify exposure sources of mercury at home. During the home visits and interviews the parents provided greater strength in the answers related to diet, which helped to clarify exposure sources identified in the questionnaires, which were confirmed and additional new ones were identified. The extension of the study at individual level allowed to give specific advices to the volunteers and families to reduce their exposure to mercury. A follow up after receiving the advices is planned to verify the effectiveness of the intervention.

TU260
Delineating sources of mercury and trace metals using epiphytic lichens in Nova Scotia, Canada
S. Klapstein, Acadia University / Earth & Environmental Science; R. Cameron, Nova Scotia Provincial Government / Department of Enviroment; A. Walker, Acadia University / Biology department; J. Murimboh, Acadia University / Chemistry; C. Hallett Saunders, Acadia University / Biology department; N. O'Driscoll, Acadia University / Department of Earth and Enviromental Science
Mercury is a persistent pollutant present in all ecosystems. The prevalence and speciation of mercury will determine its movement in the atmosphere and potential to bioaccumulate and biomagnify through food webs. Monitoring of mercury and other trace metals can be costly, whereas the use of naturally occurring epiphytic lichens can be an effective tool for these types of studies. Nova Scotia, Canada is a hotspot for mercury and other trace metal accumulation in ecosystems, partially attributed to long-range transport of anthropogenic air pollution. The region also contains a number of historic gold mining sites that are known to have persistent high levels of mercury and arsenic in sediment. The relative contribution of local and national sources of mercury to local air is unknown. This work aimed to address which elements can be effectively monitored using lichens. Trace metals in lichens other than mercury may also help elucidate the potential sources of these elements: whether from geological, re-emission, or long-range transport. Almost 200 lichen (*Usnea* spp.) samples were collected across Nova Scotia and analyzed for total mercury (THg); a subset of these samples was analyzed for other trace metals, including arsenic, nickel, copper, cadmium, lead, and selenium (n=95). Significant variation in mercury content was observed across sampling sites and GIS analysis was used to display and model these regional trends. While broad spatial resolution was the initial focus for these collections, a few target areas (biological mercury hotspot Kejimkujik National Park and historic gold mining areas) were sampled more intensively to confirm spatial patterns and if these target areas deviated as expected from background concentrations of mercury and other trace metals. Similar to other monitoring studies of lichens and mosses as bioindicators of mercury deposition, this research provides an excellent baseline for a long-term monitoring program of mercury in Atlantic Canada with ongoing industrial activity and a changing climate. .

TU261
Assessment of air pollution from a shooting range using biomonitors - impacts on physiological and biochemical parameters of lichens
G. Sujetoviene, J. Cesynaite, Vytautas Magnus University
Pollution at shooting range is an issue of growing importance due to accumulation of contaminats derived from ammunition. The aim of the study was to evaluate the changes in buiochemical and physiological parameters and accumulation of heavy metals in the lichens over time transplanted to a shooting range environment. Thalli of the epiphytic lichen *Evernia prunastri* and *Ramalina farinacea* were transplanted from an unpolluted to a shooting range area (central Lithuania). Chlorophyll content, TBARS and the damage to cell membranes in the lichen thalli were determined after 3 month exposure period. The concentrations of some heavy metals (Pb, Cd, Cu) in the biomonitors were used as an indicator of the level of air pollution in the studied area. The accumulated heavy metals in the exposed samples were assessed and the exposed–to–control ratio was calculated in each case. The highest concentrations of heavy metlas were dtermined in thalli near the bern of the shooting range. The presence of pollutants caused the loss of integrity of cell membranes in lichens.

TU262
Mercury in tree bark and lichens at the mining site of Abbadia San Salvatore, Italy: a comparison study
V. Rimondi, University of Florence / Earth Sciences; p. costagliola, University of Florence / Scienze della Terra; R. Benesperi, Università di Firenze / Dipartimento di Biologia; M. Benvenuti, Università di Firenze / Scienze della Terra; M. Beutel, University of California, Merced / Civil and Environmental Engineering; L. Chiarantini, Università di Firenze / Centro di Microscopia Elettronica e Microanalisi (MEMA); P. Lattanzi, Istituto di Geoscienze e Georisorse-CNR
Biomonitoring is often perceived by the public as more reliable than monitoring accomplished by technical devices. Recent literature indicates that tree barks are, in principle, excellent adsorbents of airborne pollutants, including toxic metals. However, tree tissues still have a relatively small niche when compared to other more widely used substrates, such as mosses and, in particular, lichens. The major disadvantages in the use of lichens are the slow regeneration rates, the irregular and patchy distribution, and the relatively weak tolerance to mycophytotoxic pollutants. Advantages of tree barks as biomonitors are that they are generally widely diffused in many environments, and they do not require a particular botanical training to be recognized and sampled in the field. Disadvantages include a general skepticism concerning the adequacy of barks as reliable bioindicators of atmospheric pollution. To compare the concentration of Hg in barks and lichens in a highly polluted area, we collected *Pinus nigra* J.F. Arnold bark samples from 13 sites in the abandoned Mt. Amiata Hg mining district (Southern Tuscany, Italy; see also the abstract of Rimondi et al., this congress, for further details) and lichen samples from the same trees sampled for barks, or at least from a nearby location. Hg concentrations in lichens (0.18 to 3.57 mg/kg) are essentially similar, at the same location, for the three recognized species (*Flavoparmelia caperata* (L.) Hale, *Parmelia saxatilis* (L.) Ach., and *Xanthoria parietina* (L.) Th.Fr.). The concentrations are of the same order of magnitude of those previously reported for other species in the Monte Amiata area (Bargagli et al., 1989; Loppi et al., 1999), and are one order of magnitude lower than in barks at the same location. The two variables are quite well correlated (R^2 for all species = 0.67), especially for *F. caperata* (R^2 = 0.96). This remarkable agreement between barks and *Flavoparmelia caperata* suggests a similar mechanism of Hg uptake. The overall consistency of Hg distribution depicted by bark indicate that *Pinus nigra* barks can be usefully adopted as well as lichens in environmental monitoring programs.

TU263
Residential Spider web samples as possible bio-indicator of heavy metal polluted environment
O. Otitoju, federal University Wukari / Biochemistry Department; L. Jwamrimam, federal University Wukari / Biochemistry
Although spider webs in residential buildings are considered a menace and a possible distortion in the aesthetics values of human environment, there are possibilities that its presence in most residential buildings may be of more benefits than being a pollutant. This study therefore aimed at evaluating the potentials of using cobwebs as possible indicators of heavy metal pollution in residential buildings. Spider web samples were collected from some residential buildings in order to determine the level of trapped heavy metals indoor. These samples were digested in hydrochloric acid and nitric acid before analysis using atomic absorption spectrophotometer (AAS). The result shows that cadmium and lead were present in the cobweb samples while As; Hg and chromium were not present. However, the mean concentration of lead and Cd were found to be significant ($p < 0.05$) when compared with the WHO set standard for residential buildings. Similarly, the concentration of Pb and Cd decreased as the sampling locations were distant away from major roads. The result of this research has shown that spider webs are useful bio-indicator and accumulator of heavy metals

in environment.

TU264
Assessment of Mercury Speciation in Contaminated Tree Bark via Thermal Desorption
M. Beutel, University of California, Merced / Civil and Environmental Engineering; p. costagliola, University of Florence / Scienze della Terra; R. Benesperi, Università di Firenze / Dipartimento di Biologia; M. Benvenuti, University of Florence / Earth Sciences Dept; V. Rimondi, University of Florence / Earth Sciences; P. Lattanzi, Istituto di Geoscienze e Georisorse-CNR; P. Parrini, University of Florence
Tree bark of Black Pine (*Pinus nigra* J.F. Arnold) is being used as a biomonitor of atmospheric mercury (Hg) pollution at the historic Abbadia San Salvatore mining district near Mt. Amiata in Southern Tuscany, Italy. Monitoring has shown extreme concentrations of total Hg in bark (as high as 17 mg/kg dry weight) decreasing exponentially with distance away from ore processing areas. But additional work is underway to better understand the speciation of Hg in bark material. Previous work by our research team using X-ray absorption near-edge structure (XANES) spectroscopy showed that Hg in bark samples was dominated by metacinnabar (β-HgS) and Hg-cysteine complexes; Hg bound to tannic acid and Hg^0 were also detected. This poster presents work using an alternative Hg speciation approach: thermal desorption. Using a Milestone DMA-80 analyzer, samples were heated (~8 minutes) and Hg concentrations were assessed incrementally using the following scheme: (1) 175 ºC = labile Hg including $HgCl_2$; (2) 225 ºC = labile organic Hg including humic bound Hg, methyl Hg, and $(CH_3COO)_2Hg$; (3) 325 ºC = insoluble Hg sulfides; (4) 475 ºC = poorly labile Hg compounds including HgO and $HgSO_4$; and (5) 750 ºC = immobile residual Hg. Methyl Hg bark content was also assessed using a warm nitric acid digestion and analysis of liquid digestant via aqueous ethylation, purge/trap, and cold vapor atomic florescence spectrometry. In addition, Hg speciation in limited lichen samples were also assessed via thermal desorption and nitric acid digestion. Testing, which is ongoing, will yield further insight into how Hg is trapped in tree bark, which in turn will help to inform the role that tree bark can play in the biomonitoring of Hg pollution in the environment.

TU265
Making robust decisions in the face of uncertainty in ecological risk management of zinc in Japanese surface waters
H. Yokomizo, National Institute for Environmental Studies; W. Naito, AIST Tsukuba West / Research Institute of Science for Safety and Sustainability; Y. Tanaka, Sophia University; T.I. Hayashi, National Institute for Environmental Studies; M. Kamo, National Institute of Advanced Industrial Science and Technology AIST Japan
In the ecological risk management, we have to make decisions under many kinds of imperfect information. A framework to make decisions under severe uncertainty is required in chemical management because there are many cases where information about the probability distributions of parameters at the outset is not available. For example, when we set limitations for point sources, there may be an uncertainty on relationship between a chemical concentration in effluent and that in environment, and hence it may be difficult to predict an environmental concentration using the information about effluent. Another example is that the environmental quality criteria are determined to protect the ecosystems, but the criteria may not lead to protect the ecosystems effectively because the ecosystems are complicated. Information-gap decision theory derives the decision that is most robust to uncertainty, by guaranteeing an acceptable outcome under the largest degree of uncertainty. By using information-gap decision theory, we evaluated the best plan to protect the aquatic species against zinc in Kasukawa river as a case study. We have to deal with uncertainties on the following two relationships (1) Environmental concentration and effluent concentration, (2) Adverse effects on the ecosystems and the environmental concentration. We demonstrated the utility of information-gap decision theory in management of pollutant for watershed.

TU266
Bioindication of transport impacts on the forest ecosystem near the main roads
J. Hegrova, V. Jandova, R. Licbinsky, M. Buckova, Transport Research Centre; P. Anděl, Czech University of Life Sciences Prague
Evaluation of the impact of transport on the surrounding environment requires an ecosystem approach and analysing components that provide information about the distribution of the monitored contaminants, and also an estimate of the dynamics of movement and the accumulation of these substances in the environment. As a model ecosystem, a spruce forest with a specific grass and moss undergrowth, located in the area of Bohemian-Moravian Highlands - in an environment which is suitable for a given type of forest, has been chosen. The selected location is located in the immediate vicinity of the highway D1 Prague - Brno in the 103 km highway, before the exposition to Vetrný Jeníkov (in the direction from Prague). This is a locality which is exposed to transport contaminants for a long time. As a result of this survey, the following types of samples were analysed: Soil - soil is the primary component of accumulation of toxic substances in the ecosystem. Samples of fallen needles, humus layer, and first mineral layer were analysed in order to evaluate the distribution of concentrations with the depth and dynamics of the movement of the contaminant in the soil profile. Spruce needles (*Picea abies*) - new, 1-year-old, 2-year-old and 3+ old needles were sampled. The importance of spruce needles as bioindicators lies in the ability to trap toxins in the surface wax layer and at the same time to accumulate substances through the root system and their sensitivity to influence of winter maintenance. Grass (*Avenella flexuosa*) was chosen as a as a model of primary source of toxic substances input into the food chain. Moss (*Pleurozium schreberi*) – was sampled as an accumulation indicator, especially of heavy metals from air pollution. Different types of lichen was sampled because of its different type of matrix (mushroom) as accumulating indicator, especially of heavy metals. To assess the range of contamination, samples were taken at a distance of 5 m from the edge of the road, 20 m and 100 m (as a local background). Transport-related elements show a 40% to 60% higher concentration at the site than in the background (100m). This study was focused on the content of platinum group elements especially in the case of 3+ year old needles, moss and lichen specimens, which are naturally considered as bioaccumulators.

TU267
Does a sum of toxic units exceeding 1.0 imply any ecological effects? A field study of metal impacts on river macroinvertebrate and fish assemblages
Y. Iwasaki, National Institute of Advanced Industrial Science and Technology AIST Japan / Research Institute of Science for Safety and Sustainability; H. Namba, Yokohama national university; K. Morita, Japan Fisheries Research and Education Agency; T. Ogino, Hokkaido Research Organization; H. Mano, National Institute of Advanced Industrial Science and Technology (AIST) Japan / Research Institute of Science for Safety and Sustainability; N. Shinohara, National Institute of Advanced Industrial Science and Technology; H. Matsuda, Yokohama national university; M. Kamo, National Institute of Advanced Industrial Science and Technology
Toxic unit approach based on environmental quality benchmarks (EQBs) such water quality standards and criteria has been used to investigate the quantitative relationship between exposure of chemical mixtures and biological metrics and infer whether there is any ecological risk of concern. Although EQBs are typically conservative (Chapman 2018), it is not conclusive if a sum of toxic units (STU) exceeding one imply any ield effects of concern. To test this question, we conducted a field study in a river receiving a treated mine discharge and a nearby reference river, located northern Japan. At a total of 9 sites including 4 reference ones, we measured several water quality parameters including dissolved concentrations of metals and investigated taxon richness and abundance of macroinvertebrates and fishes. The concentrations of metals (Cu, Zn, Pb, and Cd) at contaminated sites were generally higher than those at reference sites. The STU values based on USEPA water quality criteria (chronic) exceeded 1 at contaminated sites but not at most reference sites. Detailed results on fish and macroinvertebrate metrics are discussed in the presentation.

TU268
The effects of nickel on the structure and functioning of a freshwater plankton community under high dissolved organic carbon conditions: a microcosm experiment
C. Nys, Arche consulting / Laboratory for Environmental Toxicology and Aquatic Ecology GhEnToxLab unit; T. Van Regenmortel, Ghent University; K.A. De Schamphelaere, Ghent University / Department of Applied Ecology and Environmental Biology
European environmental risk assessments and environmental quality standard derivation for Ni are currently bioavailability-based. The underlying assumption of this approach is that the bioavailability-based EQS or PNEC derivation, with its associated hazardous concentrations for x% of the species (HCx), is protective for the effects of Ni on natural aquatic communities. In the present study, we aimed to test this assumption by exposing a natural plankton-dominated community to three constant Ni concentrations (a control [no Ni added], and the bioavailability-normalized HC5 and HC50) during a 56d-microcosm experiment under high DOC conditions (dissolved organic carbon 14 mg/L), high pH (pH 8 at test initiation) and low hardness (43 mg CaCO3/L). The protectiveness of the bioavailability-normalised HC5 was evaluated by investigating the effects of Ni on community structure (individual plankton species abundances and community composition) and on community functioning (measured as indirect physicochemical proxies for overnight respiration and carbon fluxes). At the bioavailability-normalised HC5, only short-term effects were observed for two plankton species (i.e. the rotifer '*Trichocerca* group *similis'* and the cyanobacteria *Oscillatoria sp. 1)*, which represent 5% of the species for which the statistical power was high enough to detect significant effects. Community structure and functioning were not significantly affected at the HC5. In contrast, the bioavailability-normalised HC50-treatment had clear effects on both the structure and functioning of the investigated plankton-dominated aquatic community. Yet, long-term effects (i.e. effects occurring over the entire exposure period) of HC50 were only observed for phytoplankton related endpoints. In addition, most of the indirect effects occurring in the plankton community were driven by the direct effect of Ni on the cyanobacteria *Oscillatoria sp. 1*, which was the dominating species in the control microcosms. The long-term No-Observable Effect Concentration for the

investigated community was the Ni HC5, while the long-term Lowest-Observable Effect Concentration was the Ni HC50. Since no long-term effects of Ni were observed at the bioavailability-normalised HC5, our study supports the protectiveness of the bioavailability-based HC5 at high DOC as derived with the bioavailability-normalization procedure that is currently implemented in European legislative frameworks.

TU269

How common carp (Cyprinus carpio) avoid oxidative stress during an exposure to a sublethal tertiary (Cu, Cd and Zn) mixture

M. Pillet, University of Antwerp / Department of Biology (SPHERE Research Group); G. Castaldo, S. DeWeggheleire, University of Antwerp / Biology; L. Bervoets, R. Blust, G. De Boeck, University of Antwerp / Department of Biology (SPHERE Research Group)

Aquatic environments are subjected to numerous anthropogenic stressors that are much more diverse and variable than those tested in laboratory conditions. So it is important to analyse the effects of metal mixtures to obtain a realistic understanding of the impact of pollution in such natural ecosystems. The impact of a one-week exposure to metal mixture containing copper (Cu), cadmium (Cd) and zinc (Zn) was evaluated in the common carp *Cyprinus carpio*. The concentrations of metals used in this study represent 10% of the 96 h LC_{50} of each single metal exposure (Cu = 4.8 $\mu g.L^{-1}$; Cd = 2.9 $\mu g.L^{-1}$ and Zn = 206.8 $\mu g.L^{-1}$). To evaluate the impact of mixture stress at different levels of oxidative processes and to apprehend their time course within one-week exposure, indicators of oxidative stress (malondialdehyde [MDA] level and xanthine oxidase [XO] activity), as well as activities and gene expression of key enzymes involved in antioxidant defense (superoxide dismutase [SOD], catalase [CAT], glutathione peroxidase [GPx], glutathione reductase [GR] and glutathione-S-transferase [GST]) were measured in gills and liver of *C. carpio*. In addition, the total antioxidative capacity (TAC) was quantified. No sign of oxidative stress was observed during the experiment, but CAT, GPx, GR and GST activities were significantly reduced in the liver after 7 days of exposure. This suggests a potential decrease of glutathione levels and risk of increased free radicals in case of longer exposure. In the gills, there were no major changes in the TAC or in the activities of antioxidant enzymes but the relative expression of the genes coding for CAT and GR were triggered, suggesting an effect on the transcription processes. These results prove the high tolerance of *C. carpio* to these levels of metal pollution, at least in this short-term exposure.

TU270

Toxicogenomic analysis of zebrafish responses to complex environmental metal mixtures

S. Asnake, C. Modig, H. Berg, Orebro University / The Life Science Center; V. Sjöberg, MTM Research centre Örebro University / MTM Research Center; J. Jass, Orebro University / SCHOOL OF SCIENCE AND TECHNOLOGY; P. Olsson, Orebro University / The Life Science Center-Biology

The increased use of metals in different applications has become a global environmental health concern. This has led to an urgent need to improve the tools to determine the effects and consequences of exposure to different metals, alone or in combinations. Environmental risk assessment is often based on, chemically measured, total metal levels without considering bioavailability, speciation or matrix effects. As most of the metals released into the environment eventually end up in water, aquatic organisms are at a higher risk of exposure to these metals. In the present study, we exposed zebrafish from 0 days post fertilization (dpf) to 5 dpf, from 0 dpf to 8 dpf and from 15 dpf to 21 dpf to water collected from different Swedish mining sites to study survival, hatching and gene expression patterns. As an indicator of physiological responses the expression of genes representing toxicity, reproduction, cancer and immune system responses were analyzed. The qRT-PCR analysis were conducted by using 3 different controls, a site specific control (upstream from each site), an general environmental control (a clean site) and a laboratory control (zebrafish aquarium water) to determine the influence of control selection on the outcome of environmental risk assessments. The results showed that gene expression analysis was more sensitive than the determination of physiological endpoints. In order to obtain results that are relevant from a site-specific point-of view it is important to include controls from the studied environment as this minimizes differences in bioavailability, speciation and influence of other abiotic factors. Comparing site specific controls to the laboratory control and the general environmental control, indicate that the use of general controls will result in effects that are not related to the exposure conditions. Thus, site specific analysis should be included when performing environmental risk assessment. In addition, this study supports the use of toxicogenomic analysis to correlate exposure to effect and thus should be of great value in environmental risk assessments. Keywords: Metal, gene expression, site specific, environmental risk assessment

TU271

Toxicokinetics of metals in Enchytraeus crypticus: towards an Adverse Outcome Pathway

F. Santos, Department of Biology & CESAM - University of Aveiro / Biology &CESAM; C. van Gestel, Vrije Universiteit Amsterdam / Ecological Science; M. Amorim, Universidade de Aveiro / Department of Biology and CESAM

The Adverse Outcome Pathway (AOP) concept was proposed as a tool for chemical risk assessment in 2010. This framework aims at causal understanding of biological responses on different levels of organismal complexity, from the molecular up to the apical phenotypic or population effect levels. The determination of the molecular initiating events within an AOP is challenging, and depends on various factors, e.g. chemical-biomolecule interactions, exposure concentrations and also on toxicokinetics and toxicodynamics. Assessing toxicokinetics is helps understanding the linkage between external and internal exposure, which in fact is the first step in an AOP, the chemical-biological interaction. The aim of the study is to investigate the toxicokinetics of a number of selected metals using the soil invertebrate *Enchytraeus crypticus* (Oligochaeta, Enchytraeidae). Bioaccumulation tests were performed in which the animals were exposed to soil spiked with $CuCl_2$, $CdCl_2$ and $CrCl_3$. Exposure consisted of 14 days for uptake followed by 14 days in clean soil. During this time, animal and soil samples were collected at several sampling times, following the recommendations of OECD guideline no. 317. The animals were analyzed for Cu, Cd or Cr body concentrations by graphite furnace atomic absorption spectrometry. Body concentrations will be related to total and available metal concentrations in the soil. The results will enable a better understanding of the time point at which the chemical reaches its initial target molecule, helping addressing the question of molecular initiating events, for which the toxicokinetic behavior of a chemical is essential. Currently, chemical analysis of animal, soil and pore-water samples are ongoing, after which data analysis will follow. This is part of a larger project aiming to fill in information at additional levels towards an understanding of the mechanisms and with a strong focus on the time series sampling and observations, a current gap.

Identification of thermal effect on cadmium toxicity toward Daphnia magna

J. Na, J. Song, Korea University; J. Jung, Korea University / Division of Environmental Science & Ecological Engineering

In aquatic environments, organisms are exposed to combinations of stressors and their effects have been demonstrated to be interactive. Considering that elevated temperature (natural stressor) tends to increase metal toxicity (chemical stressor) to aquatic organism, the comprehensive understanding of this interactive effect is particularly important. Therefore, the aim of our study was to identify the thermal effect on cadmium (Cd) toxicity by experimentally evaluating life-history traits of *Daphnia magna* at different conditions of temperature (20 or 25 °C) and Cd concentrations (1.0, 2.5, 5.0, 7.5, 10 µg/L). Our results indicated that chronic Cd toxicity to *D. magna* was higher at 25 °C than at 20 °C, in particular, with increasing of male production. At 25 °C and the highest Cd concentration (10 µg/L), reproduction was 63% lower and sex ratio was 44% higher than those at 20 °C without Cd. Additionally, synergistic effects were found in population growth rate for high Cd concentration groups (7.5 and 10 µg/L) at elevated temperature. Overall, this study suggests the importance of studying interaction among multiple stressors to interpret their adverse effect on aquatic organisms adequately.

TU273

Ecotoxicology of Rare Earth Elements (REE) in continental aquatic systems: biological effects and speciation

N. Lachaux, LIEC Université de Lorraine CNRS / Laboratoire Interdisciplinaire des Environnements Continentaux (LIEC) CNRS UMR; C. Cossu-Leguille, B. Sohm, LIEC Université de Lorraine CNRS; C. Bojic, LIEC CNRS Université de Lorraine; D. Pauly, C. Fouque, LIEC Université de Lorraine CNRS; S. Pain-Devin, Université de Lorraine - UL / LIEC - CNRS - UMR 7360; E. Gross, LIEC Université de Lorraine CNRS; L. Giamberini, Université de Lorraine, CNRS UMR 7360 / LIEC, CNRS

Rare Earth Elements (REE) became essential in high- and green-technology applications. Their increasing production and use have led to the release of anthropogenic REE in the environment, including aquatic systems. However, little is known about the ecotoxicology of REE, particularly in complex systems, preventing the implementation of regulatory thresholds. To understand better the behaviour and biological effects of REE, we conducted acute ecotoxicological assays on several freshwater species belonging to different food web levels: the green microalga *Raphidocelis subcapitata* (ISO 8692, 2012), the crustacean *Daphnia magna* (ISO 6341, 2012) and the fish *Danio rerio* (OCDE 203, 1992). We test three elements representative of the REE group: neodymium (Nd), gadolinium (Gd) and ytterbium (Yb) alone and in mixture. The assays were performed in absence and presence of dissolved organic matter (DOM: 8 mg/L of dissolved organic carbon including 6.8 mg/L fulvic acid). First results show comparable effective concentrations (ECx) for Nd, Gd and Yb, which suggests a similar toxicity pattern among all REE. The presence of DOM tended to decrease the toxicity of REE. These results should be considered in environmental risk assessment.

TU274

Unicellular green algae show great variation to uranium toxicity in boreal freshwaters

E. Vehniäinen, University of Jyvaskyla / Department of Biological and Environmental Science; J. Hellmuth, A.K. Karjalainen, University of Jyvaskyla
Uranium (U) is a naturally occurring element that can be toxic because of its radioactivity and its chemical properties. Due to mining activities it can cause contamination in effluent-receiving freshwaters. There its chemical toxicity is the major cause for concern rather than its radiation toxicity due to its low specific activity, which is a result of the long half-life of U-238. Boreal freshwaters are often rich in dissolved organic material (DOM) that can bind metals such as U, leading to lowered bioavailability. There is limited information on the chemotoxicity of U to algae, especially in boreal freshwaters containing DOM. We studied the effect of U on the 72 h growth of two freshwater algae *Raphidocelis subcapitata* and *Desmodesmus subspicatus* according to a slightly modified standard protocol by ISO 8692, using boreal lake waters with a range of 4---18 mg/l dissolved organic carbon (DOC) as test waters. Whereas the 72 h NOEC value for U in both species was similar in the water with the highest DOC concentration, in other freshwaters *D. subspicatus* was less sensitive to U, with up to ten times higher NOEC values and up to 14 times larger IC_{50} values. In both species, there was a clear trend of diminishing toxicity of U with increasing DOC concentration.

TU275

The effects of Se in Limnodrilus hoffmeisteri and Oreochromis niloticus

H. Chen, Environmental Research Institute, South China Normal University / Environmental Research Institute; J. Zhao, T. Chen, G. Ying, L. Xie, South China Normal University / Environmental Research Institute

Selenium (Se) is beneficial at low levels yet toxic at high levels. The present study assessed the bioaccumulation and effects of different Se species from the dietary exposure route in two aquatic organisms: the oligachate *Limnodrilus hoffmeisteri* and tilapia *Oreochromis niloticus.* The worms were exposed to 2, 5, 20, and 40 μg/g sedimental Se in the form of Se(IV) and Se(VI) for 2 months. The tilapia were exposed to dietary Se in the form of Se(IV) and Se-yeast for 90 d. The accumulation of Se in both species followed a general pattern of organic Se > Se(IV) > Se(VI), indicating a higher risk of organic Se than inorganic Se at the same exposure levels. In the worm experiment, its growth was inhibited at Se(IV) levels higher than 2 μg/g while it was inhibited at Se(VI) higher than 20 μg/g. The subcellular fractionation showed that Se existed predominantly in cell debris for both Se forms. The antioxidant system was affected differently after 2 weeks and 2 months of exposure, indicating adaption of this worm to Se during chronic exposure. In the tilapia experiment, the inhibitory effect of Se on the weight of tilapia was only observed at Se level of 12 μg/g dry wt. The accumulation of Se in various tissues of tilapia (e.g., liver, intestine, brain, muscle) was generally dose dependent. The levels of MDA were more elevated after 45 d of exposure than those after 90 d of exposure, indicating certain degree of adaptation to Se. Transcriptional expression of genes related to immunological function showed that both Se species enhanced the immunological factors at the levels 3, 6, 12 μg/g. The results showed that Se accumulation in the two species from the dietary source differed. Dietary Se showed both beneficial and detrimental effects in aquatic organisms, dependent on Se species and exposure duration.

TU276

Acute toxicity of different toxicants to Freshwater Pearl Mussel juveniles (Margaritifera margaritifera)

T. BELAMY, UMR EPOC 5805 UNIVERSITE BORDEAUX / UMR EPOC CNRS; A. Legeay, Bordeaux University / Ecotoxicology; B. Etcheverria, University of Bordeaux / UMR CNRS 5805 EPOC; M. Baudrimont, Université Bordeaux1 / UMR EPOC 5805

Margaritifera margaritifera is one of the most endangered mollusk species in Europe. The population of this freshwater pearl mussel has been declining since the 20th century due to pearl fishing, alteration of the water quality, habitat degradation, decline of the fish host or pollution. Several programs have been set up in order to preserve this species by restoring habitats and by the application of captive breeding techniques. However, there's a lack of knowledge on the sensitivity of this species to environmental and contamination factors. As part of the European LIFE Project (LIFE 13 NAT/FR/000506) which aims to preserve the most important French population of *Margaritifera margaritifera* (Dronne River – Dordogne), a part of the production from captive breeding facility is used for ecotoxicological studies. This work deals with the acute toxicity of Sodium Chloride (NaCl), Nitrates (NO_3^-), Phosphates (PO_4^{3-}), Cadmium (Cd) and Arsenic (As) to juveniles of this species. Acute toxicity tests were carried out on 10 to 21 months old juveniles in order to assess the toxicity thresholds of those toxicants and to compare the sensibility according to age. First, the experimental protocol has been developed using Sodium Chloride as reference toxicant. After that, the use of a substrate (silicate sand) for experiments has been studied compared to conditions without any as preconized by the American Society for Testing and Materials (ASTM) *Standard guide for conducting laboratory toxicity tests with freshwater mussels*. The toxicity threshold obtained for NaCl reveals a greater sensibility of *M. margaritifera* juveniles than for some other species of freshwater mussels. Also, results showed that juveniles of *M. margaritifera* aged from 10 to 21 months were tolerant to high concentrations of NO_3^-, PO_4^{3-}, Cd and As. Moreover, the comparison of sensibility in function of age reveals that younger juveniles were more sensitive than older individuals. The use of sand for acute toxicity tests has no impact on water quality, toxicants concentrations and results, validating our method of exposure in more realistic conditions for burrowing mussels. This study allowed us to improve our knowledge about this endangered species and showed that ecotoxicological studies could be a complementary approach for helping conservation strategies since it gives us useful data for targeting reintroduction areas.

TU277

Modeling dietary uptake of heavy metals in stream macroinvertebrates of different feeding classes and their food

N. Fuad, K. Turpin-Nagel, T. Vadas, University of Connecticut / Civil and Environmental Engineering

Streams serve a number of vital functions in ecosystems. In developed areas, metals along with other stressors impair these functions. The aquatic life criteria, established by the US-EPA, is one of the current practices of identifying stream quality. However, it lacks representation of a family of organisms-insects. Tools such as biotic ligand model can be used to modify acute concentration for some metals such as Cu. However, dietary uptake of different metals and differences in metal speciation or long-term exposure has always been unaccounted for in established toxicity assays. Hence, to protect stream health in chronic exposure cases, establishing different benchmarks and alternative means of assessment is necessary as opposed to setting daily average contaminant concentration limits. This requires a better understanding of the speciation of metals from different sources and their impact on biouptake. Dietary uptake is known to be an important exposure pathway for macroinvertebrates, differences in uptake and assimilation of metals as a function of the unique source waters in urban stream systems are unknown. This study aimed at modeling the differences in uptake and assimilation from water borne and diet borne pathways for different selected stream organisms representing various feeding classes exposed to various contaminated source water. Uptake of metals into the food, periphyton, was investigated in exposure experiments with ^{63}Cu and ^{65}Cu isotopes rendering ~5 mg/L total copper. Collected stream water, wastewater treatment plant (WWTP) effluent and their mixture was used as sourcewater. To model uptake into the macroinvertebrates, the organisms and their food will be exposed to exposure water reconstituted with concentrated organic matter from the source waters and metal isotopes. Results show uptake rate (6-17 mg $g^{-1}h^{-1}$) into periphyton to be higher for source water with high Cu/DOC. Metal speciation related to higher uptake rates and high percentage of copper weakly bound to OM. The exchangeable fraction was established as the bioavailable fraction by analyzing conditional uptake rate constants. Long exposure experiments show uptake equilibrium after 2 days with a maximum accumulation of 40 mg/g. Switching isotopes after this period is planned to calculate efflux rate. Results from planned experiments are expected to yield relationships between source water metal speciation and OM characteristics and net assimilation into the macroinvertebrates.

TU278

The fate of metal ions in aquatic systems: Implications for environmental hazard assessment of inorganic substances

G. Burton, University of Michigan / School for Environment and Sustainability; P. Huntsman, CanmetMINING, Natural Resources Canada; K.J. Rader, R.F. Carbonaro, Mutch Associates, LLC; H. Waeterschoot, Eurometaux; E.R. Garman, NiPERA / Ecotoxicologist; S. Baken, European Copper Institute

The assessment of long-term environmental hazard of chemicals includes consideration of their environmental fate. This is described in terms of degradability – reflecting the reduced potential for long-term exposure of organic chemicals which are quickly degraded in the environment. While the concept of degradability has limited meaning for metals and inorganic chemicals, the fate of such substances in aquatic systems may equally be affected by natural removal processes which reduce the potential for long-term exposure. Ample laboratory, mesocosm, and field data confirm this for many different metal ions. The relevant processes include binding of metal ions to suspended particles, settling and burial of particle-bound metals, chemical transformations due to ageing reactions or redox changes, and others. Clearly, there is a need for guidance to implement this concept in the hazard classification of metals and inorganic substances. The work presented here describes the development and application of a standardized test method to evaluate the removal of metal ions from aquatic systems. The existing Transformation-Dissolution protocol (OECD 29) was extended with 2 phases: a removal phase, to measure the rate and extent of metal binding to a substrate and subsequent settling, and a resuspension phase, to address the potential for metal remobilization. A small amount of substrate is added to the aquatic test medium to initiate the partitioning and removal processes. The Extended Transformation-Dissolution protocol was successfully applied to several metal ions, including copper, nickel, lead, zinc, cobalt, silver, and strontium. Mechanistic modelling showed that the measured removal rates are mainly determined by metal ion diffusion to settled particles and by the kinetics of metal binding to particles. An evaluation of the sensitivity of the test results to the most important system defaults was performed. Overall, the Extended Transformation-Dissolution Protocol is a promising tool to assess the fate of metal ions under standardized conditions, and could allow recognition of the fate of inorganic substances in environmental hazard assessment.

TU279

Probabilistic risk assessment for freshwater tilapia species exposure to mercury

C. Liao, National Taiwan University / Department of Bioenvironmental Systems Engineering; W. Chen, Kaohsiung Medical University / Department of Biomedical Science and Environmental Biology; Y. Yang, National Taiwan University / Bioenvironmental Systems Engineering

Mercury (Hg) is a highly toxic, globally ubiquitous contaminant that can be seriously damage environment and human health. A growing body of evidence has indicated that inorganic Hg (Hg(II)) and methylmercury (MeHg) exposures have elevated in Taiwan major rivers. Moreover, Hg contamination is highly likely to pose a threat for freshwater fish decline in populations. As a result, Hg exposures are intensively investigated by Environmental Protection Administration of Taiwan (Taiwan EPA) including surface water, sediment, and fish tissue measurements. Here we established the key risk indices—hazardous quotient (HQ) and exceedance risk (ER)—for freshwater tilapia species across geographic ranges of several major rivers in Taiwan based on a probabilistic risk assessment framework. This study took account three tissue burden-specific mortality rates to quantify mortality risks of tilapia exposed to Hg(II) and MeHg. Our results indicated that there was 50% probability for mortality risk of tilapia to exceed ~5% by considering three tissue burdens of gill, liver, and muscle. Noticeably, even if we considered the worst scenario of the highest accumulated internal dose in liver (ER = 0.2, i.e., the risk probability that might be unlikely to occur), mortality rate of tilapia would not exceed 5.4%, indicating low mortality risk for tilapia exposed to Hg(II) and MeHg. We further chose three safety levels to examine the potential hazard to the organisms in aquatic environment, i.e., 0.2, 0.4, and 0.5 $\mu g\ g^{-1}$ ww in whole body of tilapia. Our results indicated that with the stricter safety levels being adopted, the higher hazard would be presenting. In northern region of Taiwan, the median values of HQ in three rivers would be over 1 based on the strictest safety level. Thus, a dramatically high HQ was found in our risk assessment outcomes, implicating that the chronic sublethal risk (e.g., growth, reproduction, development, and behavior) posed by Hg was alarming. We conclude that Hg is likely to pose the potential hazard to aquatic environments constrained by safety levels for aquatic organisms. Our approach opens up new possibilities for predicting future fish population health with the impacts of continued Hg exposure to provide information on which fish are deemed safe for human consumption.

TU280

Use of monitoring data for environmental risk assessment of copper in soil at the European scale

K. Oorts, ARCHE; S. Baken, European Copper Institute; M. Weidenauer, European Union Copper Task Force

The diffuse contamination of soils with copper due to various sources (e.g. sewage sludge, manure, fungicides, releases from brake pads, etc.) can cause a significant accumulation of Cu in soils. A proper risk assessment of Cu in soil not only requires data on Cu concentrations, but also on basic soil physico-chemistry data (pH, organic carbon, clay content effective cation exchange capacity) to predict the bioavailability and hazard of Cu in the specific soils monitored. The spatial variation in metal bioavailability and in exposure concentrations is preferentially considered in risk assessments at the regional scale. Data availability for both aspects differs largely across different countries or regions, hampering a consistent approach on a large (e.g. regional or continental) scale. It is therefore often difficult to compare results for regional risk assessments among different countries when based on national datasets. Fortunately, two European–wide monitoring datasets were developed the last decade. The LUCAS (Land Use/Land Cover Area Frame Survey) project from the European Joint research Centre (JRC) provides data for soil properties and land use for about 20,000 soil samples covering the EU. All data were collected according to harmonized sampling and analysis methodologies. In addition, also the GEMAS (geochemical mapping of agricultural and grazing land soil) project, carried out by the EuroGeoSurveys (EGS) Geochemistry Expert Group in cooperation with Eurometaux, provides exposure data of metals and general soil properties in agricultural and grazing land soil at the European scale, harmonized with respect to the spatial scale (sampling density), analytical methodology and land-use (comparable level of diffuse emissions). The results of both projects allow a consistent hazard and risk characterisation for Cu in soils across Europe and country-specific results can be directly compared. Because all data are geo-referenced, the data also provide a strong basis for considering the spatial variability of both exposure and effect concentrations (through variation in soil properties and bioavailability corrections) in a risk assessment for Cu in soils and therefore avoid the need for (worst-case) assumptions on both aspects. This poster will present and discuss the use of these monitoring data for regional and local risk assessments of copper in soil.

TU281

Integrated environmental impact assessment of old mining activities along the Upper Rhine

L. Giamberini, Université de Lorraine, CNRS UMR 7360 / LIEC, CNRS; Q. Bachelet, Universite de Lorraine / Laboratoire Interdisciplinaire des Environnements Continentaux (LIEC) UMR CNRS 7360; P. Bauda, LIEC - Université de Lorraine - CNRS / LIEC CNRS UMR; C. Bojic, LIEC CNRS UMR Université de Lorraine; S. Devin, LIEC, CNRS UMR 7360, Université de Lorraine / LIEC, CNRS; E.M. Gross, University of Lorraine / Laboratoire Interdisciplinaire des Ecosystemes Continentaux; F. Guérold, University of Lorraine / Laboratoire Interdisciplinaire des Environnements Continentaux, CNRS UMR 7360; D. Pauly, Universite de Lorraine / Laboratoire Interdisciplinaire des Environnements Continentaux (LIEC) UMR CNRS 7360; E. Rotureau, CNRS UMR 7360 / Laboratoire interdisciplinaire des environnements continentaux LIEC CNRS UMR; P. Wagner, V. Robin, Universite de Lorraine / Laboratoire Interdisciplinaire des Environnements Continentaux (LIEC) UMR CNRS 7360

In mining areas, both anthropogenic disturbance of biogeochemical cycles of metallic elements and natural weathering of rock materials rich in these elements could lead to high metal concentrations in the environment. River ecosystems draining old or recent mining areas could present metallic trace element (MTE) concentrations high enough to induce toxic effects to biota. In France (Vosges) and in Germany (Black Forest), mining of silver-bearing mineralization has generated punctual high ETM pollution as arsenic and lead in downstream rivers. In order to assess the potential environmental impact of old mining activities and toxicity of ETM under more environmental realistic conditions, our strategy is to propose an interdisciplinary approach including experimental works and modeling to characterize and assess: The quality of water and sediments from several mining sites The eco-dynamics of metals from mine areas to aquatic ecosystems using passive sensors and living organisms The ecotoxicity of metals on target living organisms and communities (micro-organisms, benthic invertebrates, macrophytes) The potential trophic transfer of ETM in the aquatic food web The effects of ETM on the ecosystem functioning The historical use of wood resources for industrial/mining activities and impacts on forest ecosystem For this integrated environmental approach, we will use pre-existing databases, historical written sources, such as historical management plans and historical maps, phyto-historical indicators from charcoal production sites as well as physicochemical measurements, next generation sequencing technology to describe adapted microbial communities, passive and active biomonitoring with macrophytes and benthic invertebrates and ecotoxicological and functional biomarkers and bioassays. First results of the phyto-historical approach, based on the anthracological analysis of seven charcoal production sites in two different areas indicate that the most used trees were *Fagus* and *Abies*. Other, less present taxa, were *Acer, Betula, Quercus, Sorbus,* and *Pinus*. The radiocarbon datings of the charcoal production sites of one of the two investigated areas show an activity of charcoal production during the 18th century. These first results are coherent with comparable regional data about the history of charcoal production. More analyses are planned on other charcoal production sites and with dendro-anthracological measurements.

TU282

Probabilistic and site-specific risk assessment of heavy metals in Korean Rivers

J. Park, Gwangju Institute of Science and Technology / School of Earth Science and Environmental Engineering; S. Kim, Gwangju Institute of Science & Technology / School of Earth Science and Environmental Engineering; W. Kim, J. Park, J. Kim, J. Yeom, Gwangju Institute of Science and Technology / School of Earth Science and Environmental Engineering

Water regulations for heavy metals in South Korea have been designated for human health (e.g., regulation for the protection of human health) and usages (e.g., regulations for drinking water, agricultural water, and effluent water). However, these regulations are considered to be unsuitable for the protection of aquatic ecosystems because many organisms in water are critically affected by low levels of heavy metals. This study constructed a species sensitivity distribution (SSD) to scientifically derive thresholds for protecting organisms from heavy metals (Cd, Cu, Pb, and Zn) in Korean freshwater. The SSD has been developed by integrating individual toxicity value of various organisms and assigning the proportion among the community or population and has been agreed its scientific relevance with many researchers and jurisdictions. The toxicity values were composed of the acute response of Korean resident species and standard test species, and toxicity variability caused by different water quality was adjusted by hardness conversion. The critical thresholds were derived from predicted no-effect concentrations (PNECs) which only few organisms in the SSD are expected to be significantly affected. The ecological risk of freshwater heavy metals in Korea was investigated by comparing the PNECs derived from resident species and environmental concentrations detected in the four major rivers of Korea. This work was supported by Korea Environmental Industry & Technology Institute (KEITI) through "The Chemical Accident Prevention Technology Development Project", funded by Korea Ministry of Environment (MOE) (No. 2016001970001).

TU283

Risk and biological assessment of heavy metals in the River Aconcagua, Chile

m. del aguila, University of Gothenburg; T. Backhaus, University of Gothenburg / Department of Biological and Environmental Sciences; S. Elgueta, Instituto de

Investigaciones Agropecuarias INIA / Department of Environment and Sustainability; P.A. Inostroza, University of Gothenburg / Department of Biological and Environmental Science
The long-term exposure to heavy metals may reduce natural diversity and change the genetic variability of aquatic organisms. These alterations may end up affecting population fitness and making impacted aquatic organisms more sensitive to new and future stressors. Usually, environmental risk assessment frameworks for heavy metals are based on metal-by-metal assessment, but metals are most often found as complex mixtures in the environment. Chile has the largest copper mining activities in the world and the River Aconcagua is one of the most important rivers in central Chile. Extensive heavy metal data is available for this river; however, little is known about metal mixture ecotoxicity and the effects that this may have on local aquatic populations. This study addressed these knowledge gaps, with the main objective to investigate whether complex metal mixtures affect the biodiversity patterns of freshwater organisms along the River Aconcagua. For this purpose, the metal status of the Aconcagua freshwater ecosystem was described in detail and the biological status of microbial and macroinvertebrates communities along the river was defined using both next-generation sequencing techniques and taxonomic classification. Furthermore, an environmental risk evaluation of metal mixtures under the EU Water Framework Directive using ecotoxicological available information was performed and concentration addition and independent action approaches per each ecological level (algae, invertebrate, and fish) were applied.

TU284
Evaluating the potential of biochar and compost as a growth layer for the cover system of mine tailings in northern Finland
M. Hagner, University of Helsinki; J. Heiskanen, K. Mäkitalo, Natural Resources Institute Finland Luke
Mine tailings represent a source of toxic pollutants, mainly heavy metals, which may spread to the surrounding areas. After ore-extracting activities mine tailings need landscape reclamation to prevent environmental risks. Recyclable organic waste materials e.g. compost and biochar are nowadays progressively used for soil improvement and carbon sequestration in horticulture and landscaping. Recently, biochar and compost have also been suggested to be used in closed mine tailings to enhance their phytostabilization and being a long-term and cost-effective rehabilitation strategy to reduce the risk of pollutant transfer. However, information about the feasibility of those materials as a growth medium layer in mine tailings and their effects on the vegetation restoration, reforestation success and leaching of pollutants is scarce, especially in the boreal climatic conditions. We examined the physical and chemical characteristics of two biochar types (spruce and birch), composted sewage sludge (CSS), tailings soil and forest till soil as well as their effects in varying mixing proportions on plant growth (Scots pine, dark leaved willow, red clover, red fescue and maiden pink) during one growing period in a greenhouse study. In addition, we established the large scale lysimeter study in the Rautuvaara mine tailings site in Kolari commune using three kinds of cover layers: 1) forest till soil, 2) till soil added with CSS (10%) and 3) till soil + CSS (10 %) + biochar (of Norway spruce) (10 %). Effects of various cover layers on i) the properties of leachate water (pH, oxygen content, moisture, redox potential, metal and nutrient concentrations) and ii) vegetation success (growth, covering area, clorofyll content, concentrations of metals and nutrients) will be investigated during two growth periods.

TU285
Evaluation of landfill impacts on mountain rivers
S. Le Faucheur, Institute F.-A. Forel, University of Geneva / Département F.-A. Forel des sciences de lenvironnement et de leau; F. Pierron, Université de Bordeaux / UMR EPOC CNRS 5805; C. Moinecourt, Université de Genève; G. Daffe, Université de Bordeaux / UMR EPOC CNRS 5805; A. Boullemant, RioTinto
Physico-chemical measurements provide limited information in the environmental quality assessment of mountain rivers. Indeed, these systems have high flow rates, often artificially controlled by dams, and river beds with low quantities of coarse sediment. These characteristics make challenging to trace diffuse pollution, such as those represented by waste landfills scattered along rivers. Analysis performed on inhabiting organisms to complement these measures are also known to be rather limited in such environment due their high variability. Here, we examined the usefulness of metal accumulation measurements in bioindicators and effects on model organisms to evaluate the bioavailability of metals released from mineral processing landfills. The two studied rivers situated in the French Alps were sampled up- and downstream of landfills, four times during one year, for water, sediments, biofilms, bryophytes, and fish (*Salmo trutta fario*). Water was analysed for its physico-chemical parameters (pH, concentrations of dissolved organic carbon, anions, cations, metals) whereas metal speciation was calculated using Visual Minteq. Sediments were analysed for their metal concentrations and composition. Metal concentrations were measured in both biofilms and bryophytes (total and intracellular) as well as in fish (in gills, muscle, gonads and liver). Ecotoxicological tests were finally performed on water (algae and daphnids) and sediment (ostracods and plants). Water analysis highlighted seasonal increase of Co, Ni, and As concentrations between the control site and those located downstream the landfills in one of the studied river. That increase was accompanied by an increase of Co, Ni and As accumulation in biofilms and bryophytes as well as of As and Hg in fish tissues. However, no direct correlation could be drawn between the free metal ion concentrations and the metal accumulated in biofilms and bryophytes. For both rivers, no difference in sediment metal concentrations was observed between up- and downstream sites, which could be explained by their sediment composition containing *ca*. 90% of coarse sand and a low percentage of organic matter (0.5 – 2.0%). Ecotoxicological tests did not reveal any effects of the water quality on model organisms but demonstrated degradation of sediment quality. This study is an attempt to provide insights in comparing and reconciling ecotoxicology laboratory tests and field weight of evidences for metals impact assessment.

TU286
Barrage fishponds: fitted to reduce pesticide concentrations in downstream rivers, but ineffective against trace metal pollution
f. le cor, Universite de Lorraine / URAFPA; J. Gaillard, Université de Bordeaux / EPOC UMR 5805; S. Slaby, Universite de Lorraine; C. Feidt, Université de Lorraine UL / URAFPA INRA; D.X. XAVIER, ANSES-LHN; D. Banas, Universite de Lorraine
In France, fish ponds cover up to 3500 km², but because of their small size, they have been little studied and their ecological functioning as well as their impact on water quality are poorly known. Frequently located at the head of watersheds, their impact on water quality is of first importance for the water bodies located downstream and monitored under the Water Framework Directive (WFD). Ponds also represent ecosystems of great interest, both environmentally (biodiversity hotspot) and economically (extensive fish production). Studies carried in our labs show that the impacts of these water bodies, on downstream systems, depend on fishpond management and can be either, punctually a source of contaminants (e.g. during the draining of ponds), or on average, an efficient buffer for pesticides. Our previous study carried on three dam ponds have demonstrated a reduction of pesticide concentration peaks as well as a reduction in potentially deleterious effects for downstream ecosystems. We wanted to evaluate whether these ponds could also be an effective remediation tool for another contaminant monitored under the WFD, namely trace metals. The experimental set-up used to quantify pesticides fluxes on dam ponds also made it possible to follow the annual evolution of the upstream / downstream flows of certain metals of interest. The concentrations of cadmium, lead, zinc and copper were quantified in the dissolved phase upstream and downstream of the studied ponds. For metals, no significant reduction was observed. In two ponds, it is even a trend towards increasing concentrations downstream that is observed and not a decrease, suggesting direct cross-sectional contributions from the watershed (e.g. runoff from adjacent crops), or even intra-pond remobilization. Contrary to what was observed for pesticide flows, fish ponds do not appear to induce retention of trace metals. Given the importance and diversity of sources emitting trace metals (e.g. phosphate fertilizers, metallurgy, military munitions from world wars), it seems difficult to determine a single origin in the sampled surface waters. Ponds play a beneficial buffer role on pesticide pollution, by reducing concentrations in streams, they mitigate the risk of acute and chronic toxicology related to these contaminants, particularly in headwater streams, but they are inefficient regarding trace metal pollution.

TU287
Cost-effective mitigation of lead toxicity in rat using indigenous plant Moringa Oleifera
H. Nakata, S.M. Nakayama, A. Kataba, Hokkaido University; H. Toyomaki, Hokkaido University / Laboratory of Toxicology; R. Doya, Hokkaido University; J. Yabe, The University of Zambia / Veterinary Medicine, Paraclinical Studies; K.M. Muzandu, University of Zambia; G. Zyambo, The University of Zambia; H. Mizukawa, Ehime University; Y. Ikenaka, Hokkaido University; M. Ishizuka, Hokkaido University / Graduate School of Veterinary Medicine
Health and environmental issues caused by lead (Pb) are commonly recognized as a global challenge. Pb possesses particularly elevated anthropogenic enrichment factors which are important for the nation's development especially in developing countries. To enjoy the economic benefit given by industrial activities to the fullest extent, it is needed to establish a cost-effective technique to mitigate pollution and poisoning towards the practical use in developing countries. *Moringa Oleifera* (MO) is a multipurpose plant widely distributed in many countries of the tropic and subtropics. Previous researches suggested that the leaves and seeds of MO have a potential to mitigate Pb toxicity on rats. Similarly, it is commonly recognized that the seed of MO can be useful for the removal of metals from polluted water due to its coagulating properties. From above, MO is considered as the potential plants for both medical use for human and remediation purpose of environmental contamination. Given these backgrounds, the current study aims to evaluate the mitigative effect of MO on Pb poisoning in rat. All animal experiments were carried out under the supervision and with the approval of the Institutional Animal Care and Use Committee of Hokkaido University (approval No. 18-0042). Fifty male SD rats were divided into eight groups (N=7 for group A and B, N=6 for group C to H). 1,000 mg/L of Pb acetate were given to all groups other than group A in the drinking water for 3 weeks. The control

group A were provided with distilled water. Two different doses of MO leaves: 100 and 600 mg/kg-body weight were administrated orally using zondes to group C and D, respectively for 3 weeks. Group E and F were given the water extract of MO leaves with doses of 100 and 600 mg/kg, respectively. Group G and H were exposed to the MO seeds powder of 100 and 600 mg/kg, respectively. After exposure, rats were sacrificed for the collection of blood and organ samples. Metal analyses and blood biochemical test were performed. No significant differences were found in Pb levels in the blood, liver and kidney of all groups except for control group, whereas the mitigated trends of Pb toxicity on albumin and creatine level were discovered. Further analysis will be done to verify the effect of MO on Pb toxicity and described at the presentation. Additionally, the perspectives of another study looking at the possibility of MO for environmental remediation purpose will also be presented.

TU288

The trend of elevated blood lead levels in Kabwe mining area, Republic of Zambia

H. Nakata, S.M. Nakayama, Hokkaido University; J. Yabe, K. Muzandu, The University of Zambia; Y.B. Yohannes, Hokkaido Univesity; H. Toyomaki, A. Kataba, Hokkaido University; G. Zyambo, The University of Zambia; H. Mizukawa, Ehime University; Y. Ikenaka, Hokkaido University; R. Dowling, J. Caravanos, Pure Earth; M. Ishizuka, Hokkaido University / Graduate School of Veterinary Medicine

Lead (Pb) possesses a particularly elevated anthropogenic enrichment factor and is a toxic metal for organism. Although Pb poisoning is preventable, it accounts for approximately 0.6% of the global burden of disease, with the highest burden in developing countries. Namely, it's one of the most common and best-recognized childhood diseases of toxic environmental origin. The town of Kabwe, a central provincial capital of the Republic of Zambia has a long history of Pb and zinc (Zn) mining which operated for nearly a century without proper laws regulating emissions from the mine. There are many activities going on such as metal scraps scavenging from the abandoned tailings, use of Pb-laced soil to make bricks and agricultural activity at the contaminated area around mining site. It is considered that these processes and dust emanating from the mine dumps have continued to serve as a source of metal pollution. Our former researches have been revealed the serious contamination status in Kabwe with findings of high levels of Pb accumulation in the environmental soil sample, wild rats, livestock, poultry and even children. The current study was conducted to assess the prevalence of blood lead levels (BLLs) in the general population of Kabwe, and to compare the prevalence of BLLs within the region and with other studies worldwide. Thus, the blood sample was collected from Kabwe residents at various clinics around and far from the mining area to clarify how far Pb diffuses and makes an impact on human health. The BLLs were tested using LeadCare® II analyzer. In total, blood samples were collected from 1270 participants in 11 clinics and BLLs ranged from LOD to 162 mg/dL. High BLLs were observed from people living near to the mining site and most of them had BLLs exceeding the CDC reference value of 5 mg/dL that raises "health concern". Generally, BLLs in the vicinity of the mining area were significantly higher than those in remote sites ($p < 0.01$). In summary, the present study has demonstrated Pb poisoning in Kabwe residents, especially in areas close to the mining site. Further toxicological analysis is essential to evaluate the exact generated toxic effect in the body. Also, regular monitoring and proper countermeasure should be taken immediately.

TU289

Source Identification and Metal Analysis of Fine Particulate Matter (PM2.5) in an Industrialized Urban Area of Lagos State, Nigeria

E.I. CHIEDU, FEDERAL INSTITUTE OF INDUSTRIAL RESEARCH OSHODI (FIIRO) LAGOS STATE / PRODUCTION, ANALYTICAL AND LABORATORY MANAGEMENT

Gaseous pollutants and particulate matter are released into the atmosphere at concentrations above their normal ambient level; this is caused by the increasing human activities which eventually have a measurable effect on humans, animals and plants. Particulate matter (PM) which can be inhaled into the human respiratory system is related to most serious health effect including pulmonary and cardiovascular illness. Based on the field study conducted, the concentrations of PM2.5 at the different locations vary with respect to anthropogenic activities. The PM2.5 levels obtained ranged from 14.00 to 32.67 µg/m3during wet seasons and 18.67 to 34.67 µg/m3 during dry season. Trace elements especially heavy metals are significant components of PM2.5 in industrial environments. The heavy metals are of particular concern due to their persistence in the environmental media and their human toxicity.The particulate matter concentration was obtained using Casella cel-712 microdust pro-real time dust monitor and flame atomic absorption spectrophotometer was used to determine the elemental content. The Principal Component Analysis explained three common contributing sources of fine particulates ($PM_{2.5}$) such as entrained soil, sea salt and combustion. Correlation matrix was also determined and some of the elements were strongly correlated while some were not.

Metal accumulation in two crops across the Mbale Waste Dumpsite

F. Awino, Godwins Water and Geo-technical Consults Ltd; J. Lynch, University of Canberra; W. Maher, University of Canberra / Institute of Applied Ecology; F. Krikowa, University ofCanberra / Ecochemistry Laboratory

Over 800 million people globally practice open dump farming, and this could pose health risks. This study investigated the occurrence, spatial variations and threats to food safety of aluminium (Al), chromium (Cr), iron (Fe), manganese (Mn), cobalt (Co), nickel (Ni), copper (Cu), zinc (Zn), arsenic (As), selenium (Se), cadmium (Cd), mercury (Hg), and lead (Pb) in *Zeamays* and *Amaranthus cruentus* crops grown across the Mbale dumpsite. Mean concentrations for Fe, Al, Zn, Mn and Cu were high in the two crops whereas Pb, Cr, Co, Cd, As, Hg, Se and Ni were in trace amounts. Significant variations for Al, Zn, Fe, Cr, and Co concentrations in crop parts existed across the dumpsite.Al, Co, and Fe concentrations in *Amaranthus cruentus* leaves were higher at the dump centre (16.3, 16, 17 mg/kg) than at the slope (8.2, 9, 7mg/kg) respectively. Zn concentrations in *Amaranthus cruentus* leaves were higher at the slope (120 mg/kg) than the dump centre (52mg/kg). Zn concentrations in *Zeamays* leaves were higher at the dump centre (21 mg/kg) than the river bank (5 mg/kg). Al and Fe concentrations in *Zeamays* seeds were higher at the dump centre (23, 14 mg/kg) than the river bank (10, 9 mg/kg) respectively. Al concentrations in *Zeamays* seeds were higher at the dump centre (23 mg/kg) than the slope (11 mg/kg) while Cr concentrations were higher at the slope (23 mg/kg) than the dump centre (14 mg/kg). Leafy crops accumulated most metals, with the overall occurrence higher at the dump centre. Pb concentrations were safe in *Zeamays* seeds, however, Cr, Pb, Zn and Al in the remaining crop parts were above World Health Organization/Food and Agricultural Organization (WHO/FAO) consumer food safety limits. *Zeamays* and *Amaranthus cruentus* crops grown across the Mbale Dumpsite could pose health risks to consumers. Routine assessments are required to ascertain potential health risks towards local food safety for human consumption. Key words Toxic metals, waste dumpsite, health risk, Uganda

Indirect effects of glyphosate-based herbicide on plant-herbivore interactions and oxidative status of the Colorado potato beetle

M. Rainio, University of Turku / Department of Biology; A. Margus, L. Lindström, University of Jyvaskyla / Department of Biological and Environmental Science; M. Helander, University of Turku / Department of Biology

Glyphosate is the globally most used herbicide against a wide range of weeds. Glyphosate has been considered safe to animals as it mainly targets physiological pathways in plants. However, recent toxicological studies have shown that glyphosate can cause various toxic effects also on animals. Glyphosate can also affect directly the synthesis of plant defence chemicals. In this study, we investigated the indirect effects of glyphosate-based herbicide (GBH) on non-target plant-herbivore interactions and the GBH-induced physiological stress on herbivores, by using potato and Colorado potato beetle (CPB) as a model system. The CPB larvae were randomly divided into two groups: **1)** environmentally relevant dose of GBH (Roundup® Gold, 450g/l) and **2)** control group (water). Larvae were exposed to GBH via potato, planted either in clean or GBH treated soil. Half of the larvae were reared on potato until the 4th instar and the other half was reared into adults to study the long-term effects of GBH on CPB. Plant defence chemicals were measured twice from the potato leaves; before placing larvae on potatoes and after larvae were pupated. GBH treatment had no effects on survival and body mass of the larvae or the adults. In larvae, glutathione concentration and the enzyme activities of catalase and superoxide dismutase were increased in GBH treated group, suggesting GBH-induced activation of antioxidant enzyme activities and elevation of glutathione (GSH) levels to defend the beetles against oxidative stress. However, glutathione-S-transferase, glutathione- peroxidase and reductase activities, GSH:GSSG ratio and lipid peroxidation levels were not affected by GBH treatment. In adults, none of the oxidative status parameters were associated with GBH. From the potato defence chemicals, α-solanine levels were reduced in potatoes grown in GBH treated soil, whereas α-chaconine levels were not affected by GBH. The reduction of α-solanine levels can be advantageous for the beetles, but detrimental to plant defence against herbivores. Potato defence chemicals differed also between the time points. Both α-solanine and α-chaconine levels were lower in later time point (both treatment groups), which may be related to larval feeding or potato growth. To conclude, environmentally relevant concentrations of GBH are not likely to affect directly the survival of CPB but are associated with the oxidative status of the larvae. However, GBH had no carry-over effects from larvae to adults.

TU292

Lethal and sublethal effects of two insecticides to predatory bug Anthocoris nemoralis in laboratory

A. Lanzoni, Università di Bologna / Dipartimento di Scienze e Tecnologie Agro-Alimentari; L. Depalo, A. Masetti, E. Pasqualini, Alma Mater Studiorum University of Bologna / Dipartimento di Scienze e Tecnologie Agro-Alimentari

The management of most relevant insect pests of pear orchard in Emilia-Romagna

(Northern Italy) is achieved by insecticides. Therefore, the knowledge of the impact of pesticides on beneficial insects is a key issue in pear pest management. Predatory bugs (*Anthocoris* spp.) are key predators of the pear psyllid *Cacopsylla pyri* (L.) (Rhynchota: Psyllidae). In order to enhance conservation biological control it is important to assess the potential short- and long-term detrimental effects of insecticides used in pear orchard. This laboratory study focuses on possible effects of two insecticides on adults of *Anthocoris nemoralis* (F.) (Rhynchota: Anthocoridae), which is the most important predator of pear psyllid in Italy and potentially able to contain this pest under the economic threshold. Laboratory experiments were carried out to evaluate the lethal and sublethal effects of sulfoxaflor (Isoclast™ active, applied at 48 mg AI L^{-1}) and imidacloprid (Confidor 200 SL, applied at 100 mg AI L^{-1}) on *A. nemoralis* adults. The experimental unit consisted of a small pear plant (≈30 cm high) placed in an aerated plexiglass cylinder. Immediately after insecticide spray drying, 20 adult bugs were released into each cylinder and exposed to insecticide residues; 4 replicates were carried out for each product. Mortality was scored after a 72 h exposure. The survived bugs were removed and reared to study the impacts on life table parameters (i.e. fecundity and fertility). Key words: *Anthocoris nemoralis*, toxicity, sublethal effects, Isoclast

TU293

Lethal and sublethal effects of sulfoxaflor on the ladybird Adalia bipunctata

A. Lanzoni, Università di Bologna / Dipartimento di Scienze e Tecnologie Agro-Alimentari; L. Depalo, A. Masetti, E. Pasqualini, Alma Mater Studiorum University of Bologna / Dipartimento di Scienze e Tecnologie Agro-Alimentari

The aphid predator *Adalia bipunctata* (L.) (Coleoptera: Coccinellidae) is a key natural enemy in agricultural and natural ecosystems and it is widely commercialized in Europe for augmentative biological control of aphids. Sulfoxaflor is a new active ingredient (IRAC 4C group) particularly effective against sucking insect pests. The assessment of its compatibility with aphid predators is crucial in developing integrated pest management programs on several crops. In this study, lethal and sublethal effects of sulfoxaflor on *A. bipunctata* were assessed under laboratory conditions; imidacloprid was included as reference product. Both the standardized method proposed by the IOBC and a demographic based approach, were used. The side effects of the insecticides were evaluated by directly spraying 3rd instar larvae and adults with the field rates recommended on product labels: imidacloprid (Confidor 200 SL: 100 mg AI L^{-1}) and sulfoxaflor (Isoclast™ active: 24 and 48 mg AI L^{-1}). Sulfoxaflor resulted harmless (IOBC class 1) for both *A. bipunctata* larvae and adults, whereas imidacloprid was classified as slightly harmful (IOBC class 2) for larvae and moderately harmful (IOBC class 3) for adults. None of the population parameters, R_0, r_m, λ, T, and DT, resulted affected by direct exposition of *A. bipunctata* adults to sulfoxaflor. On the contrary, imidacloprid caused a significant reduction of population growth indices mostly due to higher mortality and reduced adult fecundity in comparison to control group. Our results lead to the conclusion that, unlike imidacloprid, sulfoxaflor could be taken into consideration in IPM programs where *A. bipunctata* is involved. Key words: Integrated Pest Management (IPM), sulfoxaflor, imidacloprid, side effects.

TU294

Activity and persistence of two insecticides on Macrolophus pygmaeus and Aphidius colemani in laboratory and semifield experiments

A. Lanzoni, Università di Bologna / Dipartimento di Scienze e Tecnologie Agro-Alimentari; L. Depalo, A. Masetti, E. Pasqualini, Alma Mater Studiorum University of Bologna / Dipartimento di Scienze e Tecnologie Agro-Alimentari

The selectivity of insecticides for beneficial arthropods is particularly relevant for glasshouse crops where the knowledge of the persistence of the toxic effects is necessary to synchronize and integrate beneficial releases together with insecticide sprays. In order to evaluate the selectivity of two insecticides, trials were carried out on *Aphidius colemani* (Viereck) (Hymenoptera: Braconidae), an aphid parasitoid, and *Macrolophus pygmaeus* (Rambur) (Rhynchota: Miridae), a predator of whiteflies. Two insecticides were evaluated: Closer™ (sulfoxaflor Isoclast™ active: 120 g L^{-1}, DOW AgroSciences) and Confidor SL (imidacloprid: 200 g L^{-1}, Bayer CropSciences) at the concentration of 48 mg AI L^{-1} and 100 mg AI L^{-1}, respectively. Experiments to assess acute toxicity (expressed as percentages of mortality) were carried out on adults of both insects and nymphs of *M. pygmaeus*. The persistence of the harmful effects of insecticides was determined by exposure of nymphs and adults of *M. pygmaeus* and adults of *A. colemani* on treated tomato leaves at 1, 5, 15, 21 and 32 days after treatment (DAT). *M. pygmaeus* adults and nymphs were also exposed to tomato leaves grown after the treatments and thus not directly sprayed. These assays were carried out at 21 and 32 DATs. Five replicates with five individuals per species were performed for each treatment. Mortality was checked after 24 and 48 h of exposure for *A. colemani* adults and after 72 h for adults and nymphs of *M. pygmaeus*. On treated leaves, both insecticides fell in IOBC classes 3 or 4 for all DATs with a slight decrease of insecticidal activities overtime. Overall low toxicity was recorded for both insecticides on leaves grown after treatment. Both imidacloprid and sulfoxaflor were ranked in IOBC class 1 (harmless) for nymphs and in class 2 (slightly harmful) for adults of *M. pygmaeus*. Key words: *Aphidius colemani*, *Macrolophus pygmaeus*, sulfoxaflor, imidacloprid, side effects, greenhouse

TU295

A comparative study of the toxicity of the insecticide fipronil to aquatic Neotropical species

R.A. Moreira, J. Freitas, University of São Paulo / São Carlos School of Engineering; T.J. Pinto, University of São Paulo USP / Hidraulica e Saneamento; L.C. Silva, University of São Paulo / São Carlos School of Engineering; M. Daam, CENSE & New University of Lisbon, Lisboa; L.C. Schiesari, University of São Paulo / Escola de Arte, Ciências e Humanidade; E.G. Espindola, University of São Paulo USP / Hydraulics and Sanitation

Sugarcane cultivation has been highlighted in the Brazilian landscape with excessive application of insecticide fipronil. The aim of the present study was to evaluate the toxicity of Regent® 800 WG (a.i. fipronil) using a test battery of organisms that are native species with common occurrence in Brazilian freshwaters: Cladocera (*Ceriodaphnia silvestrii*), Oligochaeta (*Allonais inaequalis*), Diptera (*Chironomus sancticaroli*), Amphipoda (*Hyalella meinerti* and *Strandesia trispinosa*) and Amphibia (*Leptodactylus fuscus* and *Physalaemus nattereri*). All experiments were carried out under controlled temperature (25±1°C) and photoperiod (12h light:12h dark) and performed in triplicate. The test with *C. sancticaroli* was made with 240 mL test solution, 60 g artificial sediment and six organisms. For *H. meinerti*, 100 mL test solution was used with five organisms. Both tests lasted 96h. For *S. trispinosa* and *A. inaequalis*, the bioassays were carried in 10 mL test solution, with five organisms for 48h (*S. trispinosa*) and six organisms for 96h (*A. inaequalis*). For tadpoles, contained 5L test solution and five organisms for 96h. For cladocerans, consisted in five neonates for 96h. Species sensitivity distributions (SSD) were constructed to compare the acute EC50 values derived for the native species and other invertebrate and fish species. By means of the SSD, we observed that the species *Chironomus dilutes* is the most sensitive (0.03 µg/L), followed by *Americamysis bahia* (0.14 µg/L) and the *Cheumatopsyche brevilineata* (0.15 µg/L). With respect to native species, *H. meinerti* (1.29 µg/L) showed the greatest sensitivity, followed by *C. sancticaroli* (6.19 µg/L), *C. silvestrii* (9.7 µg/L) and *S. trispinosa* (53.24 µg/L). For *A. inaequalis, L. fuscus,* and *P. nattereri*, no effects were noted on the survival even at the highest concentration tested 100 mg /L for the oligochaetes and 800 mg/L for the tadpoles. Therefore, these species were the least sensitive to fipronil, being more resistant than the fish *Danio rerio* (181 µg/L) and *Oncorhynchus mykiss* (246 µg/L). Studies in Brazil recorded concentrations of 0.1 to 26.2 µg/L of fipronil in rivers in the state of Rio Grande do Sul and 4.23 µg/g in sediment of marginal lagoon of the river Mogi-SP. Based on these records, *H. meinerti* and *C. sancticaroli* would be at risk at such an exposure scenario. The present study demonstrated that toxic effects on tropical species are likely to occur at environmentally realistic exposure levels.

TU296

Severe effects of neonicotinoid insecticides on Nitocra spinipes under different exposure conditions

S. Moeris, Ghent University / Laboratory for Environmental Toxicology and Aquatic Ecology; F. Vanryckeghem, K. Demeestere, Ghent University / Department of Green Chemistry and Technology; K. De Schamphelaere, Ghent University (UGent) / Environmental Toxicology

Neonicotinoids have been constantly replacing formerly used insecticide groups (e.g. organophosphates, pyrethroids, etc.) in the past few decades. Their physical-chemical properties including lower log K_{OW} and higher water solubility make them readily absorbed by plants and act quickly at low doses. On the other hand, these properties make them susceptible for runoff and subsequent transfer into the aquatic environment. They have been detected in surface waters in the ng L^{-1} to low µg L^{-1} range, and finally in marine waters at concentrations ranging from 0.5 to 10 ng L^{-1}. In this work, we assessed potential acute and chronic effects of four neonicotinoids (clothianidin CLO, imidacloprid IMI, thiacloprid TCL and thiamethoxam TME) on the brackish copepod *Nitocra spinipes*. Neonicotinoid exposure was performed under three different scenarios. First in a 96h acute lethal toxicity test according to ISO 14669. Second in a recovery experiment based on 96h exposure to two different neonicotinoids (CLO and TCL) followed by transfer to fresh medium and continuous observation to explore the recovery potential of exposed copepods. Finally, we performed a 7-day larval development test with TCL according to ISO 18220. In the acute tests we found immobilization to be a more sensitive endpoint than death, showing EC_{50} (96h, immobilization) values ranging from 0.81 µg L^{-1} (CLO) to 430 µg L^{-1} (TME). Our recovery experiment showed that 69 % of the organisms exposed to 100 mg L^{-1} TCL were able to recover mobility after 24h, while those exposed to 100 mg L^{-1} of CLO remained immobilized. The larval development test with TCL showed a clear delay in development of *N. spinipes* nauplii and the EC_{50} (7d) was calculated at 10.3 µg L^{-1}, while the NOEC (7d) was 1.23 µg L^{-1}. *N. spinipes* showed considerable sensitivity when exposed to neonicotinoid insecticides both in short- and long-term exposure for adults and nauplii, respectively. Immobilization was a clearly more sensitive endpoint as compared to death in acute testing and locomotion is crucial for copepod survival in terms of feeding behaviour and predator avoidance. Regarding the recovery potential, there seems to be no general agreement for different neonicotinoids. Developmental effects of TCL on copepod nauplii suggested further testing of other neonicotinoids and particularly CLO (lowest acute EC_{50}) under chronic exposure conditions.

TU297

Working with EPT-Taxa - chronic testing of mayfly species in a test system simulating running waters

M. Brüggemann, R. Leonhardt, Fraunhofer IME Institute for Molecular Biology and Applied Ecology; C. Schaefers, Fraunhofer IME - Institute for Molecular Biology and Applied Ecology / Ecotoxicology

As many other non-target arthropods, mayfly larvae originating from small creeks and streams are exposed to releases of plant protection products, which are mainly applied to agricultural areas and washed off into adjacent running waters. Even though mayfly species are considered to be very sensitive against exposure to several pesticides, there are only few toxicity data available dealing with chronic effects of pesticides on these species. Therefore, we developed a test system for the chronic testing of lotic insect larvae. The test system differs from usually known stream test systems particularly in its construction. In order to create a particular flow, small cages inside a test container filled with test medium circulate through the water phase thereby creating the target flow in the cage. The cages are equipped with gravel mats on the bottom and two black glass nuggets to simulate the natural habitat conditions of the larvae. Each cage serves as individual compartment for testing of single organisms to allow an organism specific evaluation of sublethal effects. The test system can provide data of chronic toxicity tests with different aquatic insect larvae, which can be used for a SSD (Species Sensitivity Distribution) approach for the risk assessment of pesticides. The chronic effects of the neonicotinoid Imidacloprid on field collected mayfly larvae of the species *Epeorus* and *Ecdyonurus* belonging to the family of Heptageniidae were assessed in a 28 day exposure period. Larvae, which were in an early development stage, were adapted to laboratory conditions for up to 14 days before test start. The study was carried out in moderately hard reconstituted water (according to EPA) with five test concentrations and a control. The grazing larvae were fed with green algae *Desmodesmus subspicatus*, which were grown on the glass nuggets before test start. As sublethal endpoint, the growth of the test organisms was evaluated by measuring the length of each individual larvae at test start and test end. In addition, mortality of larvae was recorded weekly. In previous studies, the test system was already used for chronic toxicity testing with stonefly larvae *Protonemura sp.* exposed to Imidacloprid for 21 days. In addition to the results of the performed mayfly study, a comparison of effects and sensitivities of mayfly and stonefly larvae to Imidacloprid will be presented.

TU298

Kinetics and toxicity of metabolites of imidacloprid to mayfly larvae

A. Huang, Wageningen University and Research; N. van den Brink, Wageningen University / Dept of Toxicology; I. Roessink, Wageningen Environmental Research / Environmental Risk Assessment; P. van den Brink, Wageningen Environmental Research

Neonicotinoids (NNIs) belong to the group of nitroguanidine systemic insecticides, which recently sparked increased environmental concerns, based on their potential risks to the aquatic and terrestrial ecosystem. However, most attention has been given to the parent compounds and less is known of the impacts of their degradation products and metabolites. Since IMI is the most used NNI, we will study the toxicity of imidacloprid (IMI) and its metabolites. A mayfly species is chosen as the focal species, as it is amongst the most sensitive species for this compound and also an essential freshwater invertebrate. During upcoming experiments, the uptake kinetics of IMI and metabolites into the mayfly will be quantified and the toxicity of the parent and its metabolites will be assessed. Our results will provide a further mechanistic understanding of the toxicokinetics and toxicity of IMI and its metabolites in mayflies. To answer the question of whether IMI is degraded or metabolised by mayflies, and whether the mother compound or its metabolites is toxic, three types of experiments will be performed. Firstly, the toxicity of each chemical (IMI-olefin, IMI-urea, 6-chloronicotinic acid, 5-Hydroxy-IMI and IMI) will be assessed by a 4 days standard toxicity experiment. Secondly, the bioaccumulation of metabolites and environmental transformation products of IMI will be identified by analysing body burdens using Liquid Chromatography-Tandem Mass Spectrometry in a four days exposure study using the EC10 as the exposure concentration. Thirdly, those metabolites of IMI which accumulated in the mayflies or showed a high toxicity will be studied further in an uptake-elimination experiment to evaluate their toxicokinetics in order to get a better understanding and evaluation of the risks these chemicals may pose to aquatic organisms. The current study will (1) show the toxicity of the metabolites of IMI to mayflies, indicating whether metabolites are of importance for future risk assessment of IMI, (2) assess body burdens of IMI and its metabolites for mayflies, (3) show whether the degradation products of IMI in water are different from the metabolites found in the mayflies. This information might explain the high sensitivity of mayflies in comparison to, for instance, Daphnia.

TU299

Developmental and vitamin A-based biomarkers for pesticide contamination in two potential arthropod sentinels, the honey bee Apis mellifera and the gammarid Gammarus fossarum

M. Gauthier, Irstea / UR RIVERLY Laboratoire Ecotoxicologie; J. Garric, Irstea Lyon / UR RIVERLY Laboratoire Ecotoxicologie; C. Jumarie, UQAM TOXEN / Departement des sciences biologiques; O. Geffard, Irstea / UR RIVERLY Laboratoire Ecotoxicologie; M. Boily, TOXEN-UQÀM / Département de sciences biologiques

The massive use of pesticides is raising awareness for terrestrial and aquatic non target species. In response and to ensure efficient biomonitoring of ecosystems, the development and routine utilization of diagnostic tools (biomarkers) are essentials. Retinoid compounds (for example vitamin A) are implicated in many crucial physiological processes in vertebrates (development, reproduction, vision, etc.) and were proposed as sensitive biomarkers for several contaminants in fish, birds, amphibians and mammals. Recent findings regarding fluctuating levels of retinoids in bees following pesticide exposure open avenues of research for new biomarkers in invertebrate sentinel species. In this project, we propose to study the retinoid system of two arthropods; an insect (*Apis mellifera*) and a crustacean (*Gammarus fossarum*). In the first place, we will establish the retinoid profile of these models throughout their development. Secondly, the implication of retinoids in the embryonic, morphogenetic and sexual development following exposure to retinoic acid (bioactive form of vitamin A) or citral (retinoic acid synthesis inhibitor) will be investigated. Lastly, we will assess the sensitivity of the retinoid system to glyphosate and methoprene. These results will lead to the proposal of new biomarkers to complement biomonitoring programs.

TU300

Analysis of ecotoxicological studies with non-target arthropods based on the PIERIS databank

M. Lehto, Agroscope Wädenswil / Research group Ecotoxicology; M. Mathis, Agroscope; J. Daniel, Agroscope / Research group Ecotoxicology

The ecotoxicological risk assessment of plant protection products (PPP) for non-target arthropods (NTA) in Europe is basically based on ESCORT 2 (2002). Since the publication of ESCORT 2 many adjustments have been implemented and new knowledge and concepts published (e.g. ESCORT 3 (2012) and EFSA Scientific Opinion (2015)). However, new approaches have not yet been incorporated into the risk assessment within the regulatory context. Before doing so, it is important to validate current and suggested new approaches for their usefulness, feasibility and consequences for the authorisation of PPP. PIERIS (Pesticides and Intermediates Environmental Risk Indication System) is a databank containing ecotoxicological information about the PPP and active substances evaluated as part of the authorisation process in Switzerland. PIERIS has been constantly developed and expanded since 2002. Today PIERIS contains information about the physio-chemical properties, environmental fate and application parameters of over 400 active substances, 800 metabolites and 1200 PPP. Furthermore, in total over 24000 ecotoxicological studies, of which ~4400 are related to NTA, have been entered in the databank making it an excellent tool for testing different questions. The aim of this work is to use data from PIERIS to investigate following aspects related to the risk assessment for the NTA: 1) Interspecific variation in sensitivity towards different active substances. 2) Comparison between different mode of action types. 3) Comparison of conclusions on recovery based on different study types (glass plate, extended, aged residue, field studies) 4) Influence of different VDF-values (vegetation distribution factor) on the outcome of the risk assessment The results will enable us to better interpret risk assessments according to Escort 2 und to judge the pros and cons of new approaches.

Sampling methods for Collembola: Comparing abundance, diversity and variability

S. Aldershof, Bioresearch & Evaluation; H. Cunningham, Corteva agriscience / The Agriculture Division of DowDuPont; J.R. Wheeler, Shell International; F. Bakker, FB Consultancy

The functional role of Collembola in agro-ecosystems is diverse and important. Collembola function in plant litter decomposition processes, in forming soil microstructure, and are key in arthropod food-webs. Species differ in habitat use. Whereas some are predominantly surface dwelling, others are mainly hypogean and again others may commute between compartments. Different sampling techniques exist, and each has their own bias. For example, pitfall traps will target surface dwellers and hypogean traps or soil cores will target euedaphic species. For regulatory studies, with spray applied products both surface and soil dwelling species will be at risk and it is not a priori clear which of the available methods will be best suited. The suitability of a sampling method is determined by the effectiveness of catching the Collembola taxa of concern. Abundance and diversity of taxa sampled, and variability of the data determine the quality of the risk assessment: the array of taxa occurring in the field that are actually covered by the risk assessment, and the detection level of potential adverse effects. In this work we compare results of three sampling methods for collecting Collembola from the soil surface (soil cores, pitfall traps and suction samples). Data are from two arable studies (winter wheat) performed in two distinct geographical locations (South-West France and The Netherlands). Quality of the data generated with the three sampling methods are evaluated, in terms of total numbers, array of taxa covered with the sampling methods, number of taxa having sufficient numbers for meaningful effect evaluations, and variability of the data. Abundance and heterogeneity of the data greatly determine detectability of treatment effects. Variability of the data is compared by calculating minimum significant differences (MSD); the minimum effect value that would be detectable in a statistically significant manner, given the variability of the data. Based on MSD values, data quality of taxa from the different sampling methods is then classified according to Brock *et al*. (2015) and Bakker and Aldershof (2018). Finally, effect values calculated for identical taxa collected with the three sampling methods are compared, to investigate the level of exposure of taxa sampled with the different methods. Recommendations are given to improve data quality by using appropriate sampling methods for Collembola, in line with EFSA (2015).

TU302

What about Lepidoptera? Future requirements and proceedings on risk assessment towards Non Target Arthropods

S. Kimmel, Innovative Environmental Services (IES) Ltd. / Ecotoxicology; T. Schmidt, IES Ltd / Ecotoxicology; B. Hodapp, Innovative Environmental Services IES Ltd; S. Hoeger, Innovative Environmental Services IES Ltd / Environmental Toxicology

Ever since the European Food Safety Authority (EFSA) firstly published their “Scientific Opinion adressing the state of science of risk assessment on plant protection products for non-target-arthropods” in 2015, a number of challenges and yet to be researched improvements concerning the risk assessment and study designing have been raised for discussion. One aspect among numerous newly raised concerns comes with including a new group of organisms to risk assessment, the large and important group of *Lepidoptera* species. The EFSA working group “considers *Lepidoptera* to be important drivers for the ecosystem services pollination and food web support”, but yet validated and reliable testing protocols for oral and contact exposure are missing, not even speaking of harmonized and accomplished official ringtests on broad international scale. A few methodologies for Lepidoptera testing exist and are also mentioned by EFSA (Appendix G), but these are either limited to special product use (e.g. *Bacillus thuringensis* strains), or not yet developed to high level end use (e.g. *Pieris brassica*). In Appendix G, the mentioned setup for *Pieris brassica* seems to be a promising approach, although it may be limited to oral exposure. Further on *Pieris brassica* is classified as pest organism to some farming cultures (e.g. cabbage) an aspect which counteracts to the overall combined approach of plant protection products and use of “beneficials”. Lastly, there are a lot of species from the *Lepidopteran* group (e.g. diamondback moths, cabbage loopers, tip moths) required for efficacy testing throughout registration process of plant protection products. The here presented work shall emphasize a possible approach for a test method on *Lepidoptera* species under oral exposure, based on an accepted and reliable chinese guideline method for silkmoths, *Bombyx mori* (ICAMA 2014). Further on, aspects and contradictions of requiring such a setup under risk assessment and registration for plant protection products for this specific group of organisms will be discussed.

TU303

Designing and conducting mesofauna field studies - what should study design consider in terms of sample storage, extraction and detectable differences?

O. Jakoby, Rifcon GmbH / Regulatory Sciences - Population Modelling and Statistics; G. Henkes, J. Amossé, D. Warnecke, Rifcon GmbH

In cases where risks of plant protection products have been identified on the basis of laboratory tests with standard soil organisms, mesofauna field studies can be conducted as a higher-tier refinement option. In such studies, effects on the species composition and abundance of the concerned taxa are investigated at community/population level under realistic exposure conditions. While planning mesofauna field studies, different conceptual and technical aspects need to be considered. For the evaluation of such studies, statistical tests are conducted to check for the effects of the toxicants. However, the ability of a test to indicate a difference between treatment groups always depends on significance criteria, the number of replicates, and variance in the data. A suitable study should allow the detection of a relevant minimum difference (MDD) between treatment groups. Hence, it is crucial to apply a suitable sampling design (e.g. in terms of number of replicates or consideration of different soil horizons) to ensure an appropriate explanatory power of the study. Additionally, from the technical point of view, it is of interest if the orientation of soil cores during the extraction of organisms (i.e. either normal or upside down) or their cold-storage (compared to direct extracted samples) has an effect on the extraction efficacy. To investigate these aspects of the study design, soil core samples were taken from fifteen spots on a grassland. Four soil cores were taken from each spot and divided into an upper (0-5 cm) and a lower (5-10 cm) horizon. The four soil cores represented four different sample handling and storage conditions: (i) normal orientation of the sample during extraction (same as in the field), no storage, (ii) reverse orientation (upside down), no storage, (iii) normal orientation, storage under cooled conditions before extraction, and (iv) reverse orientation, cold-storage. After extracting Collembola and Acari species from the soil cores, the data was analysed to investigate if any difference between the different handling and storage conditions could be detected. In a second step, this data set, comprising a large number of replicates, was used to simulate different realistic sampling designs and illustrate the relationship between the number of replicates and the explanatory power (measured by the MDD) for this type of field study. Finally, the results are discussed in the light of mesofauna field study recommendations.

TU304

A semi-field bio-assay to evaluate effect decline of chlorpyrifos using honeybees exposed to aged residues on different flowering crops.

J. Roig, Eurofins-Mitox; G. Galván, Universität Koblenz-Landau; F. Bakker, Eurofins-Mitox

Because wild bees and honey bees play an important role in the pollination of a wide range of crops and uncultivated plants there is concern over decrease in bee populations. To evaluate the risk of plant protection products *Phacelia* is recommended in Europe as a standard crop for bee studies. However, because flower morphology and longevity may determine exposure of honeybees to pesticide residues, bee-attractive crops with a different flower morphology should also be evaluated. In this experiment we used a test design that enabled a simultaneous assessment of the effects of different residue age classes on honeybee survival. The study design was a semi-field study with up to 6 treatment groups with 3 replicates each: chlorpyrifos treated at 750 g a.i./ha, 21, 14, 7, 3 and 0 days before the start of exposure to honeybees and an untreated control. Each replicate consisted of one gauze cage of 20 m2 with treated crop. Each exposure cage had an extension with 20 m2 of untreated crop separated by a gauze curtain, which was used to acclimatize the honeybees before the start of the exposure. A small bee hive was placed against the gauze separation. At DAT0 the curtain was simply moved over the hive, thus confining the bees to the previously treated crop. Application on DAT0 was done before bee flight. *Phacelia*, buckwheat, mustard and sunflower were selected based on different flower morphology and longevity. Assessments of foraging and mortality were conducted up to 5 days after the start of the exposure. For data analysis the total number of dead bees recorded 1day after exposure, corrected for control mortality was used. Because effects of different residue age classes could be assessed simultaneously, i.e. under exactly the same meteorological conditions, these effects could be compared in a straightforward manner and effect decline could be modelled using regression analysis. Mortality decline curves over time showed differences between the test crops which confirms that exposure of bees to residuals depend on flower morphology. The highest initial mortality was observed on buckwheat, which also showed the steepest decay curve, followed by *Phacelia*, mustard and sunflower. Mortality-based DT50 values were determined by fitting the data to kinetic degradation models, being 2.61 days for buckwheat and 4.09 days for *Phacelia*. The studies with sunflower and mustard had insufficient time points for the regression due to external circumstances.

TU305

Bee colony assessments with the Liebefeld method: How do individual beekeepers influence results and are photo assessments a possibility to reduce variability?

H. Bargen, A. Fauser, H. Gaetschenberger, G. Gonsior, Eurofins Agroscience Services Ecotox GmbH; S. Knaebe, EAS Ecotox GmbH / Ecotox Field

Colony strength, food storage and brood development are a fundamental part of each honeybee field study. Colony assessments are used to compare and assess those for beehive over time. At present, most colony assessments are made by experienced beekeepers according to Liebefeld. This method is based on an estimation of areas covered by honeybees, food and brood stages on each side of a comb. Areas are counted from a grid separating the comb side into 8 sections which are protocolled with an accuracy of 0.5 sections. An assessment for a hive takes up to 20 min and even with two field locations, it is necessary to split assessments between beekeepers. So, it is important to make estimates as comparable as possible. For this purpose beekeepers practice the assessments on pre-determined photographs to “calibrate themselves”. The advantage of the Liebefeld assessment is that the condition of bee hive is estimated with minimum disturbance of the bees. Digital photography is under discussion to gain data with high precision and accuracy with one major disadvantage. To be able to see food and brood stages in photographs, bees have to be removed from combs. This, however, results in a disturbance of the colony – especially if the assessments take place in short time intervals of 7 ± 1. An experiment was performed to evaluate the variation between individual beekeepers and to compare the results to data generated with photographs. For the experiment, five colonies were assessed each by five beekeepers independently according to Liebefeld method. Each comb side of the five colonies was photographed with and without honeybees sitting on it for precise analysis at the computer for a number of bees, nectar cells, pollen cells, eggs, open brood and capped brood. The number of bees and cells with the different contents were generated by an area-based assessment in ImageJ as well as a detailed counting with help of HiveAnalyzer® Software. Data from beekeeper estimations were then compared with assessments based on digital photography. With the results of the experiment, we tried to answer several questions. First of all, we wanted to determine the level of variation between the beekeepers for the live stages and food stores estimated. Furthermore, we wanted to find out, if the photo assessment is such a precise method that it would justify a replacement of the well-established Liebefeld method despite the strong disturbance of the bees.

TU306

Pollinator monitoring for evaluation of potential exposure and assessment of effects

O. Klein, Eurofins Agroscience Services Ecotox GmbH / Ecotox Field; J. Fricke, Eurofins Agroscience Services Ecotox GmbH / Ecotoxicology Field; S. Knaebe, EAS Ecotox GmbH / Ecotox Field

Over the last decades there has been a decline in arthropod numbers observed. Pollinators are one of the groups that were clearly affected. At the moment the safety of plant protection products is evaluated with the testing of honeybees but other pollinator species are not required. There are already some test designs in development that use bumble bees and mason bees but they are not suitable for all crops and seasons. Pollinator monitoring can be a way to evaluate potential exposure of pollinators to plant protection products in different crops or agricultural scenarios or to assess possible effects of treatments at a larger scale taking into account other influencing parameters like the management intensity, landscape structure etc. In a monitoring, the abundance and species richness of natural occurring pollinators in a crop and adjacent field margins will be investigated. Crops can be used by pollinators not only for foraging but also as a nesting habitat. Additionally, even the off-crop habitat close to a field can be attractive for the same reason. Therefore the assessment of pollinator abundances in both field and the surroundings can help to understand if pollinators are exposed to plant protection products. This might include temporal as well as spatial differences (timing of monitoring and placement of monitoring within the field and landscape). To evaluate a wide range of pollinator species occurring in a specific crop several methods are available and needed. As with non-target arthropod studies it is recommend using different types of assessment methods to collect the most representative community. Sampling should include non-selective and selective methods. For the non-selective methods different types of traps might be used in combination: vane traps and bee bowls. These traps can be installed at different locations: i.e. in the center, at the borders of the fields and outside in the adjacent field margins. As selective method sweep netting or observations can be used via transect walks in a defined distance and time interval. In addition, trap nests can be provided for hypergeic solitary wild bee species that breed in woody cavities. The trap nests can also be set up at the different locations and are used for sampling of pollen to assess pollen sources by pollen identification of pollen mass samples. If required, residue analysis can performed with samples of pollen mass. This would allow assessing possible exposure though a test item.

TU307

Honeybee's biological and behavioral processes can affect the outcome of the RFID homing flight test

M. Eyer, Agroscope, Swiss Bee Research Centre, CH-3003 Bern, Switzerland; D. Lueken, M. Janke, Niedersächsisches Landesamt für Verbraucherschutz und Lebensmittelsicherheit Institut für Bienenkunde Celle - Herzogin-Eleonore-Allee 529221 Celle, Germany; L. Jeker, Swiss Bee Research Center / Agroscope

The development of new ecotoxicological test-methods with honeybees requires the inclusion of fundamental bee biology and corresponding behavioral processes, in order to improve the explanatory power of a new test-method as much as possible. Generally, in ecotoxicological (lower-tier) studies with honeybees, xenobiotic substances are administered via group feeding to a certain number of bees, which distribute the test solution between each other via trophallaxis. Accordingly, group feeding represents one of the main principles in the RFID homing flight ring-test protocol "Homing flight test in honeybee (*Apis mellifera L.*) after single exposure to sublethal doses (J. Fourrier, 2018)", whereby the test-substance is administered in sugar solutions to groups of ten foragers. Due to methodological reasons of the present protocol, the age- and task composition of collected foragers may not be homogenous. As a result, corresponding food uptake could vary considerably among individual bees and/ or groups. Similarly, group-based food distribution via trophallaxis might not distribute the feeding solution homogenously among individual bees, as it has been pointed out in previous studies. The performance of slightly modified experiments based on the RFID homing flight ring-test protocol represents a good way to evaluate the effect of an individual parameter on the outcome of this new test-method. \n We demonstrated that the pooled homing ability of xenobiotic exposed foragers differed significantly when administered individually compared to group feeding. Furthermore, we showed that the current content in nectar stomachs of returning nectar foragers (collected for the trials) can affect the data (e.g. due to dilution of the test substance, or the likeliness of individual bees to take up the feeding solution). Our results bring new insights, how the RFID homing flight ring-test protocol could be improved, using individual feeding and /or choosing exclusively returning pollen foragers to create equivalent test units.

TU308

Oral Toxicity Test with Solitary Bees: Long-term feeding behavior

B. Hodapp, Innovative Environmental Services IES Ltd; T. Schmidt, IES Ltd / Ecotoxicology; M. Cornement, Innovative Environmental Services (IES) Ltd; S. Kimmel, Innovative Environmental Services (IES) Ltd. / Ecotoxicology

As the current version of the ICP-PR working document on the Oral Acute Toxicity Test with Solitary Bees is being prepared to become an OECD guideline, there are still practical issues with the test, most notably that all participants of the ring test experienced a high number of bees which do not feed on the provided solution in the given time. Two small-scale experiments over 72 hours were performed. In the first, different concentrations of sugar solutions were tested. In the second, it was checked if consumption becomes more robust over longer time periods. Looking at longer time periods had the intention of considering if a chronic test with solitary bees would be possible, but also assessed if prolonging exposure or doing a pre-exposure phase in the acute test would lead to a better consumption. Overall, the tests showed that once bees start to feed they will continue to feed over the following days. This is an important first step for the possible establishment of a chronic test. For the acute test, it shows that introducing a pre-exposure phase in which the bees can "learn" to feed would increase the number of feeders and reduce the overall number of bees required for one test. There were, however, still bees that starved to death instead of feeding on the provided sugar solution (or offered alternatives), so there is still a need to investigate how consumption can be increased.

TU309

Determination of abamectin and difenoconazole in tissues of the stingless bee Melipona scutellaris

F.S. Prado, University of São Paulo / São Carlos Institute of Chemistry; J. Brigante, University of São Paulo / São Carlos School of Engineering; D.M. Santos, University of São Paulo / Institute of Chemistry of Sao Carlos; H.L. Santos, University of São Paulo / São Carlos School of Engineering; J.M. Burgarelli, University of São Paulo / São Carlos Institute of Chemistry; T. Oliveira, University of Sao Paulo - USP / Quimica e Fisica Molecular; E.M. Vieira, University of São Paulo / Institute of Chemistry of Sao Carlos

Studies involving the assessment of adverse effects of agrochemicals in native bees are scarce in Brazil. Thus, because of the important role in pollination process, investigation about the bee's susceptibility to agrochemicals commonly applied in crops are important. In this study an analytical method was developed for the determination of the insecticide abamectin and the herbicide difenoconazole in tissues of the stingless bee *Melipona scutellaris*. For this purpose, QuEChERS acetate modified method was used for sample preparation and the pesticides were determined by LC-MS/MS. The validation parameters of tested method include: a linear range between 0.01 to 1.00 mg L^{-1}, with correlation factors above 0.99; detection and quantification limits for abamectin and difenoconazole of 0.003 and 0.01 mg L^{-1} respectively; recovery of 55.5 % for abamectin and 106.7% for difenoconazole, with an intraday accuracy ranging between 1.44 to 10.50% for abamectin and 3.19 to 7.55% for difenoconazole. Considering these parameters, this validated method can allow de detection of concentrations below the regulatory agencies stablished levels (0.02 mg L^{-1} for abamectin and 0.5 mg L^{-1} for difenoconazole) for crops as strawberry fields, where bee pollination is extremely important. Thus, method was applied in bees exposed via oral (0.006 $\mu g\, \mu L^{-1}$ and 5.0 $\mu g\, \mu L^{-1}$) and topic (0.028 $\mu g\, \mu L^{-1}$ and 67.0 $\mu g\, \mu L^{-1}$) at LD_{50} concentration for abamectin and difenoconazole respectively. Analytes were detected in all tested conditions indicating the method can be applied for the monitoring of these two pesticides in bee tissues.

TU310

Validation of analytical procedure for the determination of Abamectin and Difenoconazole in strawberry flowers (Fragaria ananassa) and pollen sampled from Scaptotrigona depilis hives

J.M. Burgarelli, University of São Paulo / São Carlos Institute of Chemistry; J. Brigante, University of São Paulo / São Carlos School of Engineering; D.M. Santos, E.M. Vieira, University of São Paulo / Institute of Chemistry of Sao Carlos

The increase of agricultural productivity associated with the emergence and the extensive use of agrochemicals is undeniable. In this sense, the harmful effects, as well as the impacts of those applied toxic agents over the ecosystem, was laid aside in the first moment. However, strong evidence indicates that the rising use of agrochemicals is one of the factors associated with the decreasing of pollinating insects, such as bees, which is considering as the animal that contributes most significantly to this process and is increasingly scarce. The present work aims the development and validation of an analytical procedure for the determination of the insecticide abamectin and the fungicide difenoconazole in strawberry flowers (*Fragaria* x *ananassa* DUCH.) and pollen sampled from beehives of the stingless bee *Scaptotrigona depilis*. The QuEChERS method was optimized for extraction and clean-up procedures, and analytical performance and determination of the two agrochemicals were verified using LC-MS/MS. For the method validation, obtained results involving linearity (0.5 to 1500 $\mu g L^{-1}$), precision (>80%), accuracy (< 20%), and recovery in three spiking levels (250, 1000 and 1500 $\mu g L^{-1}$) were satisfactory and in accordance with international guidelines on validation. Matrix effect (>74%) was observed for both contaminants in the two matrices. Thus, the method can be applied in further studies, being an important tool for the determination of these agrochemicals on investigated matrices and contributing to the environmental risk assessment involving these organisms.

TU311

Evaluation of honeybee larvae data: sensitivity to PPPs and impact analysis of EFSA Bee GD

R. Becker, BASF Aktiengesellschaft; J. Lückmann, Rifcon GmbH / Regulatory Sciences/Ecotoxicology

Based on EU Regulation 1107/2009/EC the current regulatory risk assessment on bees has to address the risk on honeybee larvae or honeybee brood. In July 2013 the European Food Safety Authority (EFSA) published a guidance document on the risk assessment of plant protection products on bees (EFSA 2013). This document is intended to provide guidance for notifiers and authorities in the context of the review of plant protection products (PPPs) and their active substances under Regulation (EC) 1107/2009 (EC 2009). The first objective of this poster is to summarize all available industry data for active substances and formulated products on honeybee larvae testing according to OECD 237 and OECD 239, in order to gain an overview of these results and the selectivity of different product groups. The sensitivity of the endpoints are presented. In addition, endpoints obtained at different development stages after 7 and 22 days in OECD 239 studies are compared. As a first step in the risk assessment, EFSA requires a screening step, which consists of the calculation of risk quotients (ETRs) for honeybee larvae. This considers exposure routes for the in-field (PPPs applied as sprays) and off-field (PPPs used as seed treatments and granules) scenarios. Where a use does not pass one of the screening level risk quotients, EFSA offers the possibility for refinement in a tier I risk assessment. This includes the refinement of exposure estimates from the screening step and also additional exposure routes, such as the exposure to flowering plants in the field margin and adjacent crops. As worst-case scenarios, the risk of honeybee larvae being exposed to treated crops and weeds were assessed. The same approach as used for the honeybee was also conducted for bumble bees and solitary bees but with the application of specific short cut values (SV) from the EFSA guidance document. As honeybee endpoints are used as a surrogate for bumble bee and solitary bee data an additional 10x safety factor is applied to the endpoints. The second objective of this poster is to evaluate the impact of the proposed screening and tier I risk assessments on the pass rates of currently available active substances and formulated products, which is an ability of the scheme to correctly identify compounds of potential concerns and consequently screen out those of low concern. In addition, the outcome of an industry proposed alternative risk assessment as described by ECPA (2017) is presented.

TU312

Chronic oral exposure of adult honeybees to PPPs: Sensitivity and impact analysis based on EFSA Bee GD

J. Lückmann, Rifcon GmbH / Regulatory Sciences/Ecotoxicology; M. Miles, Bayer CropScience UK / Environmental Safety

Based on EU Regulation 1107/2009/EC the current regulatory risk assessment on bees has to address the chronic risk on adult honeybees. In July 2013 the European Food Safety Authority (EFSA) published a guidance document on the risk assessment of plant protection products on bees (EFSA 2013). This document is intended to provide guidance for notifiers and authorities in the context of the review of plant protection products (PPPs) and their active substances under Regulation (EC) 1107/2009 (EC 2009). The first aim of this poster is to summarize industry data based on studies conducted up to 2018, for active substances and formulated products on the chronic oral testing of adult honeybees according to OECD test guideline 245 and its previous drafts, in order to gain an overview of these results and the selectivity of different product groups. As a first step in the risk assessment, EFSA requires a screening step which consists of the calculation of risk quotients (ETRs) for the chronic exposure based on the application rate, an application depending shortcut value, an exposure factor and the endpoint (LDD_{50}). This considers exposure routes for the in-field (PPPs applied as sprays) and off-field (PPPs used as seed treatments and granules) scenarios. Where a use does not pass one of the screening level risk quotients, EFSA offers the possibility for refinement in a tier I risk assessment. This includes refinement of the exposure estimates from the screening step and also additional exposure routes, such as the exposure to flowering weeds in the field and adjacent flowering crops. Screening step and tier I risk assessment were also conducted for bumble bees and solitary bees, using 1/10 of the honeybee endpoint. The second aim of this poster is to evaluate the impact of the proposed screening and tier I risk assessments on the pass rate of currently available active substances and formulated products, thereby testing the ability of the scheme to correctly identify compounds of potential concern and consequently screen out those of low concern. The third objective of this work is to present the outcome of alternative calculations as described by ECPA (2017). The aforementioned analysis follows the principles described in the ECPA impact analysis (Alix et al. 2013) which used theoretical data due to lack of real data. The present analysis compares the pass rates from this first approach with the outcome based on real laboratory data which are now available

TU313

Conservatism in first tier trigger values in pollinator risk assessment

I. Roessink, Wageningen Environmental Research / Environmental Risk Assessment

The EFSA guidance on the risk assessment of plant protection products on bees (EFSA,2013) provides examples on the calculation of trigger values used in risk assessment. These values are based on several assumptions, i.e., the normal background mortality, the amount of mortality that a hive can withstand without negative effects (7% derived from the Khoury model) and the effect the compound has on bees. The latter is the focus of our current project. Where effect curves are standard of a sigmoid shape and are being normally analysed using non-linear regression techniques, the EFSA guidance adopts another approach and assumes a linear dose-response curve. As already stated in the guidance, this introduces a certain level of conservatism in the risk assessment because an effect level derived from a linear approach will result in a lower concentration than when this level is derived from the standard non-linear approach. In order to test the amount of conservatism introduced this way, we analysed data from sixty-two 10d-chronic honeybee tests using both the linear and the non-linear approach. From this data set fifty-two effect curves were obtained comprising 18 fungicides, 13 herbicides and 21 insecticides, which were processed following the examples provided by EFSA. Comparing the results of the linear and non-linear approach showed that using the linear approach gave more conservative results, ranging from a factor 0.7 to 33.4 for individual compounds. On a whole the ETR trigger was a factor of 13.3 more conservative using the linear approach proposed by EFSA as when the normal linear approach was used.

TU314

Optimizing laboratory testing for bee species: a comparative sensitivity analysis for honey bees and bumblebees

A. Dinter, Cheminova Deutschland GmbH & Co. KG / Global Regulatory Sciences; J. Lückmann, Rifcon GmbH; R. Becker, BASF SE Agrarzentrum Limburgerhof; M. Miles, Bayer CropScience UK / Environmental Safety; E. Pilling, Dow Agrosciences / REgulatory Sciences; N. Ruddle, Syngenta Ltd / Product Safety; A. Sharples, FMC / Global Regulatory Sciences; L. Oger, ECPA

A data evaluation was conducted by European Crop Protection Association (ECPA) member companies to compare the sensitivity of bumblebees (*Bombus terrestris* L.) with that of honey bees (*Apis mellifera* L.) to pesticide active substances and plant protection products. For the evaluation endpoints from acute oral and contact laboratory toxicity tests with honey and bumblebees were compiled into a database. Studies were included where there was at least one corresponding test for both species according to the same route of exposure. This resulted in 108 test items for contact exposure and 97 for oral exposure. The data comprised of approximately 20% fungicides, 50% herbicides/plant growth regulators, and 30% insecticides/nematicides). For data sets with definite endpoints (i.e. calculated LD_{50} values) the sensitivity ratio "SR" was determined by dividing the honey bee LD_{50} value by that of the bumblebee LD_{50} value. The data evaluation indicated that bumblebees were of similar or lower sensitivity compared to honey bees for all fungicides, herbicides/plant growth regulators and for 86% of insecticides/nematicides irrespective of the route of exposure. Overall, most of the comparisons indicated that bumblebees were not more sensitive than honey bees based on an acute toxicity assessment. We conclude that based on this review routine regulatory testing of bumblebees (*Bombus terrestris* L.) of plant protection products is not justified and the application of a standard safety of 10 on honey bee endpoints to cover bumblebee sensitivity is unwarranted.

TU315

Applying the mechanistic honey bee colony model BEEHAVE to assess multiple factors impacting overwintering survival in large colony feeding studies

A. Schmolke, Waterborne Environmental, Inc. / College of Biological Sciences; F. Abi-Akar, Waterborne Environmental Inc; N. Galic, Syngenta Crop Protection Inc. / Environmental Safety; S. Hinarejos, Sumitomo Chemical Co. Ltd / AgroSolutions Division International

Honey bee Large Colony Feeding Study (LCFS) is a novel type of Tier II semi-field study for the determination of potential effects of pesticides on free-foraging whole colonies during and after dietary intake of a known pesticide concentration. LCFS are currently accepted by North American regulatory agencies and represent a progressively more realistic level of refinement compared to individual laboratory-based studies. LCFS are designed to test toxicity via consumption of fed sucrose syrup over a worst case exposure scenario of six weeks, with colony assessments conditions over a foraging season and following overwintering period. However, such studies are very cost- and time-intensive, and high overwintering losses of control hives have been observed in some studies. Loss of control colonies indicates that stressors other than pesticides, e.g. resource availability, weather, diseases and beekeeping activities, likely influence colony overwintering survival, confounding the assessment of impacts caused by pesticides. In the current study commissioned by the Pollinator Research Task Force, we apply the mechanistic honey bee colony model BEEHAVE to simulate colony dynamics observed in negative control colonies from multiple colony feeding studies. Detailed landscape-level data inform the resource availability for the simulated foragers in the model. In addition, weather data, initial colony condition and feeding patterns were analyzed across studies and translated to model inputs. In a calibration step, we adjusted parameters in BEEHAVE to achieve simulated dynamics corresponding to colony conditions reported in the studies. Study data collected in summer and fall were analyzed for predictors of overwintering success of individual colonies. BEEHAVE simulations with different combinations of external factors were used to assess their importance for colony condition. Colony conditions at study initialization and feeding patterns both influenced the colony condition in the fall, and thus, the probability of overwintering survival. Model simulations with different colony feeding patterns and initial colony conditions were then used to quantitatively estimate colony-level outcomes under conditions deviating from those in the studies. These results can be used to improve and inform LCFS study designs. Pesticide effects can be included in future model analyses, and analyzed in the context of multiple factors that impact colony health and overwintering success.

TU316
Challenges in the modelling of multiple stressors on the honeybee colony
J.C. Rumkee, Syngenta; N. Galic, Syngenta Crop Protection Inc. / Environmental Safety; H. Thompson, Syngenta Ltd / Environmental Safety
The Western Honeybee (*Apis mellifera*) is a key species of interest in the risk assessment of pesticides in part due to its major role in pollination services, a vital part of agriculture worldwide. The honeybee colony is a complex societal structure, consisting of tens of thousands of individuals each performing specific tasks depending on their age and the current state of the colony (food stores, food availability, time of year). The success of the colony stems from the complex interactions between these individuals and the ability of the entire colony to collect sufficient food to feed the brood and survive over the winter, as well as to maintain the homeostasis of the colony (cleaning, tending of brood, temperature control). In a typical year, each colony is subject to multiple stresses, from food availability to parasitism and predation, as well as exposure to pesticides. Due to the highly interwoven and complex nature of the colony, it is clear that the use of ecological models to understand the relative impacts of various stressors on both the individual and colony level is highly beneficial. The BEEHAVE model was developed to represent honeybee colony dynamics by integrating relevant colony processes into one framework. The model has a simple interface allowing non-expert users to explore colony dynamics and quantify impacts of various stressors. Since its release, the BEEHAVE model has been used to explore a number of stressors, as well as undergoing a review by EFSA, to explore its potential as a tool for pesticide risk assessment. The design of BEEHAVE permits the inclusion of multiple stressors acting simultaneously on the colony, and can capture simple acute impacts well. However, when quantifying more complex, chronic stresses, there are a number of challenges that need to be addressed. In modelling the honeybee colony, there are a number of parameters that are required to correctly capture the state of the colony at any specific point in time. Specifically, for an Individual-Based Model, such as BEEHAVE, the age structure and available resources within the colony, as well as the parameterisation of the landscape and weather are significant drivers of colony dynamics and often are difficult to derive from empirical data. In this poster, we discuss these challenges and possible ways of capturing the inner workings of the colony in a sufficient resolution to adequately scale impacts from individual bees to long-term colony dynamics.

TU317
CORAL: innovative open source QSAR model for predicting acute contact toxicity of binary mixtures of plant protection products in honeybee (A. mellifera)
E. Carnesecchi, Istituto Mario Negri / Environmental chemistry and toxicology; A.A. Toropov, Istituto di Ricerche Farmacologiche Mario Negri; A.A. Toropova, Instituto di Recerche Farmacologiche Mario Negri; N. Kramer, Utrecht University / Institute for Risk Assessment Sciences; C. Svendsen, CEH, Wallingford / Pollution and Ecotoxicology; J. Dorne, European Food Safety Authority EFSA / Scientific Committee and Emerging Risks Unit Department of Risk Assessment; E. Benfenati, Istituto di Ricerche Farmacologiche Mario Negri
Honeybees can be exposed to a wide range of multiple chemicals "chemical mixtures" as compounds from anthropogenic origin (e.g. plant protection products, PPPs) or natural origin (e.g. mycotoxins). Quantifying the impact of multiple chemicals on bees has been identified by EFSA as a priority to understand their relative contribution to bee health in comparison to other stressors (e.g. varroa) to support the development of holistic risk assessment method. However, from a risk assessment perspective, it is practically impossible to test all the possible mixtures experimentally, therefore it is needed to find smart strategies to assess the potential hazards using new strategies that incorporate alternative methods such as *in silico* tools. Here we propose the application of CORAL QSAR model in order to predict the combined effects of PPPs in honeybee (*A. mellifera*). Acute contact toxicity data for 92 PPPs binary mixtures ($LD_{50\text{-mix}}$) and corresponding single chemicals ($LD_{50\text{-single}}$) were retrieved from the literature and used to build the QSAR model. Similarly, optimal descriptor as well as quasi-SMILES were estimated. Three random splits into the training, invisible training, calibration, and validation sets were generated in order to test the statistical quality of the QSAR model. Preliminary results showed a R^2= 0.76 for the validation test. Finally, Toxic Unit (TU) approach assuming Concentration Addition (CA) as default model was applied in order to identify deviations of effects from dose addition that lead to synergistic or antagonistic interactions. This work shows the potential use of alternative methods to animal testing such as QSAR models for the hazard assessment of multiple chemicals. In particular, when applying a tiered approach for ecological risk assessment of multiple chemicals, QSARs models can be applied in order to a) predict (missing) information on individual compounds (tier 0) and (b) predict directly or stepwise the combined effects and interactions of chemicals in the mixture (tier 1). Overall, this project will allow EFSA's Working Group "MixTox" to develop its Guidance Document aimed at harmonizing the current methodologies for HHRA and ERA of multiple chemicals due in 2019.

TU318
Modelling of exposure to pesticide residues using citizen science based monitoring of pollen - part of the INSIGNIA project
H. Baveco, Wageningen University and Research / Wageningen Environmental Research; R. Brodschneider, University of Graz; N. Carreck, Carreck Consultancy Ltd; C. Ferrer Amata, University of Almería; A. Gray, University of Strathclyde; K.M. Kasiotis, Benaki Phytopathological Institute; A. Pinto, INSTITUTO POLITECNICO DE BRAGANCA; I. Roessink, Wageningen Environmental Research / Environmental Risk Assessment; J. van der Steen, Alveus AB Consultancy
In the INSIGNIA EU project, a protocol will be developed and tested for citizen-science based monitoring of pesticides using honeybees. As part of the project, biweekly pollen samples will be obtained from sentinel apiaries over a range of European countries and landscapes, validating different devices and methods. The samples will be analysed for botanical origin, using state of the art molecular techniques, and for residues of a large number of agricultural pesticides and veterinary products, both authorized and unauthorized. The data collected will be used to develop and test a spatial modelling system aimed at predicting spatially-explicit pollen diversity and pesticide mixture exposure and risk at the apiary level, from basic landscape data. The system consists of model components for spatial and temporal pollen resource distribution, application and environmental fate of pesticides, and honeybee landscape-scale pollen foraging, with a common underlying geo-data base containing European land-use and land-cover data (CORINE) supplemented with national data sets on agricultural and (semi-)natural habitats. It requires (regional, national) data on the use of agrochemicals, as well as data on the phenology and other characteristics of the crops and wild flowers constituting the main pollen resources. The modelling system is designed to develop and improve incrementally, taking advantage of the growing amount of data becoming available from the sampling in the course of the INSIGNIA project (and possible future continuation), and iteratively, when a next round of comparison between observations and predictions from a set of alternative models indicates that the initially simple models, e.g., based on distance relations only, can be replaced by more complex and detailed ones, accounting for increasing ecological realism. The approach can generate risk maps based on floral resources and residues indicative of suitability of the landscape for pollinators. Comparison between model predictions and observations will indicate to what extent apiary exposure can realistically be predicted from relatively coarse-grained Europe-wide landscape data using models of intermediate complexity, and point out steps required to arrive at more precise predictions. Comparing results for authorised and unauthorised pesticides will provide insights into actual use of the latter, including the spatial distribution and the most likely crops on which they have been applied.

TU319
Understanding hive dynamics
M. Wang, WSC Scientific GmbH / Dept Efate Modelling; T. Braasch, WSC Scientific GmbH
For the evaluation of the toxicity of chemicals honeybee field and semi field trials are routinely conducted in order to measure endpoints such as brood termination or colony strength. These rather simple endpoints are, however, a result of the incredibly complex interaction of a multitude of factors, ranging from climate, beekeeper practice, landscape structure and toxicants. As a consequence it is difficult to understand which of these factors have the most relevant impact on colonies, although in particular in the context of the debate on multiple stressors such insight would be valuable. In the present study we use computer generated visual representations of hives to illustrate how hives change over time to understand the relevance in particular of climate and hive structure. We also show how brood success is defined by hive structure.

TU320
Bee keepers and other stressors to honeybees
M. Wang, WSC Scientific GmbH / Dept Efate Modelling; C. Dietrich, WSC Scientific GmbH
In recent years a number of large scale national and international projects (e.g. COLOSS) identified the bee keeper training or practice \n as the most relevant factor regarding colony losses. To elucidate the relevance of factors such as bee keeper practice, Varroa treatment, \n weather and toxic stressors a spatially explicit population model is used to compare the relevance of these factors for the colony survival.\n Simulations with different weather scenarios, varying bee keeper practice and exposure to toxicants are conducted. Results of model \n simulations are discussed.

Climate Impacts on Polar and Alpine Ecotoxicology and Environmental Chemistry (P)

Biomagnification of PFAS in the Antarctic breeding south polar skua

L. Alfaro Garcia, Department of Biosciences University of Oslo; S. Descamps, Norwegian Polar Institute, Fram Centre; D. Herzke, NILU-Norwegian Institute for Air Research / Environmental Chemistry; N. Eckbo, Institutt for biovitenskap; O. Chastel, CEBC CNRS & Université de la Rochelle UMR 7372; a. carravieri, CEBC UMR 7372 CNRS-University of La Rochelle; Y. Cherel, CEBC CNRS Université de la Rochelle UMR; P. Labadie, UMR CNRS EPOC Universite Bordeaux / UMR 5805 EPOC; H. Budzinski, University of Bordeaux / EPOC LPTC UMR5805 CNRS; G. Gabrielsen, The Norwegian Polar Institute; J.O. Bustnes, Norwegian Institute for Nature Research / Fram Centre; K. Borga, Department of Biosciences, University of Oslo / Department of Biosciences

Exposure to manmade chemicals in the Antarctic ecosystem has historically been low, but the Antarctic breeding south polar skua (*Catharacta maccormicki*) has concentrations of some chlorinated biomagnifying lipid soluble contaminants comparable to Arctic breeding seabirds at similar ecological niches. There are few data on the protein soluble per-fluorinated compounds PFAS from Antarctic wildlife, however a previous study of south polar skua found increasing PFAS concentrations in blood during their breeding season in the Antarctica. In the present study we investigate the biomagnification of PFAS in south polar skua from its prey, in two colonies with different prey availability; in the inland Dronning Maud land colony at Svarthamaren, the skuas prey almost exclusively upon Antarctic petrels (*Thalassoica antarctica*), of which the eggs and chick are preferred. In Adélie land, at the coastal colony near Dumont D'Urville (DDU), the skua diet is more diverse and include food from the sea as well as chicks of Adélie penguin (*Pygoscelis adeliae*). Of the analysed PFAS at Svarthamaren, only PFUnA was quantified above the detection limit in all matrices (blood, egg, stomach content) and species (skuas and petrels), although not in all samples. The levels increased from stomach contents of petrels, to petrel adults, and further to petrel eggs and chicks. Skuas had the highest levels of all the PFAS. The levels of other PFAS in skuas were in general lower at DDU than in Svarthamaren, and apart from the presence of branched PFOS at DDU, the pattern was comparable. The major differences were that in prey items, more PFASs were present above detection limit at Svarthamaren than DDU; PFDoA, PFTriA and PFTeA were present in Antarctic petrel and not in Adélie penguin. This difference is likely due to the resident nature of the Adelie penguins, whereas petrels migrate to, and maybe sometimes cross the Antarctic Circumpolar Current during winter. Thus, the migrating skuas from both colonies probably reflect the PFAS exposure outside of the Antarctic regions during breeding season. The higher diversity of PFASs present in petrels suggests that these birds as well have sources of PFAS outside the Antarctic continent.

TU322

Climate and productivity affect total mercury concentration and bioaccumulation rate of fish in subarctic watercourse

S. Ahonen, University of Helsinki; B. Hayden, University of New Brunswick / Canadian Rivers Institute; J. Leppanen, University of Helsinki; K.K. Kahilainen, Inland Norway University of Applied Sciences

Climate change is increasing temperature and precipitation in subarctic Europe. These changes are enhancing tree growth enabling intensification of forestry into previously inhospitable subarctic regions. The combined effects of climate change and land-use intensification extend the warm, open-water season in subarctic lakes and increase lake productivity. To assess the joint effects of climate and productivity on total mercury (THg) bioaccumulation in fish, we conducted a space-for-time substitution study in 18 tributary lakes of a subarctic watercourse forming a gradient from cold pristine oligotrophic to warmer mesotrophic and eutrophic lakes. Increasing temperature, precipitation, and lake productivity were predicted to elevate length- and age-adjusted THg concentrations, as well as THg bioaccumulation rate in muscle tissue of whitefish (*Coregonus lavaretus*), vendace (*Coregonus albula*), perch (*Perca fluviatilis*), pike (*Esox lucius*), roach (*Rutilus rutilus*) and ruffe (*Gymnocephalus cernua*). A positive linear relationship was observed between THg concentration and climate-productivity in vendace, perch, pike and roach. Higher climate-productivity values of the lakes also had a positive linear (pike and whitefish or u-shaped; perch and ruffe) relationship with THg bioaccumulation rate. Increased THg concentrations reveal adverse effects of warming climate and increasing productivity on fishes, whereas less distinct trends in THg bioaccumulation rate suggest more complex processes.

TU323

UV radiation effects the Diatom (Skeletonema sp.) physiological responses to ocean acidification

L. Xie, NIVA - Norwegian Institute for Water Research / Environmental Toxicology; M. Norli, Norwegian Institute for Water Research; A. Macken, NIVA / marine pollution; K. Tollefsen, NIVA / Ecotoxicology and Risk Assessment

Nowadays, the increasing CO_2 concentration in atmosphere associated with anthropogenic CO_2 emissions is causing the average pH of world's oceans declining at a rate of about 0,002 per year, which could lead to a potential drop of 0,3 to 0.4 units by 2100. As the H^+ concentration increases with CO_2 dissolution, H^+ releases can partially reverse the secondary dissociation reaction of the seawater carbonate system, leading to a decrease in carbonate ions ($H^+ + CO_3^{2-} \rightarrow HCO_3^-$). Therefore, typical changes linked to ocean acidification (OA) are increased partial pressure of carbon dioxide (pCO_2), H^+ and HCO_3^-, decreased concentrations of CO_3^{2-} and decreases in the $CaCO_3$ saturation state. These changes will lead to a decrease in the alkalinity of seawater, and the subsequebnt decrease in buffering capacity will increase the magnitude of short-term pH changes in the future. In addition, in the marine environment, organisms are not only facing ocean acidification but also exposed to other stressors such as UV radiation (UVR). However, there is still lack of knowledge about how the combined effect of UV radiation and OA will impact primary producers. The objective of the present study was to investigate the effects of CO_2 and UV radiation on the diatom *Skeletonema costatum* using a combination of genomic, functional and apical (adverse) toxicity endpoints. Small-scale CO_2 experimental systems (multiple stress chambers) were constructed to provide CO_2 levels of 350-1000 ppm pCO2 (pre-industrial, present day and future oceanic CO_2) and placed into UV exposure chamber (0.25 w/m^2). 72h exposure to elevated CO_2 caused and increase in *S. costatum* reproduction rate. At the cellular level, increased CO_2 reduced ROS formation, lipid peroxidation, carotenoids and increased chlorophylls (Chl *A* and Chl *B*) accumulation in *S. costatum*. There was no significant change in photosystem II performance after single CO_2 exposures. However, single UVR induced strong ROS formation, LPO and also reduced PSII efficiency and chlorophyll content after 72h exposure. When exposed in combination, enhanced effects on chlorophylls accumulation was observed. Additive effects were observed for oxidative stress, PSII performance and growth responses which indicated OA and UVR have independent modes of action in diatoms and there is no interaction between them under the present exposure scenarios.

TU324

Identifying further chemicals of emerging Arctic concern: A review of 'In silico' screening of chemical inventories

D.C. Muir, Environment and Climate Change Canada / Aquatic Contaminants Research Division; X. Zhang, University of Toronto; C. de Wit, Stockholm University ACES; K. Vorkamp, Aarhus University / Department of Environmental Science; S. Wilson, AMAP

The recent Arctic Monitoring and Assessment Program (AMAP) assessment of chemicals of emerging arctic concern included 150 individual chemicals and groups of substances reported in the arctic environment. However, these data represent just a tiny fraction the approximately 157,000 substances that have been registered for use in Europe, USA and Canada over the past 30 years. In the past 12 years many studies have screened lists of thousands of chemicals in the industrial chemical inventories of the European Union, the USA and Canada with the goal of identifying and prioritizing chemicals which are persistent (P), bioaccumulative (B) and toxic (T). A major goal of our study was to review this recent literature on computer-based or 'in silico' screening for POPs and assemble a list of possible target chemicals and then to develop a shorter list of possible priorities. We selected 8 studies published from 2066 to 2015 which had mainly utilized lists of industrial chemicals developed by chemical management regulators in Europe, USA and Canada and which are publically available. The combined list of chemicals identified by all studies contains 3425 substances after removing duplicates as well as Stockholm Convention POPs and was limited mainly to neutral organic chemicals for which existing QSPR models for predicting P, B and T are most applicable. The substances can be roughly categorized into eight classes; brominated, chlorinated, fluorinated, organophosphate esters, siloxanes, musks, polycyclic aromatics, and a broad class of non-halogenated organics.Phys-chemical properties and overall persistence (Pov), transfer efficiency (TE), and bioaccumulation factor (BAF) were calculated with the OECD Toolkit and POPs scores were calculated based on the sum of z-scores for logPov, logBAF, and logTE. The Arctic Contamination and bioaccumulation Potential (AC-BAP) was determined based on the following thresholds log Kow > 3.5, log Koa > 6, and 0.5> log Kaw >-7. Comparisons with recently updated chemical inventories showed that 316 of the 3425 substances were on the REACH inventory (1.9% of the 16755 substances with CAS RNs as of 2018) while 279 were on the US EPA Chemical Data Reporting for 2016 (3.2% of 8700 substances in active use in the US). Thus the results show that there are significant numbers of substances in current use or previously produced in large quantities which could be of concern in terms of transport and accumulation in the Arctic environment.

TU325

Environmental Risk Assessment in Antarctica: field actions, preliminary results and ongoing assays of the project ReACT

G.A. Jeremias, University of Aveiro / department of Biology & CESAM; R. Pereira, Faculdade de Ciências da Universidade do Porto / Biology; T. Vidal, University of Aveiro / Biology department; A. Cachada, CIIMAR; A. Rodriguez Seijo, GreenUPorto, University of Porto / Department of Biology; P. Pereira, University of Aveiro / Department of Biology and CESAM; J. Canario, Instituto

Superior Técnico / Centro de Química Estrutural; S. Guilherme, Biology Department CESAM, Aveiro University / Biology; M. Pacheco, F.J. Gonçalves, J. Pereira, University of Aveiro / Department of Biology & CESAM

Antarctica is the most remote continent on Earth. Due to its remoteness and harsh environment, Antarctica has been considered a pristine environment where human activities have very little impact. However, human presence in Antarctica has been rapidly increasing and human activities are known to have been changing the landscape and impacting the autochthonous biodiversity and ecosystems for at least the past half-century. In specific, preliminary studies have highlighted environmental contamination by major and trace elements and linked environmental hazardous potential in Fildes Peninsula, King George Island, Antarctica. The ReACT project capitalizes on these preliminary studies and on the recognised need for a better support of the major challenge of the Protocol on Environmental Protection to the Antarctic Treaty, i.e. the planning of human activities to minimize impacts upon the Antarctic environment and ecosystem. Site-specific Environmental Risk Assessment (ERA) is accepted worldwide as a reliable tool to appropriately frame decision making regarding the most adequate management towards environmental protection and/or remediation strategies. Taking this into consideration, a field campaign was held in February-March 2018 and we collected 20 soil samples in Fildes Peninsula (plus two likely references in Ardley Island and Nelson Island) for numerous analyses that will feed all the three Lines of Evidence (LoE) integrating ERA frameworks: the chemical LoE with soil physicochemical parameters, as well as trace element and polycyclic aromatic hydrocarbon contents; the ecological LoE with microbial community activity and structural diversity, as well as collembolan abundance; the ecotoxicological LoE with direct toxicity tests with soil organisms and tests with the bioavailable fraction of contaminants with freshwater organisms. So far, we completed the soil general physico-chemical characterisation. While soil density was found very similar among sampling sites, there are noticeable differences in pH, conductivity and organic matter content that may relate to existent gradients of contamination. Ongoing work includes chemical quantification and ecotoxicological testing with both Antarctic and ecotoxicological model species. Ultimately, the project ReACT aims to robustly integrate information from the three LoE to deliver feasible risk estimations for the focused area.

TU326

Snow buntings (Plectrophenax nivealis) as bio-indicators for exposure differences to legacy and emerging persistent organic pollutants from the Arctic terrestrial environment

N.A. Warner, NILU - Norwegian Institute for Air Research / Environmental Chemistry; K. Sagerup, Akvaplan-niva; S. Kristoffersen, NTNU The Norwegian University of Science and Technology; D. Herzke, NILU-Norwegian Institute for Air Research / Environmental Chemistry; G.W. Gabrielsen, Norwegian Polar Research Institute; B. Jenssen, Norwegian University of Science and Technology / Biology

Eggs of snow buntings (*Plectrophenax nivealis*) were applied as a bio-indicator to examine differences in exposure to legacy persistent organic pollutants (POPs) and perflouroalkyl subtances (PFAS) from the Arctic terrestrial environment surrounding the settlements of Longyearbyen, Barrentsburg and Pyramiden on Svalbard, Norway. Significantly higher average concentrations of summed polychlorinated biphenyls (SumPCB$_7$: PCB 28/31, 52, 101, 118, 138, 153, 180) in eggs collected from Barrentsburg (350 ng/g wet weight (ww)) and Pyramiden (600 ng/g ww) compared to Longyearbyen (6.8 ng/g ww) are attributed to local sources of PCBs within these settlements. Average concentrations of Perfluorooctane sulphonate (PFOS) and several perfluorinated carboxylic acids (PFCAs) in snow bunting eggs were found to be statistically higher in populated settlements of Longyearbyen (PFOS: 3.8 ng/g ww; PFCAs: 13 ng/g ww) and Barentsburg (PFOS: 3.5 ng/g ww; PFCAs: 6.4 ng/g ww) compared to the abandoned Pyramiden (PFOS: 0.5 ng/g ww; PFCAs: 1.7 ng/g ww). Narrow foraging ranges of snow buntings during breeding season was useful in assessing point sources of exposure for PCBs and PFAS at particular sites with extreme differences observed between nest locations. SumPCB$_7$ concentrations ranged from 2 μg/g ww to below detection limits between nest sites located less than a kilometer from each other in Pyramiden. Similar findings were in Longyearbyen with several PFCAs from 2 to 55 times higher between nest sites with similar spatial distance. These findings indicate that snow buntings are a useful bio-indicator offering high spatial resolution for contaminant source apportionment in terrestrial environments on Svalbard.

TU327

Multiple exposure to legacy and emerging pollutants in populations of Boreogadus saida from inner and outer Bessel fjord (NE Greenland)

n. ademollo, IRSA-CNR / Water Research Institute; S. Corsolini, University of Siena; K. Præbel, UiT The Arctic University of Norway; J. Rauseo, National Research Council / Institute of Water Research IRSA-CNR; F. Spataro, T. Pescatore, Italian National Research Council / Water Research Institute; L. Patrolecco, Water Research Institute-National Research Council / Water Research Institute

NE Greenland is likely the last remote region of the Northern hemisphere - poorly known and understudied due to the limited access. This region is of high scientific interest, and value, as it harbour organisms with novel biological, ecological, and eco-toxicological features and adaptations. Reports by Arctic Monitoring and Assessment Program (AMAP) show an informational gap in regard to contamination in this area. Indeed, the list of chemicals found in Arctic ecosystems are continuously growing and for some current-use chemicals increasing temporal trends have been reported. Specimens of the marine gadoid *Boreogadus saida* were caught from R/V Helmer Hanssen in Bessel Fjord (BF), NE Greenland (76°N), in September 2017, during the scientific expedition TUNU-VII (UiT The Arctic University of Norway). The general aims were to evaluate the bioaccumulation of legacy end emerging contaminants in populations of *B. saida* from mid and outer Bessel Fjord waters, and from the continental shelf. Liver and muscle samples were analysed to determine the concentration of Polyaromatic Hydrocarbons (PAHs), Bisphenol A (BPA), Nonylphenols (NPs) and Organochlorine Pesticides (HCHs, Endosulfan, DDE, DDT) including some Current Use Pesticides (e.g. Chlorpyrifos, Dacthal). PLE extraction and analytical determination using LC-MS and GC-MS showed the occurrence of these contaminants in the majority of samples. Higher levels were detected in samples from the outer BF: BPA and NPs were 12.1 and 9.1 ng g^{-1} wet weight in muscle, values higher than those detected in liver samples that were 2.4 and 7.3 ng g^{-1} wet wt for BPA and NPs, respectively. Generally, higher concentrations of other contaminants occurred in the liver compared to muscle. The contaminant longitudinal pattern was outer BF > mid BF > shelf: Chlorpyrifos and Dacthal were 8.4 and 7 ng g^{-1} wet wt in the liver samples and 6.6 and 7.1 ng g^{-1} wet wt in the muscle, from of the outer BF. Results confirm the presence of selected legacy and emerging contaminants in this species, suggesting their long-range transport and the transfer of multiple contamination to the Euro-Arctic marine trophic webs.

TU328

High inputs and non-commercial polychlorinated biphenyl congeners in glacial surface snow from Svalbard: Are there new sources?

M.H. Hermanson, Hermanson & Associates LLC / Environmental Chemistry; E. Isaksson, Norwegian Polar Institute; C. Teixeira, D.C. Muir, Environment and Climate Change Canada / Aquatic Contaminants Research Division

In 2014 we collected surface snow samples from four glacial sites on Svalbard, Kongsvegen, Holtedaholfonna, Lomonosovfonna, and Austfonna, and analysed them for 209 polychlorinated biphenyl (PCB) congeners. There were 61 congeners below detection or contributed less than 0.2% to SPCB and were removed from the data sets, leaving 148 PCBs represented by 100 peaks. Two of the sites (Holtedahlfonna and Lomonosovfonna) are above the tropospheric boundary layer (BL) all year restricting atmospheric inputs from local sources, while Kongsvegen and Austfonna are within the BL during summer. The sites are within 220 km of each other. The SPCB fluxes (in pg cm^{-2} yr^{-1}) between sites are variable: Kongsvegen is 26.7 Holtedaholfonna 18.7, Lomonosovfonna 14.4, Austfonna 15.4. While these values vary by nearly a factor of 2, the air mass back trajectories (developed using HYSPLIT) are similar, all showing 40 – 45% frequency of air mass flow from expected source regions to the south and east, indicating that there may be local sources, particularly to the Kongsvegen site. All samples contain PCB-11 which was not produced in major PCB products but is likely a co-synthesis product of various yellow and orange pigments. PCB-5 was also observed in all samples and was not produced commercially in Aroclor (USA, UK) or Chlophen (Germany) products but may have been produced in the Russian PCB product "Trichlorodiphenyl". However, PCB-5 is also a co-synthesis product in manufacture of pigment violet (PV) 23. Considering that PCB-11 is common in Svalbard snow and ice samples, other pigment sources could be considered. Each of the four surface snow samples is dominated by PCB-52 which is different from a snow sample from Lomonosovfonna collected in 2010 which was dominated by PCB-70+74. PCB-52 is found in many commercial PCB formulations, however is not the dominant congener in any formulation that we investigated. What might be the source of this unusual amount of PCB-52? Investigation of the literature shows that PCB-52 is a co-synthesis product of pigment red (PR) 9, and perhaps other red pigments. Considering the somewhat unusual types and amounts of PCB congeners in these surface snow samples, investigation of unintentional PCB co-synthesis from production of non-PCB products must be hypothesized as a source of some PCB congeners to Svalbard.

TU329

Perfluoroalkyl substances in penguin eggs from the Ross Sea (Antarctica): evidence of 15 year of sampling

n. ademollo, IRSA-CNR / Water Research Institute; L. Patrolecco, Water Research Institute-National Research Council / Water Research Institute; J. Rauseo, National Research Council / Institute of Water Research IRSA-CNR; S. Valsecchi, Water Research Institute - Italian National Research Council, IRSA-CNR; S. Polesello, Water Research Institute - Italian National Research Council, IRSA-CNR / Water Research Institute; F. Cappelli, S. Pascariello, National Research Council of Italy; S. Olmastroni, University of Siena; S. Corsolini, University of Siena / Dept Environmental Science

PFASs have been detected in most ecosystems, including those in remote areas. They are long-range transported and can reach the polar regions. Antarctica and the Southern Ocean show extreme climate; due to the low temperatures and winter darkness, contaminants degrade very slowly; moreover, they can be trapped in snow and ice and eventually released during summer melting. When in the seawater, they can enter trophic webs and bioaccumulate mostly in predators that feed directly or indirectly on the cryopelagic community. PFASs include thousands of chemicals but the compounds usually detected in the environment belong to the class of perfluoroalkyl acids (PFAAs), such as perfluorooctanesulfonic acid (PFOS), and perfluorooctanoic acid (PFOA). The Stockholm Convention has recently restricted the production and use of PFOS; however, it is still manufactured and used in various industrial processes in China. Unhatched eggs are very useful non-destructive samples already successfully used to determine chemical levels; the POP transfer from mother to egg has already been reported too. The presence of contaminants in the egg is due to their transfer from the female during the ovogenesis process. Unhatched eggs of Adèlie penguin (*Pygoscelis adèliae*) (n=11) were collected at Edmonson Point (74°21'S, 165°08'E) (Ross Sea, East Antarctica) during the XVII (2001/02) and the XXX (2014/2015) Italian Expeditions, in the framework of the Italian Antarctic Research Programme (PNRA). The general aims were to assess the PFAA bioaccumulation in penguin eggs, to assess their transfer to the chick embryo, and to evaluate a temporal trend. On-line SPE-HPLC-MS revealed the occurrence of 12 PFAAs in eggs and chick embryos. PFOS and PFOA were detected in all samples collected in 2001, with concentrations ranging 0.3-0.53 ng g^{-1} wet weight (wt) in eggs (mean value: 0.42 ng g^{-1} wet wt) and 0.05-0.08 ng g^{-1} wet wt (mean value: 0.07 ng g^{-1} wet wt) in chick embryos. Lower levels were detected in 2015 samples, with mean values of 0.3 and 0.005 ng g^{-1} wet wt of PFOS and PFOA, respectively. This decreasing trend was not observed for PFHxA, PFNA, PFDA, PFUnA, PFDoDA, PFTrDA, PFTeDA concentrations. PFHxA showed the highest levels in the egg samples collected in 2015 (mean value: 0.8 ng g^{-1} wet wt), confirming an ongoing input of these compounds from long-range transport and/or local sources.

TU330

The relationship between per- and polyfluoroalkyl substances (PFASs), persistent organic pollutants (POPs) and trace elements and thyroid hormone status in glaucous gulls (Larus hyperboreus)

. Mortensen, NTNU University / Department of Biology; T.S. Hovden, NTNU The Norwegian University of Science and Technology / Department of Biology; T.M. Ciesielski, Norwegian University of Science and Technology / Department of Biology; E.S. Heimstad, NILU - Norwegian Institute for Air Research; G.W. Gabrielsen, Norwegian Polar Institute; B. Jenssen, Norwegian University of Science and Technology / Biology

The aim of this study was to investigate the concentrations of per- and polyfluoroalkyl substances (PFAS), persistent organic pollutants (POPs) and trace elements and their relationship to the levels of thyroid hormone (TH), thyroid stimulating hormone (TSH) and thyroid gland histology in glaucous gull (*Larus hyperboreus*) from Svalbard. The glaucous gull is an apex predator in the Arctic ecosystem. A total of 35 glaucous gulls were captured and euthanized in the area close to Longyearbyen, Svalbard, in the spring of 2017 and 2018. The level of POPs and PFASs were measured in liver, and trace elements have been measured in plasma, feathers, liver, muscle and kidney. The levels of free and total triiodothyronine (T3) and thyroxine (T4) and TSH were measured in plasma. THs are crucial in the regulation of several important physiological processes such as growth, development, reproduction, thermogenesis, molting and behavior. Organic chemicals, elements or other factors that disrupt the THs system can therefore potentially cause severe effects on individuals and populations. It is therefore important to investigate the combined effect of potential TH disruptors in wildlife. Association between THs and POPs and PFAS have been identified in glaucous gull, but neither the relationship between elements and THs, or between TSH, TH, pollutants and thyroid gland histology have previously been reported. In the present study, were the concentrations of perfluorooctanesulfonic acid (PFOS) and the long chained perfluorinated carboxylic acids (PFCAs) high while the short chain PFCAs and emerging PFASs were not detected or had low concentrations. The levels of PCBs and certain pesticides were high, while the levels of PBDEs were low and new brominated flame retardants were not detected. Of the elements the levels of Cd were high and the levels of Zn, Hg and Se were considerable (concentrations were compared to other Arctic seabirds). The preliminary results indicate that PFASs and Hg:Se ratio were correlated to the TSH levels and that Cd was associated with the level of TT3, FT4 and TT3:FT3. The level of Zn was associated with the level of TSH and TT3. Follicle count in the thyroid gland was positively correlated with Hg and showed a possible relationship to the levels of PFAS but the results were inconclusive. The relationship between POPs and the thyroid variables need to be further investigated. The project is funded by The Research Council of Norway, no 268419.

TU331

Influence of Permafrost Disturbances and Increased Turbidity on Trends of Mercury and other Elements in Arctic Char in East and West Lake, Melville Island, Nunavut

D.C. Muir, Environment and Climate Change Canada / Aquatic Contaminants Research Division; B. Barst, University of Alaska Fairbanks; X. Wang, Environment and Climate Change Canada / Aquatic Contaminants Research Division; A. Cabrerizo, IDAEA-CSIC / Department of Environmental Chemistry; J.L. Kirk, Environment and Climate Change Canada / Aquatic Contaminants Research Division; D. Iqaluk, Resolute Bay; M. Pope, Queens University; S. Lamoureux, Queens University / Dept. of Geography and Planning; M. Lafrenière, Queens University / Department of Geography and Planning

The Cape Bounty Arctic Watershed Observatory (CBAWO) on Melville Island in the Canadian Arctic Archipelago, includes two adjacent, geologically similar watersheds, West and East, which are currently undergoing climate-driven changes. Climate over the period 2007-2012 was unusually warm during summer months and resulted in changing hydrology and permafrost degradation across the area. In addition, West Lake experienced subaqueous slumps over this period, which may also be related to permafrost thawing along the shoreline. The East Lake catchment has experienced only minor permafrost disturbances, and no change in turbidity. We are investigating whether these changes are also seen in bioaccumulation of mercury (Hg) and other contaminants in landlocked arctic char (*Salvelinus alpinus*) and the food webs of West and East Lakes. Char have been collected annually at the end of July, from 2008 to 2018 (except for 2010), and analysed for a suite of 34 elements using ICP-MS, and Hg usingUSEPA Method 7473 with a Direct Mercury Analyser. Carbon (C) and nitrogen (N) stable isotope analysis showed that char have significantly more depleted $\delta^{13}C$ in adult char (>200 g) in East vs West Lake (mean ± SD; -27.27±0.81 ‰ (N=98) vs -24.73±1.17 ‰ (N=97)) indicative of greater terrestrial and benthic carbon inputs to West Lake. The combined results from 2008 to 2018 collections show that the West Lake adult char have significantly higher concentrations of Hg (geomean/range = 0.146 (0.036-0.581 ug/g wet wt)) compared to East Lake (0.079 (0.023-0.285 ug/g wet wt)) and this difference is even greater if results are adjusted for $\delta^{15}N$ or length. Condition factors (g*100/cm^3) for adult char in West Lake have declined since 2008 and over the period 2011-2018 have been significantly lower (0.62±0.12) than those in East Lake (0.66±0.09) indicating they are thinner than fish of the same length in East Lake. This may be due to difficulty feeding in West Lake's turbid waters. Hg concentrations have declined steadily in East Lake char over the period 2008 to 2018 (averaging -6.7 %/yr) while increasing (5.3 %/yr) in West Lake from 2009-2018. The higher concentrations and increasing Hg in West Lake char are consistent with higher inputs into West Lake resulting from extensive permafrost disturbance in the watershed as well as from higher suspended particulate concentrations in lake waters due to the turbidity

TU332

Do population parameters influence the role of seabird colonies as secondary pollutants source? A case study for Antarctic ecosystems

C.Z. Cipro, Instituto Oceanográfico da Universidade de São Paulo / LabQOM; P. Bustamante, University of La Rochelle; R.C. Montone, Universidade de Sao Paulo / Oceanographic Institute; L.C. Oliveira, Universidade Federal de Minas Gerais; M.V. Petry, UNISINOS

Antarctica is home to a large avifauna of both endemic and migratory bird species. Recent studies, including some by the authors of the present work, confirmed the role of seabird colonies in Antarctic ecosystems as relevant secondary sources of Persistent Organic Pollutants (POPs) and Trace Elements (TEs) as well. Birds undergo bioaccumulation and biomagnification of these pollutants throughout their lives and, during their reproductive period, they gather in large numbers into large colonies and excrete and die on land. This represents a local source of not only nutrients to terrestrial and possibly coastal marine ecosystems, but also of POPs and TEs. When comparing the data obtained within our previous works and published literaturen most cases, colonies of birds of higher trophic level (therefore more prone to biomagnification), generally small and sparse did not present an influence as stark and as frequent as the large and dense colonies of birds with a lower trophic level. By means of a cross examination of the datasets of two papers of the authors verifying the role of the colonies as secondary sources of POPs and TEs and also census data of the very same spots, we could explore the influence of population parameters and not only the trophic level of the species. Preliminary results obtained by correlation analyses and Generalized Linear Model building and ranking by the corrected Akaike Information Criterion (AICc) suggest that the total population parameter is of equal or more importance than the previous categorical (location, colony species, matrix species) and continuous ones (%C, %N, $d^{13}C$ and $d^{15}N$) in several cases: for Hg in soil, for Cd in mosses and soil, and for PCBs in mosses. Interestingly, the population parameter was not present in the most accurate models for lichens, likely due to the fact that most of the analytes of interest are volatilized and not absorbed by the lichens at the same rate as the organic matter originated from the colonies. The dynamic parameters of the populations are yet to be included in the analyses and might also shed a light on the issue in the upcoming publication. Yet, as both population parameters and dynamics can be affected by climate change, some indirect effects could be hypothesised in the near future based on our results.

TU333

Temporal trends of persistent organic pollutants in Barents Sea polar bears (Ursus maritimus) in relation to changes in feeding habits and body condition

A. Lippold, Norwegian Polar Institute / Ecotoxicology; S. Bourgeon, University of Tromsø / Department of Arctic Marine Biology; J. Aars, The Norwegian Polar Institute; A. Polder, J.L. Lyche, Norwegian University of Life Sciences /

Department of Food Safety and Infection Biology; J. Bytingsvik, Akvaplanniva; B. Jenssen, Norwegian University of Science and Technology / Biology; A.E. Derocher, University of Alberta / Department of Biological Sciences; J. Welker, University of Alaska Anchorage; H. Routti, Norwegian Polar Institute
Temporal trends of persistent organic pollutants (POPs: PCBs, OH-PCBs, *p,p'*-DDE, HCB, β-HCH, oxychlordane, BDE-47 and 153) in relation to changes in feeding habits and body condition in adult female polar bears (*Ursus maritimus*) from the Barents Sea subpopulation were examined over 20 years (1997-2017). All 306 samples were collected in the spring (April). Both stable isotope values of nitrogen ($\delta^{15}N$) and carbon ($\delta^{13}C$) from red blood cells declined over time, with a steeper trend for $\delta^{13}C$ between 2012 and 2017, indicating an increasing intake of more terrestrial and lower trophic level prey. Body condition, based on morphometric measurements, did not significantly change between 1997 and 2005, and increased significantly between 2005 and 2017. BDE-153 and β-HCH concentrations in plasma were stable over time, whereas Σ_4PCB, Σ_5OH-PCB, BDE-47 and oxychlordane declined linearly. Plasma concentrations of *p,p'*-DDE and HCB, however, declined until 2012 and 2009, respectively, and increased thereafter. Climate-related changes in feeding habits and body condition did not significantly affect POP trends. The study indicates that changes in diet and body condition were not the primary driver of POPs in polar bears, but were controlled in large part by secondary and/or possibly primary POP emissions.

Human Health and Environmental Risk Assessment of Chemical Mixtures: Moving Towards the Non-toxic Environment (P)

WE001
Considerations to modify "WHO/IPCS framework on risk assessment of combined exposure to multiple chemicals" for regulatory environmental risk assessment
K. Yamazaki, Ministry of the Environment / Environmental Health
The goal of our study on mixtures assessment is to develop the way to introduce "assessment of combined exposure to multiple chemicals" into environmental risk assessment practices for regulatory objectives, such as selecting high-priority chemicals, setting criteria/standards, or identifying chemicals to be regulated. The WHO/IPCS Framework on risk assessment (RA) of combined exposure to multiple chemicals would be useful for regulatory approach. We have been considering how we should adapt the framework to our RA practices, from screening-level to comprehensive ones, through case studies on environmental RA for some groups of chemicals, such as acrylates and phthalates. Two elements could be included into the Framework for regulatory application. [1] Prior to the tiered risk assessment, the Framework indicates Problem Formulation with rationale to consider combined exposure. In the chemical-by-chemical environmental RA for nationwide regulatory objectives, target chemicals have been selected based on expected or potential environmental risks. Screening-level RA of combined exposure from multiple chemicals should be considered in the similar context. Initially one or a few target chemicals would be selected, without enough information for appropriate problem formulation. Next question should be "Could risk assessment be conducted for the certain chemicals only? Or should any other chemicals with similar structure be considered for risk assessment as well?" Reasonably conservative consideration should be included in the Framework, so as not to overlook false negatives with limited/insufficient information. [2] The Framework, which was designed for human health RA, cannot be applied to regulatory environmental RA as it is. Tiers in the Framework can be correlated with respective stages of the existing regulatory RA practices, where PNEC values have been derived referring to ecotoxicological studies. Characterization of common effects might not necessarily be practical for ecotoxicity data, where knowledge on mode of action cannot always be available or identifiable. Instead we might have to be satisfied with derivation of relative potency factors (RPFs) by just knowing similarities/tendencies of ecotoxicity values. These modification should be included into the Framework. Detailed considerations to modify WHO/IPCS framework for regulatory environmental risk assessment will be presented at the Meeting.

WE002
From mapping to identification: Paving the way to UVCB risk assessment
S.E. Deglin, ILSI Health and Environmental Sciences Institute (HESI); M. Embry, Health and Environmental Sciences Institute HESI; D.T. Salvito, Research Institute for Fragrance Materials, Inc. / Department of Environmental Science; D. Lyon, Shell Oil Company / Shell Health Risk Science Team; E. Leinala, OECD
Risk assessment of complex substances such as multi-constituent substances, and substances of Unknown or Variable Composition, Complex Reaction Products, and Biological Materials (UVCBs), presents numerous challenges. International regulatory programs (specifically REACH, Canada's Chemicals Management Plan, and USEPA's PMN process) have highlighted the complexities of characterizing fate and exposure, risk assessment, and registration of these types of substances. This is why HESI's UVCB Committee is working on an approach to assess ecological risks of UVCBs, and meet regulatory needs. First, a framework was created to map the vast and complex universe of UVCB substances according to chemical and/or functional classes, exposure and use patterns, production volume, potential toxicity and other criteria. This grouping system is the foundation of all work performed on this project, by providing a better understanding of the nature of these substances and their sector of use, as well as some insight on which substances present the most significant regulatory challenges. In a second step, the Committee will develop identification and characterization strategies for the mapped substance groups. For each group, the overall goal is to determine the minimum level of information required to perform a robust and fit-for-purpose ecological risk assessment. To do so, the Committee has been exploring various issues for given substance categories, including definitions of acceptable levels of uncertainty and variability to assess risks; strategies to characterize substances with limited or no structural information; and development of criteria that could be used in a weight of evidence approach. Characterization approaches have included discussions around how knowledge of source material and production processes can help inform substance identification. This two-pronged approach is expected to ensure that the efforts and resources deployed for UVCBs risk assessment match actual needs, and help streamline the risk assessment process. Examples of UVCB mapping will be presented, and some of the most common categories of UVCBs will be highlighted along with the associated assessment challenges. Substance identification and characterization methods will be illustrated, as well as how they provide the necessary information for a reliable risk assessment.

WE003
Environmental Risk Assessment of Technical Mixtures under REACH - a regulatory view on the LCID methodology
W. Galert, German Environment Agency; E. Hassold, Federal Environment Agency (UBA) / IV 2.3 Chemicals
Chemicals are usually processed and end up in mixtures. Still, the REACH regulation focuses on single substances and their safe use conditions, while in other substance regulations mixtures are partly addressed during product authorization. For REACH an environmental risk assessment of mixtures is challenging: Manufacturers or importers of chemicals into the EU are responsible for registering their substance and provide information for intrinsic substance properties, information on fate and behavior, and hazards and risk. The registrant is required to assess the intended uses and processing, but lacks often information to assess the safe application during the entire lifecycle. The downstream users know the details on formulation and processing of their mixture(s) or product(s), but only have basic data to adapt the environmental risk assessment or derive the safe use amounts. REACH addresses the safe use of single substances in technical mixtures, but not explicitly the possible risks arising from joint effects and exposures of components in mixtures (Art. 10 of the REACH Legislation). From the regulatory point of view it is important to tackle mixtures already at the "source" concerning their uses and possible technical mixtures, before substances enter environmental compartments regardless of their common impact. Assessment and regulation of these common impacts are only possible at this level. The safe use for technical mixtures has to be ensured. Indeed, REACH actors have legal obligations (Art. 33 of the REACH Legislation) to ensure safe use of articles and substances, also substances in mixtures. Recently, some attempts have been made by industry organizations with the concept of LCID to improve the assessment and communication of safe use conditions for technical mixtures. However, essential improvements are needed with respect to data availability, quality and communication, the selection of substances to be considered during an assessment, training and guidances for downstream-user. Until now, LCID seems to be rather a prioritization and communication tool than providing a complete environmental risk assessment of chemical mixtures. Downstream user need training and support by guidances or also alternative methodologies if a derivation of safe use conditions is impossible due to scarce data. We will highlight the need to further develop mixture assessment under REACH.

WE004
Chemical activity as a unitless measure to assess the impact of chemical mixtures on the environment
S.K. Roth, Stockholm University, ACES / Department of Environmental Science and Analytical Chemistry; E. Gorokhova, A. Sobek, Stockholm University / Department of Environmental Science and Analytical Chemistry (ACES)
Aquatic sediments in river beds, lakes, and the oceans serve as a sink for many organic chemical pollutants that are persistent, bioaccumulative, and toxic, thereby posing long-term health threats towards the environment and humans. Microbial communities play an essential role in controlling the transformation and mineralization of organic compounds, rendering these consortia as suitable model systems to study the environmental impact of contaminants. Most studies focus on single pollutant effects, but knowledge about the impact of chemical mixtures is scarce. The two main reasons are: 1) measuring concentrations of all potential contaminants in the environment is unrealistic due to the technical challenges and analytical costs, and 2) the sum of the measured concentrations of different chemicals does not inform us about the exposure levels, because toxic concentrations are compound-specific. To overcome these constraints, we will investigate the effect of chemical mixtures on microbial communities using the

concept of ‘chemicalactivity’,a unitless proxy for quantification of chemical exposure in non-ideal solutions. This approach allows integratingexposure to organic contaminant mixtures using a combination of concentration and chemical solubility as a measure of chemical saturation in the system. In experiments, we will expose microbial communities to chemical mixtures, with the concentration of each chemical below the threshold level of its specific toxicity. The latter will ensure that the observed effects are not related to the specific mode of action of the test chemicals present in the mixture. Total community activity metrics, such as growth and respiration, will be used as endpoints. Moreover, to evaluate possible biogeochemical responses to the exposure, we will analyse functional gene abundance in the community. These experiments will help to understandand assess the resilience of sediment communities towards chemical pollution as well as to develop useful community-level proxies.

WE005

Predicting ecological changes downstream of wastewater outfalls

N. Furmanski, Unilever / Safety and Environmental Assurance Centre SEAC; E. Butler, Unilever RD Colworth / Safety and Environmental Assurance Centre SEAC; G. Hodges, Unilever Research / Safety and Environmental Assurance Centre; M.J. Whelan, University of leicester

In many regions of the world, untreated wastewater is discharged directly into rivers containing sanitary determinands including ammonia, nitrite and organic matter which places a demand on dissolved oxygen in the water. The wastewater may also contain chemical ingredients of home and personal care products. When sewage treatment is lacking, often in developing regions, these sanitary determinands and down-the-drain chemicals could be present at concentrations in surface waters which may adversely impact the ecological communities present downstream of the effluent outfall. Some studies have investigated these ecological effects by sampling the taxa present at regular intervals downstream of a wastewater outfall, from which a common pattern in terms of macroinvertebrate species richness, dominance and diversity throughout the impact zone is evident. The aim of this work was to develop a model to predict the ecological composition downstream of an effluent outfall, as a result of the concentration gradients of multiple stressors. The model combines water quality data and toxicity data of the stressors on aquatic organisms, in the form of species sensitivity distributions (SSDs) to predict this impact against the exposure of the stressors. The model was based on selected stressors: ammonia, nitrite and dissolved oxygen which are present, in particular, in untreated wastewater; two chemical ingredients used in home and personal care products (LAS and triclosan) which are washed down-the-drain. First order rate kinetics were applied to predict the stressors’ decreasing concentrations, while the varying dissolved oxygen concentrations were predicted using the Streeter-Phelps model. The model was applied to measured data from a field study on the South Elkhorn Creek in Kentucky, USA. Predicted effects on taxonomic composition were in line with field observations, although further enhancements to the model could incorporate more environmental realism. This was a useful step in the direction to creating a model of the impact zone ecology in rivers.

WE006

Risk-based prioritization of multiple metals in seafood among children and teenagers and implications for food safety management

Y. Lin, J. Hsiao, National Yang-Ming University / Institute of Food Safety and Health Risk Assessment

Human health risks associated with the consumption of metal-contaminated seafood have received continual public concern. Multiple metals simultaneously accumulate in a variety of seafood and therefore pose mixture health risks to humans. Given the multitude of potential foodborne hazards, limited resources should be focused on the greatest risks among the many metals and seafood products. The RISK21 visualization methodology, developed by the Health and Environmental Sciences Institute, is a useful tool in priority setting. Therefore, the major purpose was to apply the RISK21 methodology to compare and rank health risks posed by multiple metals through consumption of seafood products among children and teenagers in Taiwan for identifying which metals and seafood products should be of priority concern. The concentrations of metals in a variety of seafood sold in markets were obtained from the Taiwan government. Using data from the Nutrition and Health Survey in Taiwan, we quantify the consumption rates of various seafood products for toddlers (0 – 3 years), preschoolers (3 – 6 years), children (6 – 12 years), and teenagers (12 – 18 years). The possible joint toxic actions of metal mixtures were characterized mainly based on toxicity interaction information available from the Agency for Toxic Substances and Disease Registry. We found that the mixture of inorganic arsenic (iAs), cadmium (Cd), lead (Pb), and methylmercury (MeHg) cause neurological toxicity. The RISK21 shows that the iAs and MeHg in saltwater fish as well as Cd and Pb in shellfish were listed as high priority for food safety management for children of all ages. Moreover, Pb in saltwater fish and Cd in cephalopods were listed as high priority for toddlers and teens, respectively. We thus suggest that regular monitoring of iAs and MeHg in saltwater fish as well as Cd and Pb in shellfish and cephalopods are warranted. Our work helps to identify metals in several types of seafood products that warranted the regular monitoring, allowing risk manager to design the risk-based monitoring program and the possible strategies for food safety management.

WE007

Mixture risk assessment and prioritization of multiple aldehydes in fried foods

W. Ting, National Yang-Ming University; S. Huang, Taipei Medical University; C. Yang, J. Kang, National Yang-Ming University; Y. Lin, National Yang-Ming University / Institute of Food Safety and Health Risk Assessment

Low molecular weight aldehydes are produced during the deep-frying produces as a result of the dehydration of glycerol. Many of the aldehydes have been considered the mutagenic compounds associated with the genotoxicity, carcinogenicity, and oxidative stress, including formaldehyde (FA), acetaldehyde (AA), and acrolein (AC). The purpose of this study was to (1) assess the mixture health risks of co-exposure to FA, AA, and AC through dietary intake of fried foods for different age populations in Taiwan and (2) to identify which fried foods pose the greater dietary exposure risk to each age population through risk prioritization. In this study a total dietary study-like investigation was conducted to design a sampling list of fried foods that most commonly consumed by Taiwanese. Concentrations of FA, AA, and AC in fried foods were analyzed using the headspace solid-phase micro-extraction-gas chromatography-mass spectrometry. Hazard index (HI) was used to characterize the mixture risks posed by the dietary intake of FA, AA, and AC from fried foods. Moreover, the RISK21 approach was applied to perform risk ranking. The concentrations of FA, AA, and AC in fried noodles were 3.26 (95% CI: 1.59–5.89 mg/kg), 33.08 (8.21–92.24 mg/kg), and 1.62 mg/kg (0.49–4.07 mg/kg), respectively. For potato chips, the levels of FA, AA, and AC were 2.43 (1.21–4.90 mg/kg), 18.86 (5.94–61.05 mg/kg), and 1.91 mg/kg (0.66–5.59 mg/kg), respectively. Risk analysis showed that children had the highest risk of gastrointestinal tract damage, with 97.5th percentile HI estimate of 4.16. For teenagers, adults, and elderly persons, HI estimates were all less than one. RISK21 analysis indicated that health risks related to the consumption of fried noodles were moderate concern for children. Our analyzes indicate that the health risk associated with dietary exposure to multiple aldehydes in fried foods is unlikely to occur for most populations but is a potential health concern for children.

WE008

Accumulation of perfluoroalkylated acids (PFAAs) in Belgian home-produced chicken eggs along different directions from a fluorochemical plant

R. Lasters, UA / Biology; T. Groffen, Systemic Physiological and Ecotoxicological Research (SPHERE), University of Antwerp / Department of Biology; M. Eens, University of Antwerp / Department of Biology; L. Bervoets, University of Antwerp / Department of Biology (SPHERE Research Group)

Perfluoroalkylated acids (PFAAs) can enter the food chain due to their persistence, widespread use and global distribution. Field research has demonstrated that these substances can bioaccumulate and biomagnify in wildlife. Hence, it is very plausible that PFAAs can biomagnify to high concentrations in humans. For these reasons, PFAAs may pose a significant risk to human health as residents may inadvertently consume PFAA contaminated food. Over the last decade, humans consuming food products from self-cultivated origin has become a remarkable trend in rural, urban and even industrial environments. For instance, the housing of free-ranging chickens for egg production has gained popularity as eggs constitute an important component of the Western-European diet. At the same time, the dominant exposure pathway of PFAAs is the dietary intake route. Therefore, the main objective of this study was to analyze and examine the pattern of PFAAs in home-produced chicken eggs from households and to assess potential health-risks of PFAAs via consumption of these eggs to local residents. In total 70 individual eggs were collected from 35 volunteers who kept free-ranging laying hens within a radius of 5 Km from a fluorochemical plant in Antwerp. In total, nine PFAA compounds could be detected in the egg samples. Perfluorooctane sulfonic acid (PFOS) and perfluorooctanoic acid (PFOA) were the two most frequently detected compounds with equal detection frequencies of 97%. The concentrations of these compounds ranged from, respectively, 0.54 – 241 ng/g ww and 0.21 – 2.38 ng/g ww. PFOS concentrations followed a clear decreasing pattern from the fluorochemical plant onwards, which indicates that ingestion of soil particles and organisms through pecking behavior might be a dominant source of PFAA contamination in the eggs. PFOS concentrations in some of the eggs exceeded the tolerable daily intake (TDI) values. This study demonstrates that the consumption of home-produced eggs can be an important dietary exposure pathway of PFAAs to humans, although the concentrations mostly did not exceed the available tolerable daily intake values. Finally, PFOS may represent a possible health-risk to local residents via the consumption of home-produced eggs.

WE009

BEA (biomonitoring in adolescents) study protocol: design of a national human biomonitoring survey in spanish adolescents

J. Ramos, ISCIII / CNSA; M.G. Motas, CNSA ISCIII / CNSA; S. Gónzalez, ISCIII; M. Esteban, S. Gomez, M. Rosado, A. Castaño, ISCIII / CNSA

In 2016, the Ministry of Agriculture, Food and Environment (MAPAMA) funded the BEA (biomonitoring in adolescents) study, the first nationwide human biomonitoring survey carried out in Spain to study the levels of selected environmental pollutants in urban Spanish adolescents (14-16 years old). The different step needed to develop this human biomonitoring study, both field work preparation and the sampling campaign development will be presented. In summary, adolescents of both gender, were recruited through twenty secondary school centers from 11 cities with more than 150000 inhabitants. These cities were selected taking into account their distributed throughout the entire Spanish territory, prioritizing those in which no similar studies had been carried. The environmental pollutants include in BEA Study were metals: urinary mercury, total mercury in hair and urinary cadmium, as well as organic plasticizer additives such as Bisphenols and phthalates metabolites in urine. Sampling was carried out from October 2017 to February 2018, and it included the sample collection of hair and urine that were mandatory matrices. In addition, blood sample for future studies on persistent organic pollutants was taken as voluntary matrix. A self-administered epidemiological questionnaire was completed by all participants to compile individual information on lifestyle, environment and diet in order to assess potential exposure determinants related to the pollutants studied. The sample thus obtained had a total number of 498 adolescents. Acknowledgments: This work has been funded by MAPAMA and ISCIII

WE010

Adding up apples and pears: Mixture toxicity in environmental and human health pesticide risk assessment

J. Baumann, Bayer AG Crop Science Division / Occupational/Residential Exposure; F. Laporte, Bayer AG Crop Science Division / Dietary Safety; M. Ebeling, Bayer AG Crop Science Division / Ecotoxicology - Terrestrial Vertebrates Expert Team; K. Bender, Bayer AG Crop Science Division / Crop Science Ecotoxicology; A. Weyers, Bayer AG - Crop Science Division / EnSa. Ecotoxicology

Often it is stated that current risk assessment of pesticides insufficiently addresses mixture toxicity. To help understand the coverage in current risk assessment guidance for human health and the environment, we present the current approaches, their commonalities and differences in an orchard case study and make recommendations how to align and simplify them. Consumer (dietary) risk assessment: Combined risk assessments for those active substances present in the same (mixed) formulation can be performed in a straightforward manner, using a tiered approach that assumes dose addition and can focus on compounds with similar toxic effects. Non-dietary risk assessment: In order to ensure a safe use of plant protection products for farmers handling the products (operators), workers re-entering a treated field, or bystander and residents who are only occasionally present in adjacent areas during or after pesticide use, combined risk assessments have to be presented for all active ingredients present in one product, assuming dose addition. Hazard quotients of the single active ingredients of the formulation are simply summed up to obtain a hazard index for the mixture. Environment: For birds and mammals, to the recent past, the formulation was tested in acute oral LD50 studies on birds (usually the Bobwhite quail) and mammals (usually the rat). Under EU regulation 1107, to reduce vertebrate testing, calculation methods are normally employed to predict the mixture toxicity of formulations. Two calculation methods (for birds, LD50mix according to EFSA GD B&M 2009, for mammals ATEmix according to CLP regulation 1272/2008) are conceptionally similar; however there are also some differences. For long-term risk assessments, no straightforward approach is commonly used, except for the TERmix in some EU central zone member states. For aquatic species, usually acute studies with the a.s. and with the formulation are available. In order to conclude on similarity, calculated mixture toxicity (ECxmix-CA) is compared against measured formulation toxicity (ECxPPP). Deviations exceeding factor 5 in either direction need to be addressed. In case of overall low toxicity or in case of a clear toxicity driver (a.s. contributing >90%) the assessment can be finalized. If a higher tier assessments is needed, the respective risk quotients (RQ) of each a.s. are added to calculate an RQmix, identical to (but differently named than) the hazard index in consumer risk assessment.

WE011

Risk Assessment of Pesticide Residue in Fish Samples From Donga River; health impact on consumers

G.T. Otitoju, University of Nigeria Nsukka / human nutrition and dietetics; O. Otitoju, federal University Wukari / Biochemistry Department

The use of obsolete or banned pesticides in most developing nations gives more reasons to worry because of the health of consumers of agricultural and fish products. In this study, the levels of the pesticide residues (DDT, DDD, Dieldrin, Aldrin, dicofol, methoxychlor, endosulfan, chlordane, heptachlor, pentachlorobenzene, mirex, toxaphene, hexachlorobenzene, α-HCH, β-HCH, and γ-HCH) in river Donga, Taraba State, Nigeria were assessed using fish samples from Donga river as a case study. Five fish species (*Synodotis membranaceus*, *Protopterus annectens*, *Clarias gariepinus*, *Heterotis niloticus* and *Tilapia zilli*) were collected for from the river for possible analysis for pesticide residues. The result showed that α-HCH, β-HCH, and γ-HCH were the most abundant pesticide residues in the fish samples. The result also showed that levels of α-HCH, β-HCH, and γ-HCH in *Synodotis membranaceus cupside* were above the maximum residue limits (MRLs). Therefore the health of consumers may be at higher risks when exposed to fish products from Donga river.

WE012

Elevated blood metal levels and cytogenetic damage induced in rats exposed in-situ to underground water and ambient air emissions at a municipal landfill, Nigeria

A.M. Gbadebo, University of Ibadan, Ibadan. Nigeria / Ecology and Environmental Biology Unit, Department of Zoology; O.A. Alabi, Federal University of Technology, Akure / Department of Biology; C. Alimba, University of Lagos, Nigeria / Department of Zoology; A.A. Bakare, University of Ibadan Ibadan Nigeria / Department of Zoology

Solid waste landfills in developing nations have been known to be major source of environmental pollutants including heavy metals, thus, constituting ecological risk to exposed populations. This study herein investigated the levels of lead (Pb), cadmium (Cd), chromium (Cr) in blood and potential cytogenetic alterations in rats exposed *in-situ* to underground water and ambient air emission from Olusosun landfill in Lagos, Nigeria. Male Wistar rats (5 rats/point/duration) were exposed at three different points to air emissions and underground water (via drinking) from the landfill for 4, 8, 12, 16, 20 and 24 weeks. Rats concurrently sited at 17.3 km from the landfill site served as control. Rats' blood levels of Pb, Cd and Cr were measured after each exposure periods using atomic absorption spectrophotometer (AAS) and formation of bone marrow micronucleus and polychromatic erythrocyte/normochromatic erythrocytes (PCE/NCE) ratio were analysed. The strength of the linear relationship between blood metal levels and cytogenetic alterations were determined using Pearson's correlation analysis. Blood levels (in mg/L) of Pd, Cd and Cr in the landfill exposed rats were significantly elevated ($p < 0.05$) compared to those of the corresponding control throughout each periods of exposure. Also, there was significant ($p < 0.05$) increase in the frequency of micronucleated polychromatic erythrocytes (MNPCE) with significant ($p < 0.05$) decrease in PCE/NCE ratio at all points and periods of exposure compared to the control. No strong correlation ($p > 0.05$) was observed between blood metal levels and exposure periods; frequencies of MNPCE; and PCE/NCE ratios respectively during the study periods. The concentrations (mg/L) of heavy metals such as Pb, Cd, Cr, Cu and Fe in the underground water were observed to be above permissible limit for drinking water. *In-situ* exposure to underground water and air emissions at the landfill led to elevated blood levels of heavy metals in exposed rats. However, no strong correlation observed between blood metal levels and cytogenetic damage implies that other unanalyzed toxic agents present in the landfill compartments might have contributed either additively or synergistically with the metals in inducing the observed cytogenotoxicity in the erythropoietic stem cells. This finding is of ecological and health risk to animal and human populations who co-exist in the vicinity of major municipal waste dumpsites in developing countries.

WE013

Assessing health risk from mixture exposure to ethanol and acetaldehyde through drinking alcoholic beverages

P. Wu, National Yang-Ming University; S. Huang, Taipei Medical University; J. Kang, C. Yang, National Yang-Ming University; P. Lin, National Institute of Environmental Health Sciences; Y. Lin, National Yang-Ming University / Institute of Food Safety and Health Risk Assessment

Previous studies have explored the health risk associated with alcohol consumption; however, their studies have exclusively examined single ethanol (ETOH) or acetaldehyde (ACE) and have not yet fully considered the consider alcohol metabolism. Individuals with ALDH2-deficiency are unable to metabolize acetaldehyde, resulting in toxic ACE accumulating in the body. The prevalence of ALDH2*2 variant in Taiwanese is as high as 45–47%. Thus, this study aims to investigate the health risks of ETOH and ACE posed by drinking alcoholic beverages for adult Taiwanese with different ALDH2 genotypes. This study calculated daily intakes (DIs) of ETOH and ACE by multiplying the probability distribution of daily consumption of three types of alcoholic beverages (beers, wines and spirits) with the corresponding probability distribution of ETOH and ACE concentrations. By using data from the National and Health Survey in Taiwan, we estimated the consumption rates of different alcoholic beverages for adult Taiwanese. A previously well-developed human PBPK model with genetic polymorphism of ALDH2 was applied to quantify simultaneously the internal doses of both ETOH and ACE in liver. According to the available epidemiological and animal studies, we used benchmark dose modeling and the human equivalent dose approach to estimate point of departure (POD). We then converted PODs to corresponding internal dose metrics using human PBPK model. The concept of margin of internal exposure (MOIE) was used to assess the health risks of ETOH and ACE posed by drinking alcoholic beverages. We found that drinking spirits contributed highest DI estimates of ETOH and ACE for adult Taiwanese. Based on human epidemiological data, the estimated $BMDL_{1.5}$ was 35.73 mg/kg/day. Because of the lack of human data of ACE, the HED associated with animal NOAEL was estimated to be 21.88 mg/kg/day for hepatotoxicity. An acceptable MOIE for an internal dose-based risk assessment was considered 10 (interspecies difference). MOIE estimates of ETOH for individuals with any ALDH2 genotype were less than 10, indicating a high potential risk for liver damage from alcohol consumption. The MOIEs of ACE for individuals with ALDH2*2/*2 genotype

ranged from 68.73 to 5.02 10^5, indicating a low health concern of hepatotoxicity. We suggest that the priority action of alcohol policy for government was to reduce ETOH intake rather than to focus on ACE.

WE014

Probabilistic integrated PBPK model to assess health risk of dietary exposure to acrylamide

Y. Chang, C. Yang, National Yang-Ming University; P. Lin, National Institute of Environmental Health Sciences; Y. Lin, National Yang-Ming University / Institute of Food Safety and Health Risk Assessment

Acrylamide (AA) is formed from numerous carbohydrate-rich foods during heat treatment above 120 °C as a result of Maillard reaction between amino acids, in particular asparagine, and reducing sugars. Lots of *in vitro* and *in vivo* studies have indicated that AA and its metabolites may lead to neurotoxicity, reproductive and developmental toxicity, genotoxicity, and multi-organ carcinogenicity. The major purpose of this study was to integrate probability and physiologically based pharmacokinetic (PBPK) model to assess the potential health risks of AA in 6 different foodstuffs (twisted cruller, brown sugar, potato chips, French fries and hash browns, coffee, as well as cereal and seafood snacks) for adults in Taiwan. Dietary intakes (DIs) of AA were calculated by multiplying the probability distribution of daily consumption of 6 types of foodstuffs with the corresponding probability distribution of AA concentrations. According to the available animal studies, a $BMDL_{05}$ for neurotoxicity was 0.27 mg/kg/day. We then use PBPK modeling approaches to convert external animal $BMDL_{05}$ and human DIs into the corresponding animal and human internal dose metrics. The concept of margin of internal exposure (MOIE) was applied to compare internal dose metrics for assessing the level of health concern of AA for neurotoxicity. A novel approach, termed Risk Assessment in the 21st Century (RISK21), was used to visualize the results of MOIEs and to perform risk ranking for identifying which foodstuffs pose greater dietary exposure risk to consumers. We found that the highest concentration of AA was brown sugar followed by potato chips, whereas coffee had the lowest AA contents. Our analysis results showed that snacks contributed highest DI estimates of AA for adults in Taiwan. Both of the developed animal and human PBPK models can well predict the urinary metabolites of AA (AAMA) and GA (GAMA). The internal dose-based MOIE approach could reduce the uncertainty to 25 (2.5 for interspecies differences in toxicodynamics and 10 for human variability in toxicokinetics and toxicodynamics). Results of the RISK21 showed that health risks of AA in 6 different foodstuffs were low concern. The proposed methodology in this study facilitates to make uncertainties explicit and to clarify the potential health risk of AA in thermally-processed common foods for adults.

WE015

The Toxic Potentials assessment and mitochondrial functions alteration of disinfection byproducts by Human Embryonic Kidney (HEK293) Cell Model

y. chen, Tongji University; T. Xu, D. Yin, W. Chu, X. Yang, Tongji University / College of Environmental Science and Engineering

Disinfection byproducts are inevitably generated during drinking water disinfection processes, and their hazards have not been well characterized. Due to the key role of kidney in fluid-electrolyte balance and detoxification of some xenobiotic, it is predictable that DBPs may do toxicological and pathological damage to human kidney. The human embryonic kidney (HEK293) cell was selected, instead of the commonly reported CHO cell, as a model to investigate the toxic potential and target of different kinds of DBPs. Based on the chronic toxicity parameter EC_{10} of the 24 hour-cell viability-test, we obtained the different toxic ranks of the tested DBPs (TBAL > CDIM > CAM > DBIM ≈ DCIM > BCIM > DCAM ≈ TCAM > TCAL) with previous studies and calculated their risk quotients by combining EC_{10} with chemicals' actual concentrations in drinking water systems. The rank of potential risk quotients for tested DBPs is: DCAM>TCAM>CAM; TCAL>TBAL(N/A); BCIM>DCIM>DBIM>CDIM>BDIM(N/A). Then, mechanism-related bioassays were performed in three representative agents (DCAM, TCAL, and BCIM) from 3 classes of DBPs. The levels of extracellular LDH and intracellular ROS were increased by the exposure of 3DBPs. In addition, significant apoptosis was induced by 10-1000μg/L DCAM/BCIM-treatment and the genes expression involving mitochondrial functions in apoptosis (*CASPASE-3/7/8* and *BCL-2* mRNA) and energy metabolism(*COX17* and *SLC25A6* mRNA) were correspondingly changed by 3 compounds exposure. All results suggested the effects of 3 DBPs interrupting the molecular, physiological and biochemical processes relevant to mitochondrial functions, such as oxidative respiration, apoptosis, and energy metabolism (level of intracellular ROS, basal respiration, ATP production and nonmitochondrial respiration). Our study improved the human risk assessment of DBPs with the help of a convenient model and parameter and revealed that mitochondrion is a potential toxic focus of DBPs exposure at the cellular level. Moreover, the kidney was supposed to be a target organ of DBPs toxicological effects. Additional researches are needed to determine the effects of DBPs for kidney impairment in other kidney cells (like RPTEC/TERT1 and HK2 cells) and reveal the underlying mechanisms.

Effect of PAH mixtures over the glutathione system in HepG2 cells

M. Martins, Faculty of Sciences andTechnology, Universidade Nova de Lisboa / Dep. Science and Environmental Engineering; V. Branco, Research Institute for Medicines (iMed.Ulisboa), Faculty of Pharmacy, Universidade de Lisboa, Lisboa, Portugal; M. Diniz, UCIBIO, REQUIMTE / UCIBIO, REQUIMTE; C. Carvalho, Research Institute for Medicines (iMed.Ulisboa), Faculty of Pharmacy, Universidade de Lisboa, Lisboa, Portugal; M. Costa, MARE - Faculty of Sciences and Technology Universidade NOVA de Lisboa / Department of Environmental Sciences and Engeneering

Environmental carcinogens affect humans and wildlife by several mechanisms, most of which associated to DNA damage and related pathways. Polycyclic aromatic hydrocarbons (PAHs) constitute one of the major groups of potent carcinogens that are ubiquitous in the environment. PAH require metabolic activation by cytochrome P450 (CYP) mixed function oxidases (MFOs) to elicit their deleterious effects, involving the formation of radical cations, diol-epoxides and redox active *0*-quinones. The reactive metabolites produced during PAH activation may form bulky DNA-adducts, while nucleobase oxidation by action of ROS may also occur. It is well known the link between PAH toxicity and carcinogenicity. However, these studies are based on the results of experimental approaches using exposure to a single compound. Nonetheless, in the environment, PAHs invariably occur in complex mixtures. In fact, previous research, in vivo and in vitro, showed complex interactions when binary mixtures of carcinogenic and non-carcinogenic PAHs were involved. Still, how PAH mixtures modulate toxic pathways remains unknown, especially those which are related to the production of reactive oxygen species (ROS). The aim of the present work was to evaluate the mechanism of action of PAH mixtures on the glutathione system and disclose the interaction effects in human hepatoma HepG2 cells. *In vitro* assays were conducted, exposing HepG2 cells to individual and binary mixtures of two PAHs: phenanthrene (Phe) and benzo[b]fluoranthene (B[b]F), with distinct physicochemical properties and carcinogenic potential. Cell viability was determined by the MTT assay. Total glutathione (GSH) levels and GSH oxidation were evaluated as well as the activities and expression of GSH-dependent enzymes such as glutathione peroxidase (GPx) and glutahione reductase (GR). The production of ROS were also determined. Spectrophotometric and fluorometric techniques were applied. In addition, levels of *S*-glutathionylated proteins (PSSG) and Nrf-2 activation were determined by Western blot and the transcription of target gens was evaliated by qRT-PCR. Results showed a 3-4 fold incrase in GSH levels in mixtures relatively to single PAHs which matches the enahnced Nrf-2 signalling observed. However, PSSG was not increased by mixtures enriched in BbF which could indicate a hampering of GST activity.

WE017

Organohalogenated compounds and heavy metals in farmed and wild milkfish and mullets in Tanzania. Implication for human and fish health risk.

E.B. Mwakalapa, Norwegian University of Life Sciences / Department of Food Safety and Infectious Biology; C.K. Simukoko, University of Zambia / Department, Biomedical Sciences; A.J. Mmochi, Institute of Marine Sciences; R.H. Mdegela, Sokoine University of Agriculture; V. Berg, Norwegian University of Life Sciences; M.H. Müller, J.L. Lyche, A. Polder, Norwegian University of Life Sciences / Department of Food Safety and Infection Biology

Fish consumption is known to have several health benefits for humans. However, the bioaccumulation of organohalogenated compounds (organochlorine pesticides (OCPs), polychlorinated biphenyls (PCBs), brominated flame retardants (BFRs) and perfluoroalkyl substances (PFASs) and heavy metals in fish could pose health risks to human and fish. Therefore in 2016, farmed and wild milkfish and mullet from Tanzania were investigated for these contaminants and assessed for their potential health risk. *p,p'*-DDE and Pb were the major contaminants in the fish. Concentrations of *p,p'*-DDT were 572 times higher in the wild milkfish than in farmed milkfish from the same area. The varying ratios of *p,p'*-DDE/*p,p'*-DDT reflected both historical and recent use DDT in Tanzania. HCB, HCHs and trans-nonachlor concentration were low reflecting positive measures after their ban. Influence of various human activities in Tanzania were reflected by low but varying levels of PCBs and PBDEs. Pb was detected in concentrations above maximum limit (ML) in 100% of the analysed fish from Tanzania. Pb concentrations were higher in wild fish than in farmed fish. This suggest that Pb pollution is more prevalent in wild fish in the Indian ocean than in farmed fish. Whereas the exceeding concentration of Pb might pose potential health risk to human, the concentrations of Hg beyond EQS_{Biota} and high concentration of Pb might affect fish health and can threaten biodiversity and aquaculture development. The estimated weekly intake (EWI), total hazard quotient (THQ) and hazard index (HI) for heavy metals in farmed and wild milkfish and mullet from Tanzania indicated no potential health risk through consumption. However, Pb contributed much to the HI in the fish from Tanzania and it might pose health risk to the communities that mostly depend on fish for diet. In general, this study revealed that wild fish are more contaminated with organonohalogenated compounds and heavy metals than farmed fish. Findings of this study calls for further investigation of sources of Pb, especially in wild fish from the ocean. Moreover, future investigations should include regular monitoring of heavy metals and POPs in farmed and wild fish in Tanzania for further development of aquaculture and the welfare of the wild fish stock in the coastal waters.

WE018
Ecotoxicological assessment of the environmental impact of anti-corrosion coatings
A. Bell, S. Brand, T. Ternes, G. Reifferscheid, German Federal Institute of Hydrology; S. Buchinger, Federal Institute of Hydrology / Department G Biochemistry Ecotoxicology
Steel structures such as bridges, wind turbines and lock gates exposed to the environment are subject to corrosion and need to be protected to improve the durability and thus to ensure their structural stability. Active methods which are using a protective current, and passive methods which mechanically isolate the steel from its environment, can be applied. The latter strategy is commonly pursued by the application of organic coatings which are based e.g. on epoxide and polyurethane resins. In contact with water, various organic substances might be released from the coatings into the environment. Known ingredients of concern for example are Bisphenol A, Nonylphenols and different aromatic hydrocarbons. Furthermore, compounds with unknown ecotoxicological effects might be formed during polymerization (hardening) or the reaction with water. The investigation of possible adverse effects by anti-corrosion coatings on the environment is one aim of a Network of Experts funded by the German Ministry of Transport and Digital Infrastructure (BMVI). For this purpose different coating systems for steel and hydraulic engineering were applied on steel plates and leached with deionized water. To simulate the weathering of coating materials, a subset of plates was exposed to UV-radiation. A range of bioassays was used to investigate the prepared eluates for possible acute toxic impacts on daphnia, freshwater algae and luminescent bacteria as well as mutagenic and estrogen-like effects. Up to now, a legal framework for the assessment of anti-corrosion coatings in Germany is missing. Therefore, an evaluation concept suggested by the German Institute for Building Technology (DIBt) for the assessment of the impact of construction products on soil and groundwater was applied to compare the analyzed coating systems and interpret the toxicological results.

WE019
New natural biocides for application on concrete masonry of historical interest
E. Marconi, University of Roma Tre / Science; M. Fidanza, Link Campus University / Research; F. Geminiani, Leonardo S.r.l.; C.M. Medaglia, Link Campus University / Research; A. Galetti, Leonardo S.r.l.
In recent years, different research groups have been studying new biocidal products also usable in cultural heritage that are more sustainable for the environment and human health. In particular, these products could be used in restoration procedures to prevent or eliminate biological patinas grown on cultural heritage masonry. Growing interest is now addressed to the use of essential oils (EOs) as antimicrobial substances, in medical, industrial, food, and many other sectors. Oregano and thyme EOs are among the most effective oils and, for this reason, they have also been investigated in the field of cultural heritage. In this research, we developed an OEs-based biocide,applied on a concrete masonry in a monumental complex of historical interest. It had a patina composed of many species of fungi. We developed a blend made of oregano and thyme essential oils, whose active substances are monoterpenes and phenolic monoterpenes. The efficacy was tested by evaluating antimicrobial (and, particularly, antifungal) activity using the Bio-Tape method. The analysis was realised on an area homogeneously covered with biological patinas. The EOs efficacy was evaluated in comparison with 3 commercial biocides: (i) isothiazoline compound (AL); (ii) a combination of isothiazoline and quaternary ammonium salts (BT); (iii) a combination of carbamate and isothiazoline (BR). Our study found that the antimicrobial activity exerted by our OEs blend was comparable to other commercial biocides. Unlike the latter, essential oils have the advantage to be safer and more sustainable than traditional biocides, whose hazard statements and risk phrases have often led to withdrawal from the market of some toxic substances. The future technological development could address the minimisation of the loss of product, due to high volatility of EOs, with formulations which “entrap” the compound, allowing their controlled release to enhance the biocide efficiency.

WE020
Mixture toxicity of copper and its corrosion inhibitor benzotriazole to Daphnia magna
T. Wagner, University of Amsterdam / IBED; M. Dullaart, T. de Groot, University of Amsterdam IBED Institute / FAME; D. Kuiper, T. Verouden, I. de Wolf, University of Amsterdam IBED Institute; M. Kraak, M. de Baat, University of Amsterdam / IBED-FAME
Benzotriazole (BT) is often used as a corrosion inhibitor in cooling tower pipes, to reduce the dissolution of copper (Cu) in water. Hence, cooling towers regularly discharge wastewater containing a mixture of Cu and BT. Cu and BT are toxic to aquatic biota and affect the health of aquatic ecosystems, but since Cu and BT occur in cooling tower water simultaneously, it is possible that mixture toxicity is even more relevant than their individual toxic effects. Therefore, the aim of this study was to examine mixture toxicity of Cu and BT to the water flea *Daphnia magna*. To this purpose, *D. magna* were exposed to concentration ranges of Cu, BT and Cu+BT mixtures in the 48 h *Daphnia magna* acute immobilisation test in ISO medium. First the toxicity of the individual compounds was determined and the LC_{50} values derived from these experiments were subsequently used to compose equitoxic mixtures of Cu and BT tested in the second experiment. There were five concentrations per compound/mixture, four replicates per concentration and five daphnids per replicate. Dose response relationships were constructed from which the EC_{50}-values were calculated using a non-linear regression model. The EC_{50} value for Cu was 8.9 µg/L (95% confidence interval 6.9-11.0 µg/L) and for BT 147 mg/L (95% confidence interval 126-168 mg/L), comparable to the EC_{50} values obtained from literature. The EC_{50} value of an equitoxic mixture of Cu and BT was 1.16 TU (95% confidence interval 1.01-1.31 TU), which suggests that the combination of both chemicals shows a less than additive toxic effect. An explanation for the less than additive effect of the mixture could be the corrosion inhibiting function of BT. To inhibit corrosion, BT forms a layer on copper pipes and it may also form this layer around copper ions. This way, aquatic organisms could be shielded from the toxic effects of Cu. It is concluded that although a mixture of copper and benzotriazole had a less than additive toxic effect, both chemicals still contributed to mixture toxicity, potentially posing a risk to aquatic ecosystems.

WE021
Mixtures of Antibiotics in wastewater treatment effluents: Is there a risk to the aquatic ecosystem?
U. Kuehnen, Federal Environment Agency; D. Gildemeister, Umweltbundesamt / German Environment Agency / IV2.2 Pharmceuticals; D. Maletzki, C. Polleichner, German Environment Agency UBA; F. Sacher, TZW DVGW-Technologiezentrum Wasser; A. Coors, ECT Oekotoxicologie GmbH
Antibiotics continuously enter the environment because of incomplete removal in wastewater treatment plants (WWTPs). The elimination of antibiotics varies between < 25% and >90% depending on the active substance and technology of WWTPs. In surface water, antibiotics like sulfamethoxazole are frequently monitored and can reach concentrations at the low μg/L range. Among pharmaceuticals, antibiotics are of particular interest, not only because of antimicrobial resistance (AMR) but also due to their potential adverse effects on aquatic organisms. Environmental effectsof human pharmaceuticalsareassessed according to the guideline on the environmental risk assessment of medicinal products for human use (EMEA/CHMP/SWP/4447/00 corr 2). The current regulations take into account only risk assessments for single substances, while effects of mixtures occurring in the effluents of WWTPs are not considered. Therefore, the German Environment Agency (UBA) initiated a project that investigated the effects of several mixtures of antibiotics used in human medicine on cyanobacteria. The toxicity of single substances and mixtures were determined and compared with predicted mixture toxicity. Single-substance and mixture risk assessment were compared in order to explore the relevance of mixtures. Furthermore, the influence of the wastewater effluent matrix on the mixture toxicity was tested. In conclusion, the results demonstrate that ecotoxicological risks of mixtures cannot be excluded in realistic worst-case exposure scenarios for antibiotics.

WE022
Mixtures of Antibiotics in soil: What is known about their occurrence in manure and soil and their adverse effects on soil organisms?
D. Gildemeister, Umweltbundesamt / German Environment Agency / IV2.2 Pharmceuticals; I. Steffens, Trier University / Soil Science Deptartment, Faculty VI; S. Konradi, Federal Environment Agency (Umweltbundesamt) / Section IV 2.2 Pharmaceuticals; I. Vogel, German Environment Agency UBA / Section II 2.6 Soil Protection Measures; S. Thiele-Bruhn, University of Trier / Soil Science
Antibiotics are largely and increasingly consumed worldwide in human and veterinary medicine. However, they are only partially metabolised and excreted by humans or animals and released in their active form into the environmental compartments such as soil, surface and ground water. This review summarizes the knoweledge on the occurence and effects of antibiotic mixtures in the soil compartment [1]. It is well known that many agricultural soils are contaminated with antibiotics. Even more, it must be expected that agricultural soils not only contain one but mixtures of several compounds. Mixed antibiotic contaminations may result from (i) the administration of combinations of antibiotics, (ii) the medication of different livestock animals and different live stages of the animals with different antibiotics and collection of all excreta in one manure tank and (iii) subsequent, repeated spreading of contaminated manure, sewage sludge or other organic waste materials onto agricultural fields. This results in contaminations of organic waste materials with mixtures of different antibiotics comprising up to 20 or more individual compounds. Consequently, soils fertilized with these substrates contain mixtures of different pharmaceutical antibiotics. This is supported by monitoring data of up to 13 antibiotics found in soil. Existing knowledge on adverse effects of antibiotics on soil organisms is largely restricted to studies with single compounds, which show clear dose-dependent adverse effects for example on microbial biomass, or soil community structure and functions. However, mixtures of antibiotics are of special environmental relevance, since the

ecotoxicity of a pharmaceutical mixture is typically higher than the effects of each individual component. Furthermore, interactions exist with other boundary conditions that affect the fitness of biota such as heat or frost. Despite the outlined findings it must be stated that mostly incomplete knowledge exists on the various topics. More information from targeted, systematic research is needed. To this end, three successive research projects are proposed, aiming to increase the systematic knowledge on effects of mixtures in soil. Not last, all these research efforts should lead to or even be flanked by regulatory measures for an improved use and management of antibiotics. [1] Thiele–Bruhn S. "Environmental risks from mixtures of antibiotic pharmaceuticals in soils – a literature review", UBA Texte (in preparation)

WE023

Environmental risk assessment of emerging organic micropollutants in the Belgian Part of the North Sea

S. Moeris, Ghent University / Laboratory for Environmental Toxicology and Aquatic Ecology; F. Vanryckeghem, K. Demeestere, Ghent University / Department of Green Chemistry and Technology; C.R. Janssen, Ghent University / Department of Applied Ecology and Environmental Biology; K. De Schamphelaere, Ghent University (UGent) / Environmental Toxicology

In the European Union, Environmental Quality Standards for priority substances (and certain other pollutants) are used in regular monitoring to reduce chemical pressure on the aquatic environment. In general, the production and use of most of these priority pollutants are decreasing or have even been banned in Europe. As an example, 15 out of 23 pesticides included in the list of priority substances were banned from the EU market in the past 15 years; leading, however, to the occurrence of other emerging chemicals for replacement. In the present research we performed monitoring of 89 emerging contaminants including pesticides, pharmaceuticals and personal care products and filled ecotoxicity data gaps for approximately 25 of these substances. Effect data was determined using (i) the 72h growth inhibition test with *Phaeodactylum tricornutum* (ISO 10253), and (ii) the 96h acute lethal toxicity test with *Nitocra spinipes* (ISO 14669). This data combined with an extensive literature study was subsequently used to perform an environmental risk assessment for the Belgian Part of the North Sea. The monitoring revealed the presence of 47 organic micropollutants at minimum one of our four sampling locations. While the collected toxicity data covered 56 % of the measured substances with acute effect data for three species (of the three trophic level algae, crustacean and fish), chronic data for species of three trophic levels was available for only 9 % of them. We were able to calculate risk quotients (RQ) for 53 % of the detected micropollutants and found exceedance of the threshold value (RQ > 1) for 5 substances, i.e. flufenacet, metolachlor, metoprolol, pirimicarb and terbuthylazine. The majority (3) of these substances are herbicides which have previously been reported to dominate chemical mixtures and sign responsible for a majority of observable effects in aquatic environments. Here, their exceedance of the threshold was mainly due to low no-observed effect concentrations for algae (metolachlor and terbuthylazine) or crustacean (flufenacet, pirimicarb). While effects of herbicides on algae growth or reproduction are obviously expected, effects on crustacean reproduction are rather not. Overall, our study revealed especially herbicides to potentially threaten Belgian coastal waters. In a refined risk assessment for this ecosystem, we will include potential mixture effects since our monitoring revealed the simultaneous presence of a multitude of chemicals.

WE024

Toxicity of binary mixtures in Danio Rerio: a groundwater case-study

S. Goncalves, Department of Biology & CESAM - University of Aveiro / Department of Biology and CESAM; M.D. Pavlaki, University of Aveiro / Department of Biology; A.R. Silva, University of Aveiro / Dept.of Biology & CESAM; R. Morgado, University of Aveiro / Department of Biology and CESAM; S. Loureiro, Universidade de Aveiro / Biology

Groundwater is the primary available source of drinking water across the world, representing one of the most important natural water resources. Due to anthropogenic activities most groundwater aquifers are at risk of chemical pollution. Groundwater aquifers are also essential for agricultural irrigation and for sustaining natural ecosystems functioning and health. The Groundwater Directive (2006/118/EC) was created to protect groundwater bodies from chemical pollution by setting quality standards and establishing threshold limits for a set of priority pollutants and by this way avoid deterioration in the quality of such water bodies. These type of regulations are applied based on a one-by-one chemical assessment, disregarding any interaction between them. Therefore, it is crucial to conduct research to identify possible contaminants that may pose a risk to groundwater ecosystems and help improve quality criteria. The present work was performed in the context of the European Research Project WE-NEED (Water JPI- WATERWORKS2014 ERA-NET) focused on developing new management strategies to sustainably exploit groundwater resources. Acetaminophen, triclosan and PFOS (Perfluorooctane Sulfonate) are contaminants commonly found in groundwater aquifers across Europe and therefore were selected for this case-study using the Cremona aquifer in Italy. Synthetic water was built to mimic the aquifer's groundwater composition and acute single and binary mixture Fish Embryo Toxicity Tests (FET) were performed with *Danio rerio* (adapted from OECD 236; Lammer et al. 2009) to predict their mixture toxicity. Single exposures revealed Triclosan as the most toxic chemical tested to *Danio rerio*. The reference model of Concentration Addition was applied to analyse the binary mixture results and deviations from additivity were found, which indicated interaction between the tested chemicals.

WE025

Derivation of total polycyclic aromatic hydrocarbon (PAH) water quality standards using probabilistic approaches

O.L. Tran, D. Leverett, wca; R.J. Brown, wca consulting; T. Fletcher, Ministry of the Environment, Conservation and Parks / Standards Development Branch

PAHs are ubiquitous environmental pollutants arising from industrial activity involving oil and gas. They have been shown to be toxic, mutagenic and/or carcinogenic to the environment and human health and are thus targets for regulatory management. A number of jurisdictions have derived environmental quality standards (EQSs) for PAHs that cover only a few individual compounds (e.g. naphthalene, fluoranthene). Alternatively, some jurisdictions have set a "PAH group" quality standard, by selection of a number of PAHs for analysis (e.g. denoted as PAH-6 or PAH-16). In this study we attempted a comprehensive compilation and assessment of the available long-term ecotoxicity data for PAHs and assessed the possibility to update EQSs for individual PAHs. Ecotoxicity data underpinning long-tem PAH standards developed by various jurisdictions were reviewed, forming a foundation dataset. Further searches of the published literature were conducted to identify additional long-term hazard data relevant to the derivation of water quality standard values. The acceptability of the data were categorised as primary, secondary or unacceptable, according to the Canadian Council of Ministers of the Environment (CCME) aquatic protocol (2007). This exercise highlighted that, with a few exceptions, the available dataset of long-term ecotoxicity data is insufficient to derive long-term water quality standards for freshwaters, marine waters or sediments for individual PAH compounds. This appeared to be the case regardless of the jurisdictional approach to water quality standard employed (e.g. Europe, Canada, USA, Australia and New Zealand). Since any number of PAHs from various sources will be present in the environment, with each location having a unique PAH composition, consideration of the entire PAH dataset as a whole may be useful in addressing the data paucity for individual substances. A "total PAH" standard, considering relevant data from all PAHs, may thus be a simpler approach to monitoring PAH contamination of the aquatic environment. Primary and secondary ecotoxicity data for individual PAHs were aggregated to calculate species sensitivity distribution (SSDs) for long-term freshwater, marine water and sediment. Total PAH standards were then derived based on the SSDs, taking account of the approaches recommended for standard derivation in Europe, Canada and Australia. We compared the proposed total PAH standards with existing standards for individual PAHs and PAH groups.

WE026

The ecotoxicity profile of deep eutectic solvents through the eyes of the mixture toxicity theory

I.E. Macário, F. Jesus, J.L. Pereira, University of Aveiro / Department of Biology & CESAM; S.P. Ventura, University of Aveiro / Department of Chemistry & CICECO; A.M. Gonçalves, MARE, Dep. of Life Sciences, Coimbra University/Biologia Department & CESAM, Aveiro University; J.A. The interest on DES has been increasing, boosted by their advantages over conventional solvents. However, the ecotoxicological profile of DES, particularly non cholinium-based DES, is scarcely known. Also, despite previous studies showed that DES components dissociate in water, no previous study assessed DES toxicity using the classical models for mixture effect prediction - concentration addition (CA) and independent action (IA). In this study we evaluated the ecotoxicological profile of DES based on the quaternary-ammonium salts tetramethylammonium chloride ($[N_{1111}]Cl$), tetraethylammonium chloride ($[N_{2222}]Cl$) and tetrapropylammonium chloride ($[N_{3333}]Cl$), (as hydrogen bond acceptors, HBA) and ethylene glycol and 1-propanol (as hydrogen-bond donors, HBD). In particular, this study aims to assess the ecotoxicological profile of these DES with *Allivibrio fischeri*, using the Microtox® Acute Toxicity Test. The mixture models CA and IA were used to analyse DES toxicity allowing the identification of synergistic/antagonistic, dose-ratio and dose-level effects between the HBA and HBD components of the DES. These deviations to the baseline models allow a greater detail in understanding the relation between HBA and HBD. DES toxicity followed the same trend as observed for the salts: $[N_{1111}]Cl$-based DES < $[N_{2222}]Cl$-based DES < $[N_{3333}]Cl$-based DES, being 1-propanol:$[N_{3333}]Cl$ the most toxic (30 min-EC_{50} between 1.120 and 4.981 g/L). The IA model, with specific deviations, adjusted better in 5 out of 6 DES. Antagonism was observed for $[N_{1111}]Cl$-based DES, and synergism for $[N_{3333}]Cl$-based DES and for 1-propanol:$[N_{2222}]Cl$. As demonstrated for the first time in this study, the application of the mixture toxicity models represents a breakthrough in the problematic of assessing DES toxicity, given the potentially countless number of DES that can be created with the same starting materials. The graphical representation of the response curves will allow the prediction of DES toxicity (varying ratios of the same HBA:HBD) without having to test them all experimentally. CICECO and CESAM were financed by national funds through the FCT/MEC and when co-financed by FEDER under the PT2020 Partnership Agreement (UID/CTM/50011/2013 and UID/AMB/50017/2013). PTDC/ATP-EAM/5331/2014.

WE027

Toxicity of mixtures of ionic liquids and salts to the standard freshwater microalga Raphidocelis subcapitata

F. Jesus, Department of Biology &CESAM, University of Aveiro / CESAM Department of Biology; A. Gonçalves, MARE - Marine and Environmental Sciences Centre, Department of Life Sciences, Faculty of Sciences and Technology, University of Coimbra & Dep. of Biology and CESAM, University of Aveiro / MARE (Marine and Environmental Sciences Centre), Department of Life Sciences, Faculty of Sciences and Technology / Dep. of Biology and CESAM; K. De Schamphelaere, Ghent University (UGent) / Environmental Toxicology; J. Pereira, University of Aveiro / Department of Biology & CESAM; S.P. Ventura, University of Aveiro / Department of Chemistry & CICECO; J.A. Coutinho, CICECO - Aveiro Institute of Materials & Department of Chemistry, University of Aveiro / CICECO, Department of Chemistry; F.J. Gonçalves, University of Aveiro / department of Biology & CESAM

Ionic liquids (ILs) are salts at the liquid state at temperatures below 100 ºC. These are often described as “green solvents”, given their unique properties, such as negligible vapor pressure, good solubility for many organic and inorganic materials, and theoretically low toxicity. ILs have several industrial applications, being used solely or together with other compounds, namely salts. If mixtures of ILs and salts reach the aquatic systems, they can cause adverse effects to aquatic biota. Despite previous studies have addressed the toxicity of IL’s to aquatic organisms, the mixtures of IL’s with salts have been overlooked. The main goal of this work was to assess the toxicity of binary mixtures of ILs (cholinium bitartrate, cholinium dihydrogencitrate, cholinium bicarbonate and benzyl dimethyl ammonium chloride) and salts (potassium phospate and sodium citrate) to the microalga *Raphidocelis subcapitata*. The freshwater microalga was exposed to these chemicals individually and in mixture, during 96h, and the yield was measured to calculate EC_{50} values. The toxicity of the ILs varied by a factor of 10, highlighting the role of the anion in the toxicity of the IL. Their toxicity increased in the following order: benzyl dimethyl ammonium chloride (EC_{50}=1060.3 mg/L) < cholinium bicarbonate (EC_{50}=649.2 mg/L) < cholinium bitartrate (EC_{50}=138.2 mg/L) < cholinium dihydrogencitrate (EC_{50}=100.8 mg/L). These values agree with the benign nature of the tested ILs. Concerning salts, potassium phospate was less toxic (EC_{50}=598.0 mg/L) than sodium citrate (EC_{50}=393.9 mg/L). Regarding the effects of the mixtures, both synergism and antagonism deviations were found, however antagonism was the most common.This work raises concern about the toxic effects of mixtures of ILs and salts towards microalgae, especially for combinations where synergistic effects were found. Results suggest that the toxicity of ILs might be under- or overestimated when they are tested individually. Ultimately, this work highlights the importance of testing the toxicity of mixtures given their ecological relevance in aquatic systems. CICECO and CESAM were financed by national funds through the FCT/MEC and co-financed by FEDER under the PT2020 Partnership Agreement (UID/CTM/50011/2013 and UID/AMB/50017/2013). FCT funded AMM Gonçalves, JL Pereira and SPM Ventura (SFRH/BPD/97210/2013, SFRH/BPD/101971/2014, IF/00402/2015), and supported the research through the project Ref. PTDC/ATP-EAM/5331/2014.

Environmental Risk Assessment of Illicit Drugs in effluents from WWTPs and in the recipients

J. Ansari, Halmstad University / Department of Environmental and Bioscience School of Business Engineering and Science; J. Lindberg, Swedish Toxicology Sciences Research Center; P. Ehde, Halmstad University / Department of Environmental and Biosciences, School of Business, Engineering and Science; S. Waara, Halmstad University

The presence of illicit drugs in effluents from Wastewater Treatment Plants (WWTPs) and their recipients has raised concern over their possible negative effects on aquatic ecosystems. The purpose of this study was therefore to determine the ecological risk of five illicit drugs Cocaine (COC) and its metabolite Benzoylecgonyne (BE), MDMA, Amphetamine (AMPH), Methamphetamine (METH), and Cannabis (THC/THCA) in effluents and recipients in the Halland County, Sweden. The concentrations of illicit drugs were measured and calculated in accordance with the guidelines for the EMCDDA, 2017 on WWTP’s effluents from 10 WWTPs sampled in September and November, 2017 by the Academic Research Center for Chemicals, Health and Environment (SWETOX). The measured values were used as PEC values. Predicted No Effect Concentration (PNEC) values (acute and chronic) were estimated based upon ecotoxicological data found in the literature and by using ECOSAR software (version 2.0). Method of selecting Assessment Factors (AF) were based upon the legislation for chemicals in EU. An approach suggested by Backhaus and Faust (2012) was used to calculate the risk quotients (RQ) of the mixture of the illicit drugs (MRQ). A dilution factor of 10 was used to estimate RQs of the recipient surface waters. RQs higher than 1 (RQ>1), were considered as a potential of risk on the aquatic environment. $RQ_{chronic}$ values for the illicit drugs in the effluents varied between 0 (concentration below detection limit) and 2.6. $MRQ_{chronic}$values in the effluents varied between 0.003 and 2.7. Effluents from three WWTP showed RQ>1 and MRQ> 1 and the presence of THCA in elevated concentrations mainly contributed to the result. Using a default dilution factor of 10 for potential risk in surface water resulted in RQ and MRQ values Reference: Backhaus T and Faust M. (2012). Predictive environmental risk assessment of chemical mixtures: a conceptual framework. Environmental Science Technology 46:2564-2573.

Extreme flooding events impact groundwater quality following natural disasters in Texas, USA

D. Boellstorff, Texas A&M University / Soil and Crop Sciences; D.M. Gholson, Texas A&M AgriLife Extension Service / Soil and Crop Sciences; A.O. Jha, Texas A&M University / Biological and Agricultural Engineering; K.J. Pieper, W. Rhoads, Virginia Polytechnic Institute and State University / Civil and Environmental Engineering; A.L. Katner, Louisiana State University Health Sciences Center / Environmental and Occupational Health Sciences; J.W. Smith, Texas A&M AgriLife Extension Service / Soil and Crop Sciences; O. Ozal, Texas A&M University / Soil and Crop Sciences; K. Mapili, G. House, Virginia Polytechnic Institute and State University / Civil and Environmental Engineering; T.J. Gentry, Texas A&M University / Soil and Crop Sciences

Hurricane Harvey dropped 102-155 cm of rain totaling 76 trillion liters of water on the central and upper Gulf Coast areas of Texas in 2017 causing widespread flooding, including flooding of private water wells, oil refineries, industrial facilities and at least 13 Superfund sites in the Houston metroplex, home to about 7 million people. Following the hurricane, collaborators from Virginia Polytechnic Institute and State University, Louisiana State University and the Texas A&M AgriLife Extension Service conducted private water well sampling events. Well water samples were analyzed for indicator bacteria (total coliform and *Escherichia coli*), inorganics including trace elements and heavy metals, and waterborne pathogens including *Legionella* spp., *Naegleria fowleri, Giardia lamblia*, shiga toxin-producing *E. coli*, *Vibrio vulnificus,* and *Mycobacterium* spp. (pathogen results to be reported elsewhere). More than 1,500 private water wells were tested through 60 events serving 29 hurricane-impacted counties, allowing for examination of spatial and temporal effects on concentrations. Sample sizes varied for particular analytes. In addition to spatial-temporal effects on contaminant concentrations, results also will be coupled with private well participant survey data including 1) resident demographics; 2) extent of flooding and well damage, 3) well construction and design parameters; 4) well water use and consumption patterns, and use of water treatment; and 5) activities, attitudes, obstacles, and motivations related to well testing, maintenance and disinfection, flood preparation and recovery, and service provision. Another extreme flooding event occurred in the central Texas hill country in 2018. As during the flooding that occurred with Hurricane Harvey, survey results paired with analyses for *E. coli* indicated that 24% of water wells that well owners reported were submerged contained *E. coli* while only 3% of wells that were not submerged contained *E. coli*.

Towards Increased Realism in the Site-Specific Risk Assessment of UVCBs - Leveraging On-site Monitoring Data and Industrial Hygiene Modeling Approaches in Environmental Risk Assessment

C.W. Davis, ExxonMobil Biomedical Sciences Inc; C. Lee, ExxonMobil Biomedical Sciences Inc / Dept of Tox Enviro Chemistry; E.J. Ward, ExxonMobil Biomedical Sciences Inc; T. Brunt, Esso Petroleum Company; B. Garbade, ExxonMobil Chemical Central Europe, ESSO Deutschland GmbH

Significant work has been done over the past several decades to accurately define and predict the processes that control the environmental emissions, transport, and ultimate fate of chemicals during the manufacturing and formulation stages of a chemical’s life-cycle. Much of the improvements to chemical emissions during manufacture and formulation have come from the development of sector- and use-specific specific environmental release conditions (SpERCs). Despite significant improvements to these release scenarios, there has largely been a disconnect between environmental and worker (human health) exposure and risk assessments, in many cases leading to unreasonably high emissions factors (EFs) in environmental risk assessments, which are incongruent with both occupational exposure limits (OELs, TLVs, etc…) and on-site monitoring results for industrial sites. These problems are compounded by the complexity of UVCB substances and the presence of mixed waste streams (i.e., TPH) and non-targeted monitoring data (i.e., total VOC). The purpose of this work is two-fold – (1) to provide a consistent, reproducible approach for incorporating on-site monitoring data (air & water) to support significant reductions in environmental RCRs versus a generic exposure assessment using default emission factors (SpERCs); and (2) to provide a scientific basis for the use of industrial hygiene and worker exposure criteria and monitoring results to “ground-truth” and refine environmental emission factors.

For several UVCB petroleum streams generic exposure assessments are compared to site-specific assessments using on-site monitoring data using the PetroRisk 7.07 environmental risk assessment tool.

WE031

Fish primary hepatocytes as a tool to assess the toxicity of complex mixtures of Polycyclic Aromatic Hydrocarbons.

N. Figueiredo, Department of Environmental Sciences and Engineering, Marine and Environmental Sciences Centre (MARE), Faculty of Sciences and Technology (FCT NOVA), Caparica, Portugal; B. Matos, Department of Sciences and Environmental Engineering, Marine and Environmental Sciences Centre (MARE), Faculty of Sciences and Technology (FCT NOVA), Caparica, Portugal; M. Diniz, UCIBIO, REQUIMTE / UCIBIO, REQUIMTE; M. Costa, MARE - Faculty of Sciences and Technology Universidade NOVA de Lisboa / Department of Environmental Sciences and Engeneering; M. Martins, Faculty of Sciences andTechnology, Universidade Nova de Lisboa / Dep. Science and Environmental Engineering

Monitoring carcinogenic substances has long been considered a priority in risk assessment strategy worldwide, whether it concerns human or ecological health. Polycyclic aromatic hydrocarbons (PAHs) are classified as priority substances and are ubiquitous environmental carcinogens that occur in complex mixtures. In spite much research, environmental guidelines for PAHs are invariably drawn for single substances which compromises risk assessment. In fact, previous research with seabass revealed that the interactions between PAHs of distinct classes (carcinogenic and non-carcinogenic) may generate effects more complex than could be anticipated, by mechanisms not yet fully understood. The toxicity of PAHs is derived by their highly reactive metabolites produced by CYP monoxygenases. Simultaneously, reactive oxygen species (ROS) are also produced as by-products. These reaction products may cause DNA damage hence their recognised genotoxic, mutagenic and carcinogenic potential. Moreover, PAHs may mediate the induction of CYP enzymes through the aryl hydrocarbon receptor (AhR) pathway. However, the toxicological mechanisms of complex mixtures of PAH remains largely unknown. In vitro assays with stable cell lines are being regarded as a convenient approach to meet the 3-Rs policies (reduce, refine, replace) regarding experimenting with laboratory animals. The use of primary cell cultures from wild organisms has been gaining relevance in ecotoxicology as they are generally considered to be more sensitive than stable cell lines and retain most of their original biochemical pathways. The present research evaluates the toxicological effects of complex mixtures of PAHs using in vitro tests with primary hepatocytes from an ecologically and economically-relevant marine fish. The endpoints measured include viability assessment by the MTT assay and LDH leakage, evaluation of phase I metabolism (e.g. CYP1A1 activity and expression) and Phase II enzymes of PAH metabolism, such GST activity. Integration of results seeks to validate this in vitro approach as an efficient tool to disclose the interaction effects of distinct PAH mixtures.

Examining the interrelationships between chemical/non-chemical stressors and inherent characteristics in children with ADHD

F. Nilsen, US EPA / ORISE Fellow / National Exposure Research Lab; N.S. Tulve, US Environmental Protection Agency / Office of Research and Development National Exposure Research Laboratory

Children may be more vulnerable to the combined interactions of chemical and non-chemical stressors from their built, natural, and social environments when compared to adults. Up to 20% of children are diagnosed with a mental illness annually in the United States with a large number not receiving adequate treatment. The Centers for Disease Control and Prevention estimates that 11% of children have ADHD. ADHD is characterized by developmentally inappropriate levels of hyperactivity, impulsivity, and inattention, with the neurotransmitter serotonin regulating these symptoms. Monoamine oxidase A (MAOA) aids in serotonin uptake and has two genotypes that affect its enzymatic activity (low: L; high: H). MAOA-L carriers are more frequently diagnosed with behavior and emotional disorders, including ADHD. When children are exposed to cigarette smoke, bisphenol A (BPA), or organophosphate pesticides, MAOA activity is inhibited. Non-chemical stressors, such as traumatic childhood experiences, ethnicity, and lifestyle factors, complicate the relationship between genotype and chemical exposures. But, the co-occurrence among outcomes between chemical exposures, genotype, and non-chemical stressors with MAOA-L suggest that mental illness in children may be caused by multiple interacting factors. This project aims to elucidate the links between chemical and non-chemical stressors and inherent characteristics on children's mental health outcomes using a systematic review and meta-analysis to align results within our multifactorial conceptual framework. Preliminary results show that prenatal and childhood exposures to recreational drugs, lead, organic contaminants, and phthalates are associated with greater odds of being diagnosed with ADHD. MAOA genotype and early childhood experiences also influence mental health outcomes associated with ADHD. An improved understanding of inherent vulnerability and the onset of mental illness may provide better intervention and treatment options to children in need.

Statistical Science and Ecotoxicology: Bright Lines and Dark Alley Ways (P)

WE033

When p is not of value anymore - effect sizes and their uncertainties as an alternative to interpret ecotoxicological data

A. Feckler, Swedish University of Agricultural Sciences (SLU) / Department of Aquatic Sciences and Assessment; M. Low, Swedish University of Agricultural Sciences / Department of Ecology; J.P. Zubrod, University of Koblenz-Landau / Institute for Environmental Sciences; M. Bundschuh, Institute for Environmental Sciences University of Koblenz-Landau / Department of Aquatic Sciences and Assessment

Null-hypothesis significance testing (NHST) is still a commonly applied statistical tool in ecotoxicology despite decades of controversy about its focus on the *p*-value irrespective of the biological relevance of effects. However, for many questions in science and management, it is generally more valuable to know the probability of a specific hypothesis or effect size, rather than a statement about whether data differ significantly from those expected under the null hypothesis. Thus, we suggest results should emphasize effect sizes and the degree of uncertainty surrounding their estimations in a frequentist or Bayesian framework. To examine this, we compared how NHST and effect size-based statistics can affect inference from ecotoxicological datasets by applying (i) analysis of variance models using NHST and (ii) effect sizes using both frequentist confidence intervals and Bayesian frameworks. In many cases, the results were similar among the three approaches: NHST *p*-values were < 0.05 when effect sizes were $\geq$10% and Bayesian probabilities exceeded 80%, thus indicating biologically relevant effects. In several cases, however, NHST-results provided different interpretations than those revealed by effect sizes and respective Bayesian probabilities: biologically relevant effects were not revealed by NHST (p>0.05) despite effect sizes in the range of 10-40% and Bayesian probabilities of 80-100%. Furthermore, NHST drew attention to a biologically irrelevant effect, which happened to be statistically significant (p=0.049; effect size: 5%; Bayesian probability: 72%). Effect sizes and respective uncertainties as well as Bayesian probabilities provide a more nuanced interpretation of results, as these methods allow scientists to form conclusions regarding biological relevance based on their expert judgement and effect thresholds. We conclude that ecotoxicology should ultimately move from conventionally applied NHST that relies on *p*-values towards an effect size-based approach to maximize the probability of identifying biologically relevant effects.

WE034

How to prove there is no effect: The MDD concept and alternative indicators for the interpretation of ecotoxicological study results

M.M. Mair, University of Regensburg / Theroretical Ecology; M. Kattwinkel, University of Koblenz-Landau / Quantitative Landscape Ecology; O. Jakoby, Rifcon GmbH / Regulatory Sciences - Population Modelling and Statistics; F. Hartig, University of Regensburg / Theroretical Ecology

Risk assessment of pesticides has to evaluate potential effects on non-target organisms. In addition to laboratory tests, mesocosm and field studies are regularly conducted to show the absence of such effects, often with small sample sizes. When statistical non-significant results are reported by such a study, it is often challenging to distinguish between the true absence of an effect (true no-effect), and lack of power, meaning that the study failed to detect an existing effect (type II error). Methods for judging whether a non-significant result does in fact indicate the absence of an effect include confidence intervals (CIs), post-hoc power analysis and the post-hoc calculation of a minimum detectable difference (MDD). Although limitations of post-hoc power analysis and MDD have been acknowledged widely (including EU and US regulatory agencies), the MDD is still recommended in current guidelines for ecotoxicological risk assessment. Moreover, the MDD concept, traditionally mainly applied to simple experimental contrasts, has recently expanded in use also to LMMs and GLMMs, without solid evidence of its validity in this context. We use simulations and real-world case studies to investigate the ability of CIs, post-hoc power analysis and MDD to distinguish between true no-effects and type II error. We also investigate whether a direct relationship between MDDs and CIs exists in general, in particular for more complex (generalized linear) models, as suggested in the literature. We compare the different concepts regarding their ability to create correct decisions in a regulatory context and give recommendations for revised statistical protocols to show the absence of an effect.

WE035

Validation of augmented species sensitivity distributions for fish - a new non-testing approach to refine acute risk assessments of fungicides

P. Janz, BASF SE, Agrarzentrum Limburgerhof / Agricultural Solutions - Global Ecotoxicology; L. Weltje, BASF SE / Agricultural Solutions - Global Ecotoxicology

The aquatic risk assessment of plant protection products (PPPs) in the EU follows a tiered approach. The standard acute risk assessment for fish (tier 1) is based on the rainbow trout 96-h LC_{50} value divided by an assessment factor of 100. If unacceptable risk is indicated at tier 1, a species sensitivity distribution (SSD) approach is one method to refine the acute risk to fish. SSDs are cumulative distribution functions of toxicity values of multiple species, which are used to estimate the hazardous concentration potentially affecting 5% of the species (HC_5). According to the EFSA Aquatic Guidance Document at least 5 toxicity values are required for a fish SSD. However, this additional acute fish testing conflicts with the wish to minimise vertebrate testing as much as possible for animal welfare reasons. The most effective method to solve this dilemma is by leveraging the existing data. Following this idea, experimental fish toxicity data for standard species were augmented with toxicity values calculated with interspecies correlation estimation (ICE) models to construct SSDs. ICE models predict the acute toxicity of untested taxa from experimental toxicity data of a tested species. HC_5 values derived from fish SSDs augmented with ICE-derived toxicity values (augmented SSDs) were validated by comparison with HC_5 values from SSDs based on experimental data (reference SSDs). This exercise was done for fungicides covering different modes of action, because fish frequently drive the aquatic risk assessment of fungicides leading to the need for refinements. Our work shows that this method provides robust SSDs for use in risk assessment without the need for additional fish testing.

WE036

Improved Experimental Design for Non-Target Terrestrial Plant Studies

J.W. Green, JohnWGreen-ecostats.com / Data Science and Informatics

Regulatory guideline studies for Non-Target Terrestrial Plant (NTTP) are Seedling Emergence (OECD TG 208) and Vegetative Vigor (OECD TG 227). Both have growth responses (dry or wet weight and shoot height) and survival (TG 227) or emergence (TG 208). An extensive database was explored to find what experimental designs allowed adequate ability to estimate ECx, x= 10 to 50, and determine a NOAER. Design considerations were the number of application rates, replicate test vessels (pots) per application rate, plants per rep, and whether to have the same number of reps at all rates or to increase the number of control reps (e.g., using a square-root allocation rule). The decision criteria were the power of multiple comparison methods to establish a NOAER and the distribution of ECx estimates and their confidence bounds. The database determined the distribution of the within- and between-rep variances (VARERR and VAREEP, respectively) and the ratio VARREP/VARERR, as well as the range of rate-response shapes in such studies. A realistic simulation study was then developed to explore alternative designs. For emergence studies, a design with 6 application rates (including a zero-rate control), 8 reps/rate, 5 plants/rep, with equal allocation of reps to rates, provides NOAER determination and EC10 and EC25 of comparable power and quality to those possible from larger designs. For Vegetative Vigor studies, a design with 8 rates with 5 reps of 4 plants each, with equal allocation of reps to rates allows NOEC determination and EC10, EC25, and EC50 estimation with comparable power or quality to that possible under larger standard experiments. These conclusions must be qualified: Shallow rate-response curves occur frequently and vary across species and chemicals in mostly unpredictable ways. Both NOAER and ECx estimates suffer for such data. Quality of results depends on the statistical models and model selection criteria, and multiple comparison tests. Specific recommendations are provided.

WE037

Model Selection Criteria for Growth Responses in Non-Target Terrestrial Plant Studies

J.W. Green, JohnWGreen-ecostats.com / Data Science and Informatics

Growth responses in NTTP studies are dry or wet weight and shoot height. There is no *apriori* model for such data and for a single dataset, ERx estimates can vary substantially across different models that are plausible, at least in the abstract. It is thus necessary to define objective goodness-of-fit criteria and model selection criteria to select which, if any, model from an appropriate suite of models, provides reliable estimates of ERx and for what values of x. The suite of models explored are Bruce-Versteeg "probit type," 3-parameter log-logistic, Brain-Cousens hermetic, and 2- and 3-parameter exponential models with and without an additional parameter defining a minimum level possible or "floor." Including a floor is sometimes useful avoid estimating responses below any biologically plausible level (e.g., a plant will die before it shrinks to 1% of normal weight). Goodness-of-fit criteria include the following. ERx is estimated as a change from the model estimated control mean, so model agreement with the observed control mean is important. Somewhat less important is agreement of the model with observed treatment means, especially near the estimated ERx rate. If notable low dose stimulation is observed, the model should reflect it, since otherwise, the estimated control mean tends to be pushed towards the stimulated value. The width of the confidence intervals for ERx and the predicted response at ERx should not be overly wide. The model should not be sensitive to one or two observations and all model parameters should be significantly different from zero. Model selection criteria include Akaiki's AICs or BIC and an assessment of how well models being compared meet the goodness-of-fit criteria. Results from a large NTTP database indicate the relative success of these models in fitting NTTP growth data using the stated criteria and the size effects that can be estimated from such studies under current test guidelines.

Causal inference in ecological risk assessment of heavy metals for benthic invertebrate community in rivers

K. Takeshita, National Institute for Environmental Studies, Japan / Center for Health and Environmental Risk Research; T.I. Hayashi, H. Yokomizo, National Institute for Environmental Studies, Japan

In ecological risk assessment for heavy metals, field surveys in rivers provide valuable information about the community-level responses of aquatic organisms to heavy metal pollution. Field survey-based datasets have frequently been analyzed based on correlation analysis such as a method of quantile regression analysis. Correlation analysis neglects the effect of confounding factors that affect both a biological indicator and its limiting factors. Confounding factors may cause spurious associations, and the misestimation of ecological risk derived spurious associations from leads to inappropriate management action. Here, we demonstrated the importance of causal inference in ecological risk assessment of heavy metals using a field survey-based dataset targeted to heavy metals and benthic invertebrates in 19 rivers in Japan. We developed the causal diagram comprised of the biological indicator (Ephemeroptera, Plecoptera, and Trichoptera [EPT] richness), quality of river water (e.g., pH), and physical characteristics of river (flow velocity of river and riverbed structure). Based on the diagram, we constructed a multiple regression model with covariates satisfying the back-door criterion for estimating the causal effect of heavy metals. We did not confirm the causal effects of heavy metal concentrations on EPT richness in the multiple regression model. There was a significant causal effect of flow velocity on EPT richness. The concentrations of heavy metals were correlated to flow velocity in our dataset; therefore, a spurious negative association between EPT richness and heavy metal concentrations was attributed to the correlation. These results suggested that flow velocity needed to be regulated to examine the causal effects of heavy metals on EPT richness in the field. When field survey-based dataset is comprised of several rivers, EPT richness, heavy metal concentrations and flow velocity usually differ in each river. Therefore, all these variables in our dataset were affected by the variable of "river" which is the confounding factor. Consequently, misestimation of ecological risk assessment of heavy metals occurred when assessment was based only on correlation analysis.

WE039

Improving the reliability of ecotoxicological impact assessment metrics - A combination of Quantitative Structure-Activity Relationships and Interspecies Correlation Estimation equations

M. Douziech, Radboud University Nijmegen; R. van Zelm, Radboud University / Environmental Science; R. Oldenkamp, J.A. Hendriks, Radboud University Nijmegen / Department of Environmental Science; H. King, Unilever; R. Oktivaningrum, University of Wageningen; M.A. Huijbregts, Radboud University Nijmegen / Department of Environmental Science

The Hazardous Concentration (HC50) is used as a measure of the potential effect of a chemical on an ecosystem. HC50s describe the concentration of a chemical in the environment above which 50% of the species in a given ecosystem are above their EC50, meaning the effective concentration at which 50% of a population displays an adverse effect. EC50s are either experimentally derived or estimated with Quantitative Structure-Activity Relationships (QSARs), both implying a certain level of uncertainty thus influencing the uncertainty of the HC50. The uncertainty of the HC50 is further also driven by the number of species for which EC50s are available: the lower the number, the higher the uncertainty. The resulting uncertainty ranges of HC50s make the interpretation of ecotoxicological assessments challenging. We therefore propose an approach to increase the reliability of HC50s by combining EC50s estimated with QSARs and Interspecies Correlation Estimation (ICEs) equations. ICEs estimate the ecotoxicity of a chemical to a species from the known toxicity of the chemical to another species. This approach was applied to a large set of chemicals focusing on the ecotoxicity for freshwater species. In total, four sets of HC50s were compared: HC50s derived from (1) three species-specific EC50s estimated from QSARs, (2) three species-specific EC50s from QSARs and the 97 available ICEs, (3) three species-specific EC50s from QSARs and per species the least uncertain ICE, and (4) experimental EC50 values for four to six different species. The uncertainty of the HC50s was quantified with a Monte Carlo analysis (10'000 iterations) propagating the uncertainty of the EC50s derived from experiments, QSARs, and ICEs as well as the sampling uncertainty. We used the uncertainty ratio (UR = 95^{th} percentile over 5^{th} percentile) to measure the change in uncertainty for each set of HC50s. Using four commonly used solvents as case studies, we showed that for the HC50s derived from estimated EC50s increasing the number of species from three to six reduced the average UR from 7.8E7 to 6.6E3. When all ICE equations were used the UR dropped to 5.6E1. This was higher than the UR of experimentally derived HC50s (1.5E1). We showed an increased reliability of HC50 values derived from more EC50s despite the use of estimation techniques implying a certain uncertainty level. Future work will present results for a wider set of chemicals and other ecotoxicological impact assessment metrics.

WE040

MOSAIC: a web interface for statistical analyses in ecotoxicology

P. VEBER, CNRS / Laboratory of Biometry and Evolutionnary Biology; G. GENCE, self-employed / Villeurbanne; V. Baudrot, CNRS / BioSP; S. Charles,

University Lyon 1 / Laboratory of Biometry and Evolutionnary Biology

In ecotoxicology, toxicity tests are standardly conducted in order to measure acute or chronic effects of potentially toxic substances on reproduction, growth and/or survival of living animals. Based on statistical models, mainly exposure-response/effect models, these data are analyzed to derive toxicity thresholds associated with their uncertainty, thus helping risk assessors in taking argued decisions. But choosing the most appropriate model and tracking uncertainties is not always an easy task if not implemented in ready-to-use software. MOSAIC, standing for MOdeling and StAtistical tools for ecotoxICology, is developed since 2013 to meet this user request for a freely available user-friendly web interface dedicated to the mathematical and statistical modelling of standard toxicity test data. MOSAIC is available at http://pbil.univ-lyon1.fr/software/mosaic/. Its simple use makes MOSAIC a turnkey decision-making tool for ecotoxicologists, regulators and risk assessors. Indeed, without requiring immersing in extensive mathematical and statistical technicalities, users are provided with advanced and innovative methods to get quantitatively robust estimates of toxicity thresholds in support of their daily work in environmental risk assessment (ERA). Most of MOSAIC functionalities are based on Bayesian inference. From the joint posterior distribution of parameters, Bayesian inference allows a clear handling of uncertainties, that is propagated to the derivation of the toxicity thresholds. In this poster, we first illustrate how to derive LCx and ECx estimates in few steps from standard toxicity data. Then we illustrate how to perform an SSD analysis including censored data, that is data defined as intervals (e.g., an LC50 value known to be smaller than an upper bound, greater than a lower bound or between two uncertainty limits). At last, we present the most recent tool available in MOSAIC, which is dedicated to the use of toxicokinetic-toxicodynamic (TKTD) models, especially General Unified Threshold models of Survival (GUTS models), to fit survival data as a function of both time and concentration. This new functionality could become the new paradigm to derive precise LCx estimates with a better precision than the ones obtained from classical exposure-response/effect models.

MORSE: An R-package dedicated to ecotoxicology

V. Baudrot, CNRS / BioSP; B. Goussen, IBACON GmbH; P. VEBER, CNRS / Laboratory of Biometry and Evolutionnary Biology; S. Charles, University Lyon 1 / Laboratory of Biometry and Evolutionnary Biology

The effects of chemicals on living animals are usually measured on individual life history traits according to standardized toxicity laboratory tests. This ensures the control of experimental conditions and the reproducibility of the toxicity tests which generally concern survival, reproduction and/or growth of animals. The statistical analysis of the corresponding collected data leads to the estimation of critical effect concentrations. If toxicity tests have been carried out with a reasonable number of concentrations of the studied chemical substance and if the responses or the effects are statistically significant, a regression model is recommended in order to estimate LCx and/or ECx at the end of the experiment. However, choosing the most appropriate exposure-response/effect model may be not trivial while it may have a strong impact on the resulting threshold estimates. In addition, these models prevent the full exploitation of available data, monitored over time, thus leading to a statistical bias in time-dependent toxicity threshold estimates. They are also only defined for constant exposure concentrations, making not possible the extrapolation of the results to more realistic, time-variable exposure profiles. Fortunately, such situations can be accounted for with the use of toxicokinetic-toxicodynamic models, as for example the General Unified Threshold model of Survival for survival data. Nevertheless, proper and relevant estimates of parameters for all these models are rarely possible within a unique software, nor barely feasible for non-statisticians. To bridge this gap, we developed ready-to-use functions within an R-package entitled 'morse' (standing for MOdelling tools for Reproduction and Survival data in Ecotoxicology), freely available at https://CRAN.R-project.org/package=morse. The R-package 'morse' is based on a Bayesian framework to provide parameter estimates as probability distributions, from which uncertainties can be propagated to any output of interest. This poster illustrates: (1) how simple it is to fit an exposure-response/effect or a GUTS model with only few lines of R code; (2) how to estimate LCx either from a classical exposure-response/effect or a GUTS model; (3) how to make predictions of the survival rate under untested time-variable concentration profiles; and (4) how to get an estimate of the new concept of x% lethal profile (LPx) as promoted by the recent Scientific Opinion from EFSA.

WE042

GUTS Shiny App: a web platform to simulate survival rate under time-variable exposure concentration profiles.

A. SIBERCHICOT, University Lyon 1; V. Baudrot, CNRS / BioSP; S. Charles, University Lyon 1 / Laboratory of Biometry and Evolutionnary Biology

Environmental Risk Assessment is based on fitting standard dose-response models to toxicity test data, and LC/EC50 are estimated at the end of the experiment. This common practice prevents the full exploitation of available data, which are monitored over time, leading to a statistical bias in the estimation of time-dependent toxicity thresholds. In addition, standard models are only defined for constant exposure concentrations, making impossible the extrapolation of the results to more realistic, time-variable exposure profiles. Toxicokinetic-toxicodynamic (TKTD) models may help in bridging this gap, as they describe chemical effects by considering the exposure dynamics. The most significant advantage of TKTD models is the possibility to calculate LC/ECx for any exposure duration t, even at time points outside the experimental design. TKTD models also support a mechanistic understanding of the chemical mode of action, the derivation of time-independent effect parameters and the prediction of risks under time-variable exposure profiles. Despite these manifest advantages, TKTD models are not widely used in practice, due to their mathematical complexity that requires advanced methods such as numerical integration and non-linear optimization to fit them to experimental data. In its recent Scientific Opinion, among TKTD models, EFSA promotes the use of General Unified Threshold models of Survival (GUTS) for regulatory risk assessment of pesticides for aquatic organisms. GUTS models are fitted on experimental data to estimate parameters, the survival rate is predicted under environmental exposure scenarios, and predicted numbers of survivors are compared to observed data. Predictions are then validated based on three criteria: the % of data predicted within uncertainty limits of predictions, the normalized root mean square error and the final survival probability prediction error. This poster presents the GUTS Shiny App (http://lbbe-shiny.univ-lyon1.fr/guts-shinyapp/), a new web platform to simulate GUTS models online for any time-variable exposure concentration profile. If uncertainty on input parameters is available, it is propagated to the model outputs. Following EFSA recommendations, the GUTS Shiny App allows the estimation of the multiplication factor causing an additional x% of mortality at the end of the profile (the so-called x% lethal profile or LPx). If users download observed data, the GUTS Shiny App automatically delivers EFSA validation criteria.

Assessment of Social Impacts for Decision-Making Processes and Communication (P)

WE043

Investigation of medicines consumption and disposal by the Brazilian population

G. Rabelo Quadra, P. Silva, J.R. Paranaíba, Universidade Federal de Juiz de Fora; I. Josué, H. Souza, Universidade Federal do Rio de Janeiro; R. dos Santos Costa, Universidade Federal do Rio de Janeiro / LABTOX; M.A. Fernandez, Universidade Estadual do Rio de Janeiro; J. Vilas Boas, Universidade Federal de Juiz de Fora; F. Roland, Universidade Federal de Juiz de Fora / Laboratório de Ecologia Aquática

The environmental concern regarding pharmaceuticals pollution has been increasing. There are many pathways of pharmaceuticals to reach the environment, in which the incorrect disposal of medicines by the population is one of those, and many countries still lack effective regulation. When pharmaceuticals reach the ecosystems, they may cause adverse effects on organisms. Therefore, generating information about the disposal of medicines by the population is essential as well as bring knowledge to society. Then, the objective of this research is to investigate the consumption habits and disposal of medicines among the Brazilian population. This study also aims to bring knowledge to the community, as well as generate awareness about the use and disposal of drugs by the Brazilian population. For this, questionnaires were applied by an online platform. In total, 540 forms were answered. Within the participants taking medicines currently (57.4%), the majority takes one to two medicines per day (41.7%). 64% of the respondents have the habit to self-medicate, and 40.2% have already felt some side effects. Analgesics were the class of medicines more mentioned by the participants. 60.4% of the respondents discard their disused or expired drugs in common garbage, and 54.4% of respondents do not know if their cities have specific collectors of medicines. A large respondent percentage (71.9%) never receive any information about correct disposal of medicines, and 95.2% of the respondents believe that pharmaceuticals residues can be harmful to the environment. Many conferences have already mentioned the need for environmental education since it is the base to environmental health and management. Therefore, efforts to raise environmental awareness will beneficially affect drug disposal practices. Although many countries still do not have adequate protocols for unused medicines disposal, it is essential that the population is aware of the incorrect forms and consequences for the environment. This study emphasizes the need for greater incentive in environmental education and public policies related to the pharmaceuticals use and disposal. Furthermore, we believe that the conscious consumption of medicines, which means in the correct accomplishment of medical treatments, reduction of self-medication, and proper destination of these compounds are significant for the mitigation of environmental impacts caused by pharmaceutical pollution.

WE044

Sustainable Sediment Management: Whose Values Are We Sustaining?

S.E. Apitz, SEA Environmental Decisions Ltd

Sediment management is not a sustainable practice. We manage sediment to support specific goals or to address past, unsustainable practices. All active management results in (desirable and undesirable) environmental, economic and social impacts. Given the uncertainty inherent in many management activities, sometimes we are addressing how to balance certain harm against uncertain benefit when considering a range of alternative strategies. The challenge is optimization – how does one achieve the maximum benefit with the minimum undesirable impact? Whenever a decision is couched in terms of sustainability, this should be defined for the question at hand: What attributes or conditions does the decision aim to sustain; Who is affected by actions (costs and benefits); For what period of time will actions convey benefits; At what cost ? and Who answers the first four questions? These are normative questions rooted in societal values, requiring engagement and a careful consideration of diverse stakeholders' priorities, bearing in mind that risks, benefits and costs are not borne equally, in terms of time, space, stakeholders, or demographics. Trade-off evaluation should take into account affected communities' vulnerabilities, needs and values, and how these might be impacted by remedial options. Many stakeholders who do have the time and resources to engage in the decision process have a primary focus on a single or narrow set of remedial impacts. The use of frameworks that guide stakeholders to consider the extent to which they prioritize all (rather than just a narrow subset) of the impacts to of their values can support a more balanced public comment process, less subject to single- or narrow-issue lobbying, but capturing, understanding and addressing the needs of diverse stakeholders can be challenging. Identification of risks and benefits of most interest to stakeholders can support negotiation and optimization of alternatives, but unengaged subjects, due to a lack of resources, interest, or awareness, may not have their needs and values addressed unless a special effort is made to identify and consider them. There can be fundamental disagreement between stakeholders on the desirability of various management impacts. Environmental scientists seeking to support more equitable decision making must address the embedded assumptions and limitations of tools we commonly use. These issues, and potential strategies to address them, will be discussed.

WE045
What and where are the important social impacts?
A. Brekke, K. Lyng, J. Baxter, Ostfold Research
The LCA framework has proved useful to assess social impacts for products and product systems. Still, the field can be regarded as relatively immature even after more than twenty years. Reasons for this include the great number of possible impact categories, the ambiguity inherent in many social impacts, and the esoteric nature of the impact categories for a field predominantly developed by natural scientists and engineers. The development of tools such as the social hotspot database (Benoît Norris, 2014) and the PSILCA database (Ciroth and Eisfeldt, 2017), which combines economic input output data and various data on social impact indicators, has been an important achievement in furthering the application of S-LCA. These provide a possibility for quick assessments of value chains based on limited information – however, the answers from such assessments are difficult to interpret. This work aims at a better understanding of social impact categories and identification of risk of negative social impacts. The analysis addressed three questions: Are the social and socio-economic subcategories correlated? A high degree of correlation means that a higher risk of a social impact within subcategory A in sector X in country 1 than in sector X in country 2 also implies a higher risk of a social impact within subcategory B in sector X in country 1 than in sector X in country 2. Are the risks of social impacts across industrial sectors in a country consistent? If the risks are consistent across industrial sectors in the countries, then a country with a higher risk of social impacts within sector X will also have higher risk of social impact within sector Y. Are the risks of social impacts across countries for various sectors consistent? If the risks are consistent across countries, it shows that if country A has higher impacts than country B in one subcategory, it will also have higher impacts in another subcategory. The assessments showed strong correlations between the variables. This means that social hotspots can be anticipated from knowing which countries processes will take place. It also means that there is a large need for specific data for social LCA as generic data are most often on the country level and does not provide details to better understand the production system under scrutiny.

WE046
Current state and methodological challenges of life cycle sustainability assessment: a review
D. Costa, CESAM & Department of Environment and Planning, University of Aveiro / Department of Environment and Planning; P. Quinteiro, A.C. Dias, University of Aveiro / Centre for Environmental and Marine Studies (CESAM) - Department of Environment and Planning
Life Cycle Sustainability Assessment (LCSA) is a life cycle oriented tool that encompasses environmental, economic and social aspects. Despite the growing interest in LCSA methodology in recent years, it remains unclear on how to apply it. Therefore, the major objectives of this paper is: (1) to carry out a systematic review of the scientific literature (until 2018); (2) to identify how LCSA is currently addressed, including the methods used to conduct it, and; (3) to identify the main challenges for a wide implementation of LCSA. The review was conducted according to the guidelines protocol proposed by Pullin and Stewart [1]. The studies (139 peer-reviewed articles) were selected considering research questions and keywords that focus on the LCSA development. These publications were categorized as case studies (45), reviews (33), methodological development (32), mixed approaches (22) and viewpoints (7). Mixed approaches (articles that propose LCSA methods and apply it to case studies) and case studies where classified considering three approaches: (1) LCSA = LCA + LCC + SLCA, LCSA as the sum of Life Cycle Assessment (LCA), Life Cycle Costing (LCC) and Social Life Cycle Assessment (SLCA), (2) LCSA as a new assessment, and (3) other approaches. The 'LCSA =new' approach requires the definition of a single inventory to assess environmental, social and economic impacts [2]. The category 'other approaches' include LCSA as the sum of eco-efficiency with SLCA or LCSA as the sum of LCA with socioeconomic analysis, as well as the dynamic LCSA. This review shows that the use of LCSA in case studies has been growing in recent years, being the 'LCSA = LCA + LCC + SLCA' the most applied approach. However, further developmment is required to better understand the interactions between the environmental, economic and social dimensions. The review also shows that the main challenges for LCSA are the need to ensure consistency between the different system boundaries, the lack of databases for the assessment for social and economic data, definition of impact categories, methods to conduct sensitivity and uncertainty analysis, and strategies towards the communication of results. Organic Micropollutants in Urban Waters (P)

WE047
Adsorption of ionizable pharmaceutical compounds onto microwave-hydroxide functionalized biochar
S. Pap, Environmental Research Institute, North Highland College, University of the Highlands and Islands / Environmental Contamination and Ecological Health; O. Paunovic, Faculty of Technical Sciences, University of Novi Sad / Department of Environmental Engineering and Occupational Safety and Health; M. Taggart, Environmental Research Institute / Environmental Contamination and Ecological Health; M. Turk Sekulić, University of Novi Sad Faculty of Technical Sciences / Department of Environmental Engineering and Occupational Safety and Health
Wild plums are among the most common fruits in Serbia, and kernels are generally disposed of as waste. A new generation of functionalized biochar (WpOH) was prepared from wild plum kernels by simultaneous pyrolysis and microwave KOH functionalization, and used for ionizable pharmaceutical (naproxen (NPX)) removal from water. NPX belongs to the aryl acetic acid group of non-steroidal anti-inflammatory drugs and has been detected all over the world, at up to 2.3 μg/L in effluent from wastewater treatment plants, confirming that NPX, and many others similar compounds, are not effectively removed by conventional treatment. NPX is now on the Global Water Research Coalition (GWRC) priority list and is already a more common NSAID than diclofenac in Scotland (due to a significant increase in dispensing rates). Characterization of synthetized biochar was carried out using pH_{pzc}, SEM/EDX, BET, FTIR, XRD and the governing adsorption mechanisms were thoroughly studied. The microporous biochar possessed a large specific surface area (601.9 m^2/g) and micropore volume (0.231 cm^3/g). The development of porosity during the KOH microwave activation can be explained by the diffusion of metallic potassium (formed during the pyrolysis process) into the internal structure of the lignocellulosic material. This had an impact on existing pores (causing spreading) and acted to create new ones. A pseudo second-order kinetic model described the reaction kinetics and the Langmuir isotherm gave a best fit to the results. The maximum adsorptive interaction (73.137 mg/g) occurred between pH 5 and 7, through electrostatic attraction (the main interaction mechanism) for the negatively charged NPX species and the positively charged biochar surface. The mass transfer analysis showed that the adsorption of NPX first took place through surface reactions with functional groups until these were saturated; thereafter, NPX diffused into the biochar porous structure, adsorbing within the inner pores. FTIR and XRD revealed that hydrogen-bonds, π–π and n–π electron-donor-acceptor interactions also played a role. The results highlighted the high potential for the use of wild plum kernels to produce biochar and its efficiency in removing emerging contaminants such as pharmaceuticals from contaminated water.

WE048
Concentrations of Polybrominated Diphenyl Ethers, Hexabromocyclododecane, and Perfluoroalkyl Substances in Landfill Leachate from Ireland
S.J. Harrad, The University of Birmingham; D. Drage, University of Birmingham / School of Geography, Earth & Environmental Sciences; M. Sharkey, H. Berresheim, National University of Ireland Galway / School of Physics
Introduction This study tests the hypothesis that past disposal to landfill of waste will have led to significant contamination of landfill leachate with polybrominated diphenyl ethers (PBDEs), hexabromocyclododecane (HBCDD), and perfluroalkyl substances (PFASs). To do so, we report concentrations of such contaminants in samples of leachate from landfills in the Republic of Ireland. Materials and methods Leachate was collected between June and November 2017 from 40 landfill sites across the Republic of Ireland. At least 1 sample of leachate was

collected from each landfill studied with 46 samples collected in total. Cleaned leached extracts were subjected to GC-MS for determination of PBDEs, with LC-MS used to determine concentrations of alpha-, beta- and gamma-HBCDD, and PFASs. **Conclusions** Our data reveal substantial inter-landfill variation in concentrations of our target BFRs and PFAS detected in leachate from Irish landfills. Likely due to their greater aqueous solubility, concentrations of PFASs generally exceed those of PBDEs and HBCDD. Interestingly, the median concentration of perfluorooctane sulfonate (94 ng/L) only just exceeded that of one of its replacements, perfluorobutane sulfonate (79 ng/L). Concentrations detected of PFASs in this study are of similar magnitude to those reported recently for Australian and Canadian landfill leachate, with those of PBDEs also falling within the range of previous studies elsewhere in the world. Further work in this project will examine the influence on contaminant concentrations in leachate of both landfill characteristics (e.g. time window over which waste was accepted at the landfill, whether landfill is lined or unlined etc.) and leachate properties (e.g. organic carbon content, pH etc.). In addition, in the second phase of this project, 10 of the landfills whose leachate was analysed here will be studied in more detail, with concentrations of target BFRs and PFAS measured in air and soil in the vicinity of the landfill, as well as in samples of groundwater potentially impacted by landfill leachate (e.g. for unlined landfills).

WE049

CWPharma - case study about active pharmaceutical ingredients emissions and sources in Estonia

V. Kõrgmaa, Estonian Environmental Research Centre / Environmental Chemistry; E. Haiba, The Estonian Water Works Association / Department of Techology; M. Laht, Estonian Environmental Research Centre / Analytical and Environmental Chemistry; E. Lember, The Estonian Water Works Association / Architecture Civil and Environmental Engineering; L. Lagle, V. Tarkmees, The Estonian Water Works Association; . Leisk, Estonian Environmental Research Centre; P. Aarma, The Estonian Water Works Association

Emissions of active pharmaceutical incridients (APIs) to the water environment is a rising concern around the world. Residues of APIs contaminate the water and marine life of the Baltic Sea, therefore presence of these residues in enironment is of great concern. Information about emissions, sources and environmental levels of APIs is still insufficient. During this study the consumption data of both human and veterinary medicines was collected. For estimation of emissions to the water environment targeted sampling campaigns on potential sources. 65 active pharmaceutical ingredients were analyzed, samples were taken from surface water, fish farm and municipal wastewater treatment plant effluent, influent. Almost half of the analyzed APIs were under 2 ng/L in surface water and fish farm samples. Highest concentrations in surface water were detected for Bisoprolol (158 ng/L) that is used to treat high blood pressure and heart failure and for an anti-inflammatory agent Mesalazine (71 ng/L) from the effluent of fish farm. 91 % of the analysed API residues were found from the waste water treatment plant effluents. The concentrations ranged from as low as 20 pg/l up to 147 Âg/L. Wastewater treatment plants are the first defensive line between aquatic environment and emissions of APIs. During this study consumption data, potential sources and levels of environmental emissions as well as an efficiency of present wastewater treatment technology (activated sludge process with biological nutrient removal) will be analysed for developing the measures for pollution reduction. **Acknowledgements** Study is carried out as a part of p_Clear waters from pharmaceuticals – CWPharma" project funded by the European Union Interreg Baltic Sea Region program along with co-financing from Estonian Environmental Investment Centre.

DETECTION OF SYNTHETIC POLYCYCLIC MUSKS IN SEDIMENTS OF THE UMGENI AND MSUNDUZI RIVERS IN KWAZULU-NATAL, SOUTH AFRICA

J.O. Soji, University of KwaZulu-Natal / Chemistry; B.S. Martincigh, University of KwaZuluNatal / Chemistry and Physics; G. Birungi, Mbarara University of Science and Techlology / Chemistry

Synthetic polycyclic musks (SPMs) are emerging contaminants mostly arising from personal care products where they are widely used as fragrances in cosmetics, soaps, shampoos, detergents, deodorants, lotions, perfumes, food, cleaning products, cigarette additives and other products. They are ubiquitous contaminants that are lipophilic in nature. They are widely present in environmental samples, for example, in water sources, because they are continually released into the aquatic environment, and, due to their lipophilicity, they tend to be persistent and accumulate in sediments, sludge, water, soil, aquatic life, air, marine mammals, human breast tissue and breast milk. These SPM compounds are considered endocrine modulators as they affect fish embryo and larva stage development; are carcinogens and impair fertility in rats. An investigation of these SPMs was prompted because they are observed to be only partially eliminated in sewage treatment plants, and there is an increasing trend in their production volume and usage. Currently, there is a paucity of data from Africa on these substances, since they are not commonly monitored. There is no information on their concentrations and distribution in KwaZulu-Natal Rivers, especially the two rivers of interest, namely, the uMgeni and Msunduzi rivers. These rivers have anthropogenic, agricultural and industrial activities, as well as return flow from different wastewater treatment plants, dams and tributaries along their courses. Sediment samples were collected at eighteen sites along the courses of these two rivers for the summer season in January 2015. The sediment samples were dried in a clean drying room and partitioned into different mesh sizes with a sieve. Extraction of the sediments was carried out with the aid of an ultrasonic bath and hexane/acetone (1:1) as the extracting solvent. The extracts were cleaned by using silica gel and anhydrous sodium sulfate. Quality assurance and quality control measures were ensured. The sediment samples were analyzed for SPMs by means of gas chromatography-mass spectrometry. The method has a good recovery of 78 to 120% with an intra-day and inter-day percentage relative standard deviation (%RSD) observed to be < 7%. Results obtained indicate the presence of the SPMs of interest in the sediment samples of the uMgeni and Msunduzi Rivers except at Camp Drift where the concentration is observed to be lower than the limit of detection.

WE051

Does chiral inversion change the ecotoxicity of pharmaceuticals?

P.A. Neale, Griffith University / Australian Rivers Institute; A. Branch, University of New South Wales / School of Civil & Environmental Engineering; S.J. Khan, University of New South Wales / School of Civil and Environmental Engineering; F.D. Leusch, Griffith University / Australian Rivers Institute

Wastewater treatment plants are a significant pathway of pharmaceuticals to the aquatic environment. Many commonly used pharmaceuticals, including some non-steroidal anti-inflammatory drugs (NSAID), are chiral chemicals and their enantiomers can exhibit different biological activity. However, very few studies have considered the potential ecotoxicological differences of pharmaceutical enantiomers. Recent studies have shown apparent chiral inversion of pharmaceuticals during wastewater treatment, with higher concentrations of (R)-naproxen detected in wastewater effluent despite naproxen being manufactured as pure (S)-naproxen. The overall project aims to determine if biological wastewater treatment can increase the ecotoxicity of chiral pharmaceuticals. To assess the ecotoxicological differences of NSAID enantiomers, (R) and (S) enantiomers of naproxen, ibuprofen, ketoprofen and flurbiprofen were run in a battery of bioassays using bacteria, algae and fish cells. While many of the enantiomer pairs had a similar effect in the bacterial toxicity screen, the (S) enantiomer of flurbiprofen was more toxic than the (R) enantiomer. The opposite was observed in the combined algae test, where (R)-flurbiprofen had a greater effect than the (S) enantiomer. Further, several of the enantiomer pairs showed differing ethoxyresorufin-O-deethylase (EROD) activity in fish cells. This study shows there are differences in effect for some pharmaceutical enantiomer pairs and indicates the importance of considering enantiomers when assessing the risk of pharmaceuticals to the receiving environment.

WE052

Estimation of annual active pharmaceutical ingredients emission from small municipal waste water treatment plant in Poland

R. Kalinowski, Institute of Environmental Protection - National Research Institute / Department of Ecotoxicology; D. Kopiec, Miejskie Przedsiębiorstwo Wodociągów i Kanalizacji w Błoniu; A. Bogusz, Institute of Environmental Protection - National Research Institute / Department of Ecotoxicology; M. Lehtonen, Finnish Environment Institute SYKE / Laboratory Centre; H. Ek Henning, County Administrative Board of Östergötland / Department of Environmental Protection; B. Gworek, Institute of Environmental Protection - NRI; N. Perkola, Finnish Environment Institute, SYKE

Pharmaceuticals and their active ingredients (APIs) in the environment have become one of the most emerging issues nowadays. Lots of efforts are put to estimate both the environmental levels of APIs as well as their ecotoxicological impacts on living organisms. In this study the estimation of annual loads of APIs from small MWWTP located in Blonie, Poland is presented. 24 h flow proportional composite effluent samples were collected in two seasonal campaigns –autumn 2017 and spring 2018. Totally 65 and 63 compounds were detected by UHPLC-MS/MS method in the samples in autumn and summer respectively, representing different therapeutic groups e.g. antibiotics, antihypertensives, non-steroidal anti-inflammatory drugs (NSAIDs), betablockers and lipid-lowering agents. Twenty substances were analysed but not quantified (< LOQ) in autumn and 26 in the summer. The most abundant compounds in effluents (with concentrations above 1 mg/L) were: Carbamazepine < Fenbendazole < Mesalazine < Telmisartan < Gabapentin < Diclofenac < Allopurinol < Nebivolol < Ciprofloxacin < Ivermectin in autumn season and Ivermectin < Diclofenac < Carbamazepine < Gabapentin < Telmisartan in summer season, respectively. For substances with concentrations The annual loads for compounds with the highest concentrations were: **API Concentration in effluent [ng/L] Annual load [kg/y] Autumn Spring** Ciprofloxacin 1241435,05 92,20 1344,509 Nebivolol 32037,72 3,14 34,699 Allopurinol 12565,28 < 13,72 13,614 Diclofenac 8462,28 1703,91 10,843 Telmisartan 1963,48 6493,64 8,526 Gabapentin 2368,85 5822,67 8,304 Carbamazepine 434,72 2485,60 2,920 Mesalazine 1906,61 < 1,58 2,066 Fenbendazole 1399,23 54,10 1,569 Ivermectin < 177,45 1104,42 1,184 The variation in the API concentrations was observed in this study. The overall emission of 10 selected compounds was estimated to be at least 1 kilogram per year from single MWWTP. *Acknowledgement – Research was performed in the framework of EU's Interreg Baltic Sea Region project "Clear waters from pharmaceuticals – CWPharma" under WP2 "Comprehensive status of pharmaceuticals - improved knowledge on consumption, emissions, environmental levels and risks of pharmaceuticals".*

WE053

Ethylparaben adsorption onto activated carbon

R. Maia Valença, University of Sao Paulo - USP / Chemistry and Molecular Physics; R.T. Verbinnen, University of São Paulo USP / Department of Molecular Chemistry and Physics; E.M. Vieira, University of São Paulo / Institute of Chemistry of Sao Carlos

There are lots of environmental issues but the water resources quality always deserves attention, considering its essentiality to life maintenance. With the industrial and urban growth, a large number of hazardous chemicals are detected in the water bodies due to the lack of proper wastewater treatment systems. This practice may affect the human life and aquatic ecossystems. Over the years, different organic compounds have been classified as endocrine disruptors and a great number of scientific studies have suggested that parabens could interfere negatively on endocrine and hormonal system of different species. Many studies in the literature report the presence of parabens in water bodies around the world. Thus, the necessity of pursuing alternative technologies to mitigate the environmental impact caused by toxic organic compounds is evident. In this context, this work evaluated the use of adsorption as an alternative technology to the paraben contaminated water treatment. Among other tests a coconut shell activated carbon was capable of removing up to 90% of ethylparaben, which is one of the most used parabens for preservation of personal care products and food.

WE054

Exploring the occurrence of emerging organic contaminants in Nigerian aquatic environments through a combined target and non-target screening approach

O. Olaitan, Olabisi Onabanjo University / Department of Pharmaceutical Chemistry; Z. Li, Stockholm University / ACES; A. Chimezie, Centre for Applied Research on Separation Science / Department of Pharmaceutical Chemistry; A. Adepoju-BellO, UNIVERSITY OF LAGOS / Department of Pharmaceutical Chemistry; C.L. Chen, South China Normal University / Environmental Research Institute

The occurrence of emerging organic contaminants, e.g., pharmaceuticals, personal care products, and artificial sweeteners, has increasingly gaining scientific and public attention due to their ubiquitous presence in the aquatic environment and their potential of causing harmful effects on ecosystems. Research on the occurrence and distribution of emerging organic contaminants in Africa so far has been relatively scarce. In this study, we aimed at addressing this knowledge gap by exploring the occurrence of these contaminants in various types of waters including surface water, well water, tap water, and effluent samples collected from different geographical regions in Lagos, Nigeria. Both target and non-target analysis were performed to enable quantification and semi-quantification of the detected emerging organic contaminants. All samples were analyzed by direct injection on an UHPLC-Orbitrap-MS/MS operated under both positive and negative electrospray ionization modes. In total, 366 compounds were identified using the online database mzCloud, including among others pharmaceutically active ingredients, personal care products, and industrial products. Level 1 identification confidence was achieved for 31 compounds for which reference standards were available and level 2 was achieved for the rest. In the quantitative analysis of 38 target compounds, 18 were detected, including both parent compounds and metabolites. For the compounds detected in common between target and non-target analysis, the quantitative results using concentrations and the semi-quantitative results using peak areas are fairly consistent, indicating a high reliability of our non-target approach. In general, acetaminophen, caffeine, and sulfamethoxazole were the organic contaminants detected at the highest average concentrations (up to 145 mg/L for acetaminophen in the samples collected from Lagos Lagoon). Wastewater and lagoon water contained the most organic contaminants with noticeably high concentrations. In addition, seven contaminants were found in the tap water, with a concentration ranging from 0.062 μg/L for acesulfame to 103 μg/L for caffeine. These findings point to a high potential of hazards for the population and ecosystems in the regions.

WE055

Extraction, isolation and characterisation of selected benzodiazepines in wastewater

S. Nzube, V.S. Somerset, CPUT / Chemistry

Pharmaceutical pollutants entering the aquatic environment have become a growing environmental concern. These pharmaceuticals are unique pollutants because of their special characteristics and behaviour that cannot be simulated with other organic pollutants. The untreated wastewater effluent that contains pharmaceuticals poses considerable threat to the aquatic ecosystem because of the negative effects of non-target organisms in the water. Recent years have seen a growing concern about the benzodiazepines, as emerging pollutants, and their effects on the aquatic environment. These compounds are nowadays widely detected in sewage wastewater. It is important to increase the emphasis on the characteristics of the benzodiazepines in order to differentiate them from industrial chemical compounds. In this study various solid phase extraction techniques have been employed focussing on isolation of benzodiazepines in wastewater matrices. Employing this methodology has shown improved detection and analysis of clonazepam and lorezapam as benzodiazepines.

WE056

Fate of TBBPA in rhizosphere of wetland plants: Removal under shifting oxic-anoxic conditions

K.S. Bitter, RWTH Aachen University; Y. He, Nanjing University / State Key Laboratory of Pollution Control and Resource Reuse School of the Environment; A. Schaeffer, RWTH Aachen University / Institute for Environmental Research; R. Ji, Nanjing University / State Key Laboratory of Pollution Control and Resource Reuse School of the Environment

Tetrabromobisphenol A (TBBPA) is a brominated flame retardant used worldwide. Due to its high lipophilicity and poor water solubility, TBBPA tends to accumulate in the environment. TBBPA has been detected in various environments such as air, sewage sludge, sediment and soil, and even in organisms such as mussels and birds. Therefore, the need for TBBPA removal from the environment is indispensable. The degradation of TBBPA has been examined in various studies and it has been found, that a full metabolization takes places neither under oxic nor under anoxic conditions. A sequential shift of oxic conditions seems promising, just as it is naturally occurring in the rhizosphere of constructed wetland plants. The aim of this study is therefore to establish a method to simulate the shifting areation conditions of rhizosphere decoupled from other rhizosphere effects and thereby achieve a complete removal of TBBPA. The model plant for this study, *Phragmites australis*, was sampled from a field constructed wetland and cultivated in a greenhouse. To spatially quantify the radial oxygen loss (ROL) of the plant roots, quantitative imaging by luminescence sensing of a planar oxygen optode was used. Artificial roots were built from ultrafiltration membrane and connected to an air pump. The oxygen flow rate of the artificial roots was adjusted to meet the plant ROL, also by measuring with the planar optode. Within the next months, the artificial roots will be used in a TBBPA removal study. Removal at diurnal shifting areation conditions will be compared to removal at constant oxic conditions, removal without oxygen supply and a sterile control. The artificial roots will be placed in sediment sampled from the constructed wetland saturated with wastewater in closed systems. ^{14}C-labelled TBBPA will be used to trace the substance and its metabolites. Using liquid scintillation counting (LSC) and ultra performance liquid chromatography-mass spectrometry (UPLC-MS), the formation of metabolites and mineralization will be determined. This work is part of the collabrative project of the National Natural Science Foundation of China (NSFC) and the European Union (Grant No. 31861133003).

WE057

Finnish Watch list - The screenings results 2015-2018 in surface waters

V.A. Junttila, K. Siimes, Finnish Environment Institute SYKE / Centre for Sustainable Consumption and Production; A. Allonen, Eurofins Environmet Testing Finland Oy

We present results of Finnish surface water screening of watch list substances (EC implementing decision 2015/495). Samples were collected from 9 sites according to the directives demand during 2015–2018. The sites presented varying types of pressures from urban to agricultural while some of the sites represented background conditions. The sites included 7 rivers, a lake near city of Tampere and a pipe from Lake Päijänne, which water is used to produce drinking water for Helsinki metropolitan area. The substances included 3 estrogens, 3 macrolide antibiotics, diclofenac, 5 neonicotinoids, 3 other agricultural pesticides, BHT and ECHM. A requirement for quantification limit (LoQ) for analysis was given in the EC decision for each substance or group of substances basing on the compound predicted no effect concentration (PNEC). The samples were analysed in a laboratory of Eurofins and the LoQ requirements were fulfilled. The concentration of estrogens in Finnish surface waters have never before been analysed using as low LoQs. The synthetic estrogen 17-α-ethinylestradiol (EE2) was detected in concentration of 0.035 ng/L, which is its PNEC level (Loos et al. 2018), in 3 sites. Estrone (E1) was detected in several sites but its PNEC was not exceeded. Diclofenac was detected widely and its concentration was above its PNEC of 50 ng/L (Loos et al. 2018) in several river samples. The occurrence of diclofenac, EE2 and macrolides, which were detected in trace levels in several sites, were strongly associated to effluents from waste water treatment plants (WWTP). Their concentration fluctuation in time was affected by the volumes of diluting water (river discharge). In 2018, some spills in up-stream WWTPs during low discharge period caused high peak concentrations. Neonicotinoids clothianidin and thiamethoxam were detected frequently in the rivers under agricultural pressure, but their concentration did not exceed PNEC levels. Over half of the compounds were not detected at all: e.g. estradiol, which is estimated to enter into sludge in WWTP, the pesticides which are not used/usage is very limited (acetamiprid, imidacloprid, tri-allate, oxadiazon, methiocarb) and BHT, which sources are unknown. EHMC was detected in a sample. The launching of watch list accelerated the development of analytical methods. Results show that diclofenac and EE2 may occur in possibly harmful concentrations in Finnish surface waters under urban influence and their monitoring should continue.

WE058

Hydrolysis of modern antifouling biocides: Zinc Pyrithione and Zineb

J.T. Koning, Aarhus University, Department of Environmental Science / Department of Environmental Science; K. Bester, U.E. Bollmann, Aarhus University / Department of Environmental Science

The environmental fate of two metal-organic biocides, zinc pyrithione (ZnPT) and zineb, is difficult to assess, which is partially due to i) the difficulty to dissolve the respective compounds, ii) questionable stability of the compounds in water or solvents, and iii) their ability to exchange their metal ion in a process called transchelation. This transchelation process, combined with an inability to dissolve in common solvents, make them difficult to analyze. In this study, we aimed to investigate how these complexes behave when released into the aquatic environment. Therefore, ZnPT and zineb were suspended in natural seawater, artificial seawater, sterilized seawater (all salinity about 1.2%) and in deionized water. In these samples, ZnPT, zineb and their transformation products were monitored using an LC-MS/MS, in order to study the ongoing transformations in each sample. In this experiment, it became clear that ZnPT and zineb themselves were not detected using LC-MS/MS. The two transformation products monitored for ZnPT were the sodium pyrithione transchelate and dipyrithione. Sodium pyrithione is found in all samples. It was formed mainly in the deionized water, where it reaches a plateau. However, in artificial seawater and natural seawater, the sodium pyrithione was found to hydrolyze after initial formation. Dipyrithione has been detected as a transformation product of sodium pyrithione. Formation and degradation of dipyrithione follows the sodium pyrithione in the sterilized brackish water, brackish water and deionized water. However, dipyrithione does not show similarities to sodium pyrithione in the artificial seawater, where dipyrithione is formed at a much slower rate and does not show any dynamics resembling those of sodium pyrithione. For zineb, only a single transformation product could be monitored, which is ethylene bis-isothiocyanate sulfide (EBIS). This product was readily detected and no differences between the treatments could be observed. Moreover, no degradation of EBIS could be detected, meaning it might be a stable transformation product. This study shows, not only, that the transformation products should be included during environmental monitoring of ZnPT and Zineb, but, also, that the environmental fate of these metal-organic biocides depends on specific environmental conditions.

WE059

Identification and quantification of polybrominated dipheyl ethers (PBDEs) in environmental samples using gas chromatography coupled to Orbitrap mass spectrometry

J. Renpenning, J. Cooper, Thermo Fisher Scientific; J. Parera, Spanish National Research Council (CSIC) / Department of Environmental Chemistry; E. Abad, Spanish National Research Council (CSIC) / Institute of Environmental Assessment and Water Research (IDAEA); R. Law, C. Cojocariu, Thermo Fisher Scientific

Polybrominated diphenyl ethers (PBDEs) are a group of organobrominated contaminants that inhibit or suppress combustion in organics material, and due to these properties have been widely used since the 1970s as flame retardants. Most PBDEs resist degradation, and bioaccumulate in environment, and food chains, and can be transported through air, and water over long distances. Many PBDEs have been identified as toxic, with links to cancer, and endocrine disruption and the use of certain PBDE have been banned. There are many analytical challenges to consider when developing a GC-MS method for the analysis of PBDEs, especially related to the active nature of high molecular mass PBDEs (e.g. BDE-209), and to the large number of compounds, resolution, and peak symmetry requirements (e.g. chromatographic separation of BDE 49 and BDE 71 can be challenging in complex environmental samples). This work demonstrates the use of high resolution accurate mass GC-Orbitrap technology for the targeted analysis of 27 PBDE native congeners in air, ash, sediment, and sludge samples using a sensitive, fast, and robust high throughput method. Sediment, filter dust, air, and sludge samples were assessed for their PBDE content. In the sludge samples analysed, the predominant PBDE congeners identified were BDE-209, 47 and 99, where as in the filter dust samples BDE-47, 119, 99, 53 and 183 were prevalent. This preliminary results offers excellent selectivity, and sensitivity for the analysis of PBDEs in complex samples. Moreover, the use of high resolution to achieve selectivity in difficult matrices, and the mass accuracy obtained allows for unambiguous identification, and elemental composition confirmation of chemical contaminants.

Leaching of diflufenican and transformation products in the urban environment

P. Carvalho, Aarhus University, Department of Environmental Science / Department of Environmental Science; C.N. Albers, O. Jacobsen, Geological Survey of Denmark and Greenland / Department of Geochemistry; K. Bester, C.S. Jacobsen, Aarhus University / Department of Environmental Science

In the urban environment, courtyards, driveways, tiled squares, and other places are sprayed with persistent, pre-emergent herbicides to avoid plant growth. Extensive use of such herbicides has resulted in serious contamination of groundwater in Denmark (e.g. dichlobenil transformation to the metabolite 2,6-dichlorobenzamide (BAM)). We are presently focussing on the herbicide diflufenican that, along with glyphosate (Keeper-L), is used in paved areas. However, its product registration was based on the data obtained from agricultural soil that typically presents much higher organic matter and sorption capacity. Thus, we hypothesized that in urban applications, diflufenican and its transformation products can more easily end up contaminating both surface water (via stormwater run-off) and groundwater. Two separate outdoor experiments, subject to natural rain and meteorological conditions, have been set up to separately study both emission routes. 1) to study surface runoff and leaching from paved surfaces, big steel trays with a depth of 12 cm were filled with sand/gravel overlaid with either concrete tiles or standard gravel paving forming a full-section of 1 m^2. 2) to compare the potential leaching to groundwater from five different soil types, a multicolumn lysimeter (21 columns, each 50 cm long and 15 cm in diameter) was set up. A sandy and a loamy agricultural soil, and three types of commercial gravels found in the Danish stores were assessed. Both experimental setups were sprayed with Keeper-L following the manufacturer indications. Leachate from the systems was collected up to 1-year period and analyzed by HPLC-MS/MS. The two paved surfaces leached diflufenican immediately in the first rain event, both through surface run-off and infiltration. Concentrations were as high as 11 μg/L in the run-off and leachate, while both known aerobic transformation products (AE-O and AE-B) were detected 7 days after the spraying. Different retention patterns were observed depending on the pavement material. The leachate from the outdoor multicolumn lysimeter revealed no leaching of diflufenican within a 1-year period. Nevertheless, concentrations up to 1.6 μg/L of both transformation products, AE-B and AE-O, were measured for the gravels but not for the agricultural soils. The different gravels showed also different TPs formation and retention patterns. In sum, we may be emitting diflufenican and its TPs to urban waters.

WE061

Micropollutants present in wastewater emitted in the Baltic Sea catchment - an overview

E. Undeman, Stockholm University / Baltic Sea Centre; M.T. Leppänen, Finnish Environment Institute SYKE; K. Pazdro, Institute of Oceanology, Polish Academy of Sciences / Department of Marine Chemistry and Biochemistry

Hazardous substances are recognized as a threat to waterbodies in the Baltic Sea region and the EU, which is acknowledged in the EU's water legislation. However, the importance of municipal WWTPs as entry routes for these substances is in many cases neither well studied nor acknowledged in current wastewater policy. There is a lack of knowledge regarding which chemicals are present in wastewater and their observed negative effects. The lack of knowledge leads to a lack of policy action as currently available data do not suffice to establish requirements for acceptable loads or removal efficiencies of micropollutants entering MWWTPs. In this study, we aim to map micropollutants measured in wastewater emitted in the Baltic Sea catchment. A literature search for scientific publications reporting concentrations of any micropollutants in effluents was performed. In addition, data were compiled from national monitoring databases and project reports. National monitoring contacts were approached directly and asked for publically available monitoring and screening data. The type of chemicals typically measured, detection frequencies and detected levels, data availability for different Baltic Sea nations were analyzed and data gaps highlighted. We found data for ca 830 unique substances measured in ca 25 000 samples of effluents emitted in the Baltic Sea catchment. In approximately half of the ca 25000 recorded samples, the concentration of the analyzed substance was above the analytical limit of the method (detection limit or quantification limit). The type of compounds with highest detection frequency were organophosphates, sweeteners, fluorescent whitening agents and components in household products. In absolute numbers, pharmaceuticals was the most commonly detected type of substance, although ca 50% of these analysis were reported as non-detects. Screening campaigns are needed in particular in the eastern Baltic Sea countries and Denmark in order to assess national differences and better understand the role of MWWTPs as filters between urban and aquatic environments in the Baltic Sea region.

WE062

Modelling of pharmaceutical loads to the Baltic Sea - A case study in Southern Finland

L. Äystö, K. Siimes, Finnish Environment Institute SYKE / Centre for Sustainable Consumption and Production; M. Joukola, Finnish Environment Institute SYKE / Data and Information Centre; J. Koskela, Finnish Environment Institute SYKE / Freshwater Centre; V.A. Junttila, Finnish Environment Institute SYKE / Centre for Sustainable Consumption and Production; N. Perkola, Finnish Environment Institute / Laboratory Centre

Active pharmaceutical ingredients (APIs) are detected globally in surface waters and in a variety of other matrices. The knowledge on the API load to the Baltic Sea environment is currently inadequate, and the spatial coverage of information produced in screening campaigns and surveys is sparse. The objective of this study was to estimate the overall emissions of selected APIs into the Baltic Sea as well as estimating the concentration of these substances in the estuary area. To a large extent, APIs are emitted through human consumption of pharmaceuticals and subsequent waste water emissions. The pathway of a consumed pharmaceutical product to API emission into the environment is affected by several processes, such as metabolism, elimination in waste water treatment processes and possible elimination in the environment. In this study we estimated the loads and concentrations of selected APIs using a GIS-based model. Assuming the consumption of pharmaceuticals is uniform within each country, the human population in each area can be seen as the driving parameter for the input of APIs into the environment. The model combines information on inhabitants and national statistics on the consumption of pharmaceuticals to calculate the API usage in each grid cell. We further coupled the usage information with API-specific parameters, such as excretion rate of the active substance and removal rate in waste water treatment processes to estimate the environmental load of these substances. Furthermore, API-specific behavior, such as degradation in the environment was taken into consideration to estimate the total load of the selected substances reaching the Baltic Sea. To evaluate the impact of the processes occurring in the environment, we approximated the distance and travel time from each grid cell to the Baltic Sea. The poster presents the preliminary results for a case-study area located in Southern Finland as well as discusses the possible sources of error. The calculation method will be used in estimating the potential of different emission reduction measures. The study is part of the project Clear waters from pharmaceuticals (CWPharma), which is funded by EU's Interreg Baltic Sea Region Programme.

WE063

Modified biochar for efficient removal of pharmaceuticals from water

Z. Shirani, A. Bhatnagar, University of Eastern Finland

Activated biochar (ACT-B) was prepared from *A. sylvestris* or cow parsley (a locally grown plant that can be a problematic weed) by modifying it with NaOH. The prepared material was characterized by several techniques, viz., scanning electron microscopy, Fourier transform infrared spectroscopy, pH_{zpc}, elemental analyzer and Brunauer–Emmett–Teller in order to gain an insight of its physico-chemical properties. The potential of ACT-B was assessed for the removal of diclofenac sodium (DF) and cephalexin (CPX), two important pharmaceuticals from water. Batch studies were first conducted and different adsorption parameters such as effect of solution pH, contact time, temperature, adsorbent dosage, adsorbate initial concentration and co-existing ions were investigated to optimize the process. The kinetic and equilibrium data were fitted into different kinetic and isotherm models. ACT-B exhibited high adsorption capacity for DF and CPX. The removal efficiency of DF and CPX was influenced by temperature and the competing ions, while the highest removal of DF and CPX occurred at normal pH. Moreover, to understand the applicability of ACT-B in real scale for the removal of DF and CPX, column studies were also carried out using different adsorbate concentrations and flow rates. Mainly, pi–pi bonding was found to be responsible for the adsorption of the studied pollutants onto ACT-B. The results of this study revealed that modified biochar has high potential in removing DF and CPX from water.

WE064

Occurrence of aromatic micropollutants and their chlorinated derivatives in wastewater and river of Taichung metropolitan area

W. Chen, National Taiwan University / Institute of Food Safety and Health; X. Lin, TUNGHAI University / Department of Environmental Science and Engineering

Pharmaceuticals and personal care products (PPCPs) with aromatic structures are likely to be transformed into chlorinated derivatives even in low-dose chlorination (0.2-0.7 mg/L). In this study, we investigated the occurrence of ten aromatic PPCPs and their 16 transformation products (TPs) in a domestic wastewater treatment plant located at the metropolitan district of Taichung, Taiwan. The wastewater and water in the river which receives the effluent were sampled (100 mL, n = 3 each) according to the hydraulic retention time in October 2018. Samples were pretreated using solid-phase extraction. The aromatic PPCPs and their TPs were determined or semi-quantified using ultra-performance liquid chromatography coupled with triple-quadrupole mass spectrometry. The dynamic ranges of the PPCPs were mostly between 2.5 ng/L to 20 µg/L with most of the quantification biases within ± 10%. Methylparaben, bisphenol A, and diclofenac were found in all of the samples at the levels ranged from tens to more than 100 ng/L. The concentrations of these three aromatic PPCPs were generally higher in the wastewater than in the receiving river water, probably due to dilution. However, unrecorded sources of contamination may have brought into the receiving river acetaminophen and propylparaben (tens ng/L), which were absent in the wastewater. The unspecified sources and physicochemical reactions may also have resulted in the positive detections of the chlorinated TPs of propylparaben and triclosan ($C_{10}H_{10}Cl_2O_3$ and $C_{12}H_6Cl_4O_2$, respectively) in the river water. The results demonstrated the occurrence of chlorinated TPs, which are more toxic than their precursor PPCPs, in the complex urban water system. Future work will be concentrated in elucidating the temporal trends of the transformation of aromatic PPCPs by observing the relative concentrations of the chlorinated TPs in the following seasons.

WE065

OPTIMISATION OF A MICROWAVE ASSISTED EXTRACTION PROCEDURE COMBINED WITH LIQUID CHROMATOGRAPHY TANDEM MASS SPECTROMETRY FOR THE DETERMINATION OF TAMOXIFEN AND CYCLOPHOSPHAMIDE IN FISH TISSUES

S. Viera, Universidad de Las Palmas de Gran Canaria / Chemistry; L. Marzullo, University of Florence / Department of Chemistry; M. Torres-Padrón, Universidad de Las Palmas de Gran Canaria / Department of Chemistry; M. Del Bubba, University of Florence / Department of Chemistry; Z. Sosa-Ferrera, J. Santana-Rodríguez, Universidad de Las Palmas de Gran Canaria / Department of Chemistry

A serious problem today is marine pollution caused by human activities. Part of this contamination is due to pollutants that come from wastewater treatment plants due to an ineffective treatment in the elimination of certain compounds (Montesdeoca-Esponda et al., 2018). Some of them are antineoplastic compounds, which are drugs used as treatments against cancer and can cause important adverse effects if they reach the environmental waters (Parrella et al., 2014). Antineoplastic compounds have been detected in hospital effluents, wastewater treatment plants influents and effluents, river and surface waters, and sludge (Santana-Viera et al., 2016). To date, no procedure has been optimized for the extraction of antineoplastic compounds from fish tissue. In this work, we optimised a procedure for the extraction and determination of Cyclophosphamide and Tamoxifen in fish tissues by using microwave assisted extraction with liquid chromatography tandem mass spectrometry. The developed procedure was applied to the extraction and determination of these two compounds in muscle and liver tissues of to three different fish species of different levels of the trophic chain captured in the vicinity of three marine outfalls. **REFERENCES** Montesdeoca-Esponda, S., Checchini, L., Del Bubba, M., Sosa-Ferrera, Z., Santana-Rodriguez, J.J., 2018. WE066

Profile of emerging contaminants and their transformation products in drinking water in Taiwan

C. Hsieh, W. Chen, National Taiwan University / Institute of Food Safety and Health; Z. Chen, National Taiwan University / Institute of Environmental Health; X. Lin, TUNGHAI University / Department of Environmental Science and Engineering

Sequential water treatment processes in drinking water treatment plants (DWTPs) may be capable of removing organic micropollutants from raw water. However, recent concerns have risen over the transformation of pharmaceuticals and personal care products (PPCPs) into chlorinated derivatives. In this study, we evaluated the removal efficiencies of ten PPCPs and the generation of their 16 transformation products (TPs) in the DWTPs in Taiwan. Raw and finished water samples (500 mL, each n = 8) were collected from six major DWTPs, which are located in northern, central, and southern Taiwan and perform similar water treatment processes. These water samples were pretreated using solid-phase extraction (SPE) with methanol elution. The extracts were concentrated and reconstructed to 1 mL with methanol before being analyzed using reversed-phase liquid chromatography coupled with triple-quadrupole mass spectrometry. The relative quantification of the PPCPs and TPs were performed by comparing their peak areas to those of diclofenac-d_4, which was spiked before the SPE. Three PPCPs and one TP were found in the water of DWTPs. While acetylsalicylic acid and methylparaben appeared in almost all of the water samples, diclofenac was found in only one finished water sample. On average, 17.6% and 27.6% of acetylsalicylic acid and methylparaben, respectively, were removed in the DWTPs. However, the highest levels of acetylsalicylic acid and methylparaben in the finished water were 31.4 and 8.1 times, respectively, more abundant than those of the lowest. A TP of acetaminophen ($C_8H_7Cl_2NO_2$) was found in both the raw and finished water of a DWTP, of which the raw water was composed of the water from a river and a reservoir. The retention of acetaminophen in the reservoir may have increased the probability of TP formation. This study demonstrated that given similar treatment processes, the source of raw water should have a decisive influence on drinking water quality in terms of micropollutant contamination.

WE067

Quantitative and qualitative analysis for emerging organic pollutants in wastewater from WWTP in Busan, Korea via target, suspect and non-target screening

Y. Choi, Changwon National University / FEED of Eco-Friendly Offshore

Structure; J. Jeon, School of Civil-Environment-Chemical Engineering, Changwon National University / School of Civil-Environment-Chemical Engineering

Emerging organic pollutants such as pharmaceuticals, personal care products, and pesticide are entering into water system via effluents from WWTP. Although much research has been performed about environmental pollutants in wastewater, there are many substances that are still unknown and/or excluded from regular monitoring work mainly due to the lack of analytical tools. To identify them, emerging analysis techniques such as suspect and non-target screening using HRMS required. The aim of the present study is to quantitatively analyze well-known emerging pollutants and identify less-recognized ones in effluent from WWTP via advanced analytical methods such as suspect and non-target screening using LC-HRMS(QExactvie+ Orbitrap). The effluent samples were taken from four WWTP located in Busan in October 2018 and enriched with multi-layer SPE method. Among 180 target compounds, 32 pharmaceuticals (Ampicillin, antipyrine, bisoprolol, carbamazepine, caffeine, cimetidine, clarithromycin, celecoxib, climbazole, cetirizine, diphenhydramine, lidocaine, fexofenadine, fluconazole, fluoxetine, irbesartan, lamotrigine, lincomycin, losartan, mefenamic acid, naproxen, niflumic acid, oxcarbazepine, propranolol, ranitidine, roxithromycin, sitagliptin, sulfamethoxazole, sulpiride, telmisartan, trimethoprim, venlafaxine), 5 metabolite (albendazole sulfoxide, carbamazepine 10,11-epoxide, O-desmethyl venlaxaxine, paraxanthine/theophylline, valsartan acid) and 4 Etc (azoxystrobine, benzotriazole, carbendazim, O-toluenesulfonamide/P-toluenesulfonamide) were detected in the effluents. The concentrations range was ~ 680ng/L of pharmaceuticals, ~ 123 ng/L of metabolites and ~ 368 ng/L of others. Ranitidine used to decrease stomach acid production has shown the highest concentration and detection frequency. As results of suspect and non-target screening, 19 pharmaceuticals (1-adamantanamine, amisulpride, dextrorphan, vildaglitpin, olmesartan, tapentadol, flecainide, minoxidil, dibucaine, methocarbamol, phentermine, dihydrocodeine, candesartan, escitalopram, hydrocodone, sulfapyridine, flubendazole, benzydamine, phendimetrazine), 8 metabolites (1,7-dimethyluricacid, 2-aminobenzimidazole, 2-amino-6-methylmercaptopurine, 10,11-dihydro-10,11-dihydroxycarbamazepine, 10-hydroxycarbamazepine, clopidogrel carboxylic acid, triehtyl phosphate, tropine) and 4 etc (ensulizole, citroflex 2, tris(2-butoxyethyl) phosphate, triethyl phosphate) were tentatively identified in the effluents.

WE068

Removal of ozonation products by biofilm reactors

K. Bester, Aarhus University / Environmental Science; H. el taliawy, Aarhus University Department of Environmental Science; E. Edefell, Sweden Water Research; S. Kharel, Aarhus University Department of Environmental Science; P. Falås, M. Cimbritz, LTH Lund University / Department of Chemical Engineering

Organic micropollutants are emitted with the effluent wastewater. They thus endanger surface water quality and drinking water resources. However, they can be removed by ozonation. While ozonation appears to generally work and can be conducted with acceptable costs both for wastewater and for drinking water, it often does not destroy the compounds completely, but it oxidises them. Thus from diclofenac which can be removed easily by ozone, 6-9 ozonation products are known, while for other compounds (macrolide antibiotics, venlafaxine, tramadol) the main ozonation products are the respective *N*-oxides. To avoid these compounds are emitted due to the ozonation, a successive biological treatment based on biofilm reactors is discussed without a clear idea which biofilm reactor might be used: different sandfilters, fluidised bed filters, bilogically activated activated carbon filters, pond systems, or moving bed biofilm reactors (MBBRs). All of the tested ozonation products were degraded faster in the incubations with biofilm than without. However, the reaction kinetics were diverse: While most compounds were degraded following first order kinetics, some were degraded by zero order. Both concentrations of the same ozonation product were degraded following the same order, though the reaction rates differed. This might be due to the fact that these experiments were conducted with relative thin biofilms and saturation effects might indicate for Michaelis Menthen kinetics. Especially concerning the *N*-oxides the authors were suspicious that the parent compounds of the N-oxides might be re-formed, but this was not the case. Ozonation products can be removed by biofilm reactors such as MBBRs, whether or not that approach is feasible depends on how much biomass can be stabilised downstream of the ozonation reactor.

WE069

Removal of trace substances using a modular WWTP - evaluation of the purification performance through different treatment options.

D. Kämpfer, Institute for Environmental Research (RWTH Aachen University) / Institute for Environmental Research (Bio V); A. Leibner, RWTH Aachen University / Institute for Environmental Research (; M. Radi, S. Schiwy, H. Hollert, K. Smith, A. Schaeffer, RWTH Aachen University / Institute for Environmental Research

In the course of industrialization more and more chemicals are being used. Nowadays in industrial processes, agriculture, and private households, chemicals are indispensable. As a result, they are widely dispersed in the environment. Wastewaters in particular are a significant source for so called emerging contaminants – substances which are poorly removable during traditional wastewater treatment steps and are persistent in the environment. The aim of the project AWAREGIO is to open up new opportunities especially for small enterprises through the development of modular wastewater treatment processes for the re-use of water, wastewater based nutrients and energy in agriculture, fish farming and drinking water substitution. For this, a modular pilot plant has been constructed, consisting of a primary treatment coupled to an anaerobic reactor and a moving bed biofilm reactor followed by four different secondary treatments arranged in parallel (soil filter, UV treatment, ultrafiltration and reverse osmosis). With regards to the water re-use aspect of the project, treated water from the soil filter, the UV treatment and the ultrafiltration is used for aquaponics (a combination of plant and fish cultures). Monitoring of the removal efficiency of organic trace substances is an essential part of the evaluation for water reuse. Grab and passive sampling, as well as bioassays, have therefore been applied for this purpose. In general, the more traditional treatments including the primary treatments and the soil filter appeared to be insufficient for the removal of several of the chemicals. We will present in our poster the analyses of the effluents of the different treatment steps.

Screening of pharmaceuticals in Motala ström river basin district in Sweden

H. Ek Henning, S. Hoppe, County Administrative Board of Östergötland / Department of Environmental Protection; M. Lehtonen, N. Perkola, Finnish Environment Institute / Laboratory Centre

The occurrence of active pharmaceutical ingredients (APIs) in the environment is of global concern. One of the aims within the EU-project Clear Waters of Pharmaceuticals (CWPharma) is to get a more complete and reliable picture of the extent of contamination by pharmaceuticals in the Baltic Sea. Data on veterinary and human consumption of selected APIs has been collected to be used in environmental risk assessment and modelling. Mapping of environmental levels has been performed in selected river basin districts in the Baltic Sea Region covering about 200 field measurements during winter 2017 and early summer in 2018. Sampling in Sweden has been performed in the river basin district of Motala ström. Water has been collected in four lakes; Vättern, Boren, Dovern and Glan, as well as in two water courses; Stångån and Svartån. In the receiving estuary of Bråviken bay both water and sediment samples were taken. Included were also pharmaceuticals from two major hospitals and three municipal waste water treatment plants (MWWTPs) in Motala, Linköping and Norrköping. Analyses were performed both on influent, effluent and sludge from the MWWTPs and on soil samples in fields where sludge has been applied. About 60 of 75 substances were detected representing e.g. antibiotics, antihypertensives, non-steroidal anti-inflammatory drugs (NSAIDs), betablockers, antidepressants and lipid lowering agents. The results will be used to identify priority measures within the Baltic Sea Region that need to be addressed to reduce the load of APIs into the Baltic Sea. \n

WE071

Seasonal concentrations of nevirapine in wastewater at a wastewater treatment plant in Cape Town

S. Nzube, V.S. Somerset, CPUT / Chemistry

Emerging pollutants (EPs) are defined as substances that have been detected, which is not included in the routine monitoring programmes at the EU level, and whose fate, behaviour and ecotoxicity effects are not well understood. Pharmaceuticals used in the treatment of HIV, known as anti-retrovirals, are becoming prevalent and there is a need to quantify these pollutants and minimise any adverse affects to aquatic and human health. Nevirapine (NVP) is commonly used in the anti-retroviral treatment of HIV infection. It is known as a non-nucleoside reverse transcriptase inhibitor of the dipyridodiazepinone class, commonly used to minimize viral resistance. This study reports the isolation and chromatographic characterisation of NVP in wastewater samples, with concentrations ranging between 250 to 500 ng/L. Further evaluation of the impact of NVP on the aquatic ecosystem was also considered and reported in this study.

WE072

Stereoisomer-specific occurrence and fate of HBCD and TBECH in different wastewater treatment systems in Hong Kong

Y. Ruan, The State Key Laboratory in Marine Pollution / State Key Laboratory in Marine Pollution; K. Zhang, City University of Hong Kong / State Key Laboratory of Marine Pollution; J.C. Lam, The Education University of Hong Kong / Department of Science and Environmental Studies; R. Wu, City University of Hong Kong / Department of Chemistry; P.K. Lam, City University of Hong Kong / State Key Laboratory of Marine Pollution

The occurrence and fate of 1,2,5,6,9,10-hexabromocyclododecane (HBCD) and 1,2-dibromo-4-(1,2-dibromoethyl)cyclohexane (TBECH), two chiral brominated flame retardants (BFRs) including sixteen different stereoisomers, were investigated in 4 wastewater treatment plants (WWTPs) featuring diverse treatment processes in Hong Kong via a 2-year sampling campaign. Mass balance analysis revealed that: 34.3 g of HBCD and 3.68 g of TBECH daily entered the 4 WWTPs, with sludge carrying much higher amounts than effluent after wastewater treatment; larger quantities of these BFRs were released in summer; effective HBCD removal was achieved via biodegradation rather than sludge sorption, while both chemically enhanced primary treatment and secondary treatment yielded high TBECH elimination (>90%). For HBCD diastereomers, α-HBCD (54–75%) predominated in all of the samples, with its proportions increased in effluent compared with influent/sludge; while for TBECH diastereomers, α- and β-TBECH (72.3–84.4% in total) were the predominant species, with a proportional shift from the latter to the former diastereomer mostly observed between influent and effluent/sludge. A faster biodegradation of β- and γ-HBCD than α-HBCD as well as β- than α-TBECH might account for this changing pattern. This is the first study reporting the enantiomer-specific behavior of chiral BFRs during wastewater treatment processes. A preferential elimination of (+)-α- and (+)-γ-HBCD and E_2-β-TBECH occurred consistently after biological treatment, likely due to microbially mediated degradation.

WE073

Temporal and spatial analysis of pharmaceuticals in tropical freshwater ecosystems

G. Rabelo Quadra, Universidade Federal de Juiz de Fora; Z. Li, Stockholm University / ACES; F. Roland, N. Barros, Universidade Federal de Juiz de Fora / Laboratório de Ecologia Aquática; A. Sobek, Stockholm University / Department of Environmental Science and Analytical Chemistry ACES

Anthropogenic activities have strongly modified aquatic ecosystems. Among agents of global change, the concern about synthetic chemicals has grown. One example is pharmaceuticals, the consumption of which is increasing around the world. Pharmaceuticals are often not completely removed in sewage treatment plants; therefore they are detected in aquatic matrices worldwide. Another route for pharmaceuticals to the environment is the incorrect disposal of medicines. Pharmaceuticals can be harmful to ecosystems even in low concentrations. Therefore, knowledge about the occurrence of these compounds in aquatic environments is needed. In Brazil, occurrence and fate of pharmaceuticals in the environment are still poorly studied. This study was designed to analyze some of the most consumed pharmaceuticals in water samples from different freshwater systems in Brazil. Three water reservoirs (Chapéu D'Uvas, Funil, and Curuá-Una) in different parts of Brazil were studied during one season with five sampling points in each reservoir. Chapéu D'Uvas (Minas Gerais state) is a reservoir used mainly for water supply purposes, and is located at the head of a major river. It does not have any significant sources in its catchment area. The Funil reservoir (Rio de Janeiro state) is located in a densely industrialized and urbanized region. The Curuá-Una reservoir (Pará state) is located in the Amazon region, where there are small communities with no sewage treatment. In addition, River Paraibuna, which flows in to the Chapéu D'Uvas reservoir passes through a large city, was studied in a temporal approach over six seasons with four sampling points downstream of the city. All water samples will be filtered and analyzed with UHPLC-Orbitrap-MS/MS using direct injection. With this approach we can test the effect on environmental concentrations of a municipal law from 2016, prescribing drugstores to receive overdue or unused medicines for correct disposal. For all sampled water reservoirs and the river, this will be the first assessment of pharmaceutical occurrence in Brazil, where currently pharmaceuticals are not part of water quality guidelines. This study will also provide information that may support Brazilian decision makers to regulate discharge of these compounds to the environment.

WE074

The fate of pharmaceuticals in river Vantaanjoki and in the Helsinki coast

K.S. Siimes, Finnish Environment Institute SYKE / KTK / Contaminants; M. Lehtonen, Finnish Environment Institute SYKE; L. Äystö, Finnish Environment Institute, SYKE / Centre for Sustainable Consumption and Production; J. Mehtonen, Finnish Environment Institute SYKE; V.A. Junttila, Finnish Environment Institute SYKE / Centre for Sustainable Consumption and Production; N. Perkola, Finnish Environment Institute / Laboratory Centre

Current knowledge on pharmaceutical loads, occurrence and environmental fate, especially in northern European conditions, is sparse. More information about the concentrations of pharmaceuticals is needed for knowledge-based risk assessments and the prioritization of substances as well as for justifying possible risk reduction measures. We conducted a pharmaceutical screening study in River Vantaanjoki, located in southern Finland and running to the Gulf of Finland in Helsinki. The river basin area is about 1 700 km^2 with around one million inhabitants (1/5 of Finnish population). Urban and industrial areas cover approximately 15% of the basin area, which is very high proportion in Finnish scale. For the study area, we selected two waste water treatment plants (WWTP), a landfill site, river sites and sites from the river estuary as well as sites located close to the off-shore outlet of the treated waste water from WWTP Viikinmäki (800 000 inhabitants). In Viikinmäki WWTP, the annual average volume of treated waste water is 100 million m^3. The selected middle-sized WWTP Kalteva (40 000 inhabitants) is located 65 km north from the river mouth. From Kalteva the treated waste water (almost 4 million m^3 per year) is directed into river Vantaanjoki. River samples were taken in one upstream and several downstream sites from Kalteva. The third "point source" sampling site was a landfill, Metsä-Tuomela, where some WWTP sludge is composted among other processes. Its leachate is collected and treated in a small WWTP (about 0.001 m^3 per year) located in the landfill area. Pharmaceuticals were found in all studied matrices from the WWTP influents and effluents to river water and the Baltic Sea. Several active ingredients of pharmaceuticals were analysed first time in Finnish point sources and in the environment. The observed concentrations of selected compounds are presented in the poster with their daily loads from the WWTPs, land-fill site and river sites at the three sampling dates. The approximated annual loads are given with a rough uncertainty estimation. This study is one of the eight case studies carried out around the Baltic Sea area in a project "Clear waters from pharmaceuticals" (CWPharma) funded by EU's Interreg Baltic Sea Region Programme. The results will be utilized in a pharmaceutical loading model. Concentration data is used also in the ecological risk assessment of pharmaceuticals in the Baltic Sea Region.

WE075

The impact of human drug metabolism and disposition on the occurrence of pharmaceuticals in wastewaters - A case study on Finnish influent wastewater

S. Karlsson, University of Helsinki / Faculty of Pharmacy, Drug Research Program; L. Äystö, T. Nystén, Finnish Environment Institute; N. Vieno, Law and Water Ltd; J. Yli-Kauhaluoma, T. Sikanen, University of Helsinki / Faculty of Pharmacy, Drug Research Program

The ecotoxicological risks related to pharmaceutical emissions are an increasing concern socially, both locally and globally. With societal transformation (urbanization, population growth and ageing), pharmaceuticals are emitted into urban water cycles and into the environment at an accelerated pace. To be able to understand the full impact of pharmaceutical residues on the environment, it is important to identify and select the most risk-bearing compounds for environmental monitoring. Presently, the occurrence of pharmaceuticals in wastewaters is almost entirely assessed based on the original, therapeutic form of a pharmaceutical ingredient, while many of them undergo significant metabolism (molecular reaction) in humans. As the result of metabolism, many pharmaceuticals are excreted (in urine and faeces) in a completely different molecular form, which remains undetected if the analytical method is targeted solely for monitoring of the original form. However, the human metabolites may also be pharmacologically active and thus toxic to non-target organisms. The key question therefore is, how to choose the correct molecular form(s) of each pharmaceutical for environmental monitoring. In this study, we show how the existing drug metabolism databases (e.g., DrugBank) and scientific literature can be exploited to interpret the expected and unexpected observations on the occurrence of pharmaceuticals in wastewaters. Here, we examined the concentrations of selected pharmaceuticals (original, therapeutic form) in influent wastewater at four wastewater treatment plants (WWTPs) located in Southern Finland. The influent concentrations, coupled with information on wastewater flow, were used in calculating an estimated cumulative load of each substance to the WWTPs. The estimated loads were then further extrapolated to a national level based on national statistics on wastewater flow. The correlation between the estimated national cumulative load and national drug consumption based on annual sales statistics was then assessed case by case with a view to explain the conformities (e.g., high consumption, high load) and deviations from the correlation (high consumption, low load) with help of drug metabolism and disposition data.

WE076

The influence of microbial community and chemical properties on biodegradation rates in municipal wastewater

T.J. Van Bergen, Radboud University / Department of Environmental Science; A.B. Rios Miguel, Radboud University / Department of Microbiology; T. Nolte, Radboud University / Department of Environmental Science; R. van Zelm, Radboud University / Environmental Science; A.M. Ragas, Radboud University / Department of Environmental Science; C. Welte, M.S. Jetten, Radboud University / Department of Microbiology; J.A. Hendriks, Radboud University Nijmegen / Department of Environmental Science

Around 300 million tons of synthetic organic micropollutants (MPs) are being produced annually. Via industry and households, part of these MPs end up in the sewage and are transported to wastewater treatment plants (WWTPs). Removal rates vary between WWTPs and the driving factors behind that variation are likely related to the different microbial communities in WWTPs, but largely unknown. Next to the microbial metabolism, biodegradation of MPs is also influenced by physicochemical properties of the MP and WWTP conditions. Currently, the effect of MP properties on biodegradation can be fairly well described with quantitative structure activity relationships. However, effects of the biological system are often not included and a measure for microbial activity is lacking in models predicting primary biodegradation. Although the number of microorganisms is relatively constant in WWTPs, the active microbial community and biodegrading enzymes are not. Adaptation of microbial community occurs, depending on the composition of the wastewater. Here, we study the effect of micropollutant concentration on biodegradation in order to unravel the effect of MP properties and concentration on biodegradation by the microbial community. We aimed to describe the first biodegradation step with a Monod equation in addition to QSAR modelling, considering biodegradation as a second order reaction. We hypothesized we could predict biodegradation at low MP concentrations by means of QSAR modelling. With an increasing MP concentration, we expected biological processes to become more important because of substrate competition, limitation and adaptation of the microbial community. The selected MPs consisted of chemicals that were expected to undergo C-N cleavage and that show a variable biodegradation rate. Biodegradation rates were assessed in batch reactors and we observed microbial community change in 5 days, after spiking wastewater from a nitrifying reactor at a municipal WWTP (Groesbeek, the Netherlands). Carbamazepine, diclofenac, fluoxetine and acetaminophen were incubated at a concentration of ~ 1, 10 and 100 μg/L. Subsequently, sorption of the MPs onto sludge and the biodegradation rate were calculated. We observed microbial community change and transcript abundance of the ammonium oxidizing gene 'amoA' over time. On my poster, you can see how a concentration gradient of micropollutants affected the microbial community and corresponding biodegradation rate.

Ecological Impact and Management of Dumped Munition Sites (P)

WE077

Overview of the results of the monitoring campaigns for analysis of Baltic Sea sediment samples for sea-dumped chemical warfare agents

P. Vanninen, VERIFIN, University of Helsinki / VERIFIN, Department of Chemistrt; H. Lignell, VERIFIN University of Helsinki; S. Popiel, J. Nawala, Military University of Technology; G. Garnaga, Environmental Protection Agency; P. Bartłomieje, Polish Naval Academy; M. Szubska, J. Bełdowski, Institute of Oceanology of the Polish Academy of Sciences

After the Second World War, large amounts of chemical munitions containing chemical warfare agents (CWAs) were dumped into the Baltic Sea. In 2006-2018, Bornholm, Gotland deep, Skagerrak, and Gdansk deep dump sites were studied in many projects firstly in the EU FP6 project *Modelling of Ecological Risks Related to Sea-Dumped Chemical Weapons" (MERCW)*. This project was later amended by Baltic Sea Region Interreg Project *Chemical Munitions, Search and Assessment (CHEMSEA)*, NATO SPS project *Towards the Monitoring of Dumped Munition Threats" (MODUM)* and a joint EU project *Decision Aid for Marine Munitions" (DAIMON)*. The presence of various CWAs was studied. The results indicate a widespread contamination reaching far beyond the dumpsite boundaries, as CWA degradation products were detected in most of the sediment samples taken from and outside the dumpsites. The contamination is mostly related to arsenic containing compounds like Clark I/II, Adamsite, arsenic oil, and inorganic arsenic. Some samples also indicated the presence of sulfur mustard and its degradation products. Due to the presence of multiple, overlying sources of contaminants, the correlation between detected compounds and CWA concentrations is not always straightforward. However, overall results strongly suggest that the sea-dumped munitions are indeed leaking and the contamination has eventually reached the seafloor sediments. Overview of the analysis results and located hotspots are visualized in the geographical maps. The analysis data is also fully loaded into a Decision Support System (DSS), which has been produced in the DAIMON project and is available for authorities, providing risk assessment and decision aid related to operations in the contaminated areas.

WE078

Integrated biomarker analysis and assessment in cod (Gadus morhua) from dumpsites of chemical munitions in the Baltic Sea

K. Straumer, Thünen Institute of Fisheries Ecology; K.K. Lehtonen, A. Lastumäki, Finnish Environment Institute / Marine Research Centre; R. Turja, Finnish Environment Institute, SYKE / Marine Research Centre; A. Ahvo, Finnish Environment Institute / Marine Research Centre; M. Brenner, Alfred Wegener Institute / Biosciences; T. Lang, Johann Heinrich von Thünen-Institut

Dumping of chemical munitions and chemical warfare agents (CWA), mainly from German production, took place in the deep basins of the Baltic Sea after WW 2 by order of the allied forces, and it is estimated that between 30,000 and 50,000 t were disposed. In the framework of the CHEMSEA project (2011-2013), cod (*Gadus morhua*) from CWA dumpsites located in the Bornholm Basin, Gotland Deep and Gdansk Deep as well as from a munitions-free reference site outside the Gdansk Bay were studied for spatial patterns in biomarker responses. A battery of established biomarkers was analysed, reflecting exposure, early or chronic contaminant effects. These included enzymatic (acetylcholinesterase, glutathione S-transferase, glutathione reductase, catalase), cell and tissue (lysosomal membrane stability, lipofuscin accumulation, apoptosis, liver histopathology) as well as fitness and health biomarkers (condition index, diseases and parasites). For the integrated analysis of biomarker data obtained, a modified version of the Integrated Biomarker Response (IBR) approach was applied, introducing weighting factors for each biomarker as an additional component, emphasizing the significance of the response/effect for the host. The results reveal marked spatial differences in the IBR results, with the major CWA dumpsite (Bornholm Basin) showing the strongest and the reference site outside Gdansk Bay the lowest multi-biomarker response. For the assessment, also an integrated approach is suggested that either utilizes established or newly developed assessment criteria (BAC: background assessment criteria; EAC: environmental assessment criteria) for each biomarker, which are combined into an integrated multi-biomarker assessment based on individuals and sampling areas.

WE079

Toxic effects of chemical warfare agent mixtures on the mussel Mytilus trossulus in the Baltic Sea: a laboratory exposure study

N. Höher, Alfred Wegener Institute; R. Turja, Finnish Environment Institute, SYKE / Marine Research Centre; M. Brenner, Alfred Wegener Institute / Biosciences; J. Rattfelt Nyholm, A. Ostin, P. Leffler, Swedish Defence Research Agency; L. Butrimavičienė, J. Baršienė, Nature Research Centre / Institute of Ecology; M. Karjalainen, Finnish Institute for Verification of the Chemical Weapons Convention; P. Vanninen, VERIFIN, University of Helsinki / VERIFIN, Department of Chemistrt; H. Niemikoski, Finnish Institute for Verification of the Chemical Weapons Convention / Department of Chemistry, University of Helsinki; K. Broeg, Alfred Wegener Institute; K.K. Lehtonen, Finnish Environment Institute / Marine Research Centre; R.S. Berglind, Swedish Defence Research Agency

Approximately 50 000 tonnes of chemical weapons containing estimated 15 000 tonnes of chemical warfare agents (CWA) were dumped into the Baltic Sea after the World War II. Metal shells are corroding and contents leaking into the environment at an unknown rate posing a potential risk for the Baltic Sea ecosystem. In addition to mustard gas, arsenic based irritants Clark I and II (diphenylchloroarsine), Adamsite (10-chloro-5-hydrophenarsazine) and the tear gas α-chloroacetophenone (2-chloro-1-phenylethanone) were the most important CWAs dumped. Organo-arsenic compounds are considered as CWAs of major concern for biota; however, knowledge of their effects in marine organisms is scare. Degradation products of Adamsite are persistent and have great bioaccumulation potential. Moreover, Clark hydrolyses to diphenylarsenious acid that is known to be even more toxic than the parent compound. Degradation products of Adamsite and Clark have been detected in sediments and pore water in and outside of the major Bornholm dumpsite. In the present study, Baltic mussels (*Mytilus trossulus*) were exposed to different CWA mixtures containing low, medium and high concentrations of Clark I (1.25, 2.5, 5μg/L), Adamsite (2.5, 5, 10μg/L) and chloroacetophenone (5, 15.8, 50μg/L). The CWA mixtures were added based on the D-optimal design encompassing a treatment combination with all CWAs at low concentrations, combinations with one chemical at the low and all others at the high concentration as well as a triplicate centre point with all chemicals at medium concentrations. Mussels were exposed to differing mixtures of the three CWAs, solvent controls (50 μl/L methanol), and controls (no added chemicals) for 96 h. Each treatment consisted of 8 glass aquaria of 12 L in size containing 7 mussels (3.0 ± 0.25 cm). Water exchange and re-dosing of test compounds was conducted daily. Using a multi-biomarker approach the mussels were assessed thereafter for biological effects at different organisational levels ranging from geno- and cytotoxic effects to enzyme kinetics and immunological responses. The results showed that mussels bioaccumulate the oxidized forms of Clark I, Adamsite (DAox and DMox) and, to a certain extent, also chloroacetophenone into their tissues. Impairments including cytotoxic, immunotoxic and oxidative stress effects were visible in the test organisms even at the lowest test concentrations.

WE080

Toxicity of an oxidation product and a metabolite of the chemical warfare agent Clark I/II determined using the rainbow trout liver cell line RTL-W1

H. Niemikoski, Finnish Institute for Verification of the Chemical Weapons Convention / Department of Chemistry, University of Helsinki; A. Ahvo, Finnish Environment Institute SYKE / Marine Research Centre; I. Heiskanen, Finnish Environment Institute SYKE; K.K. Lehtonen, Finnish Environment Institute / Marine Research Centre; P. Vanninen, VERIFIN, University of Helsinki / VERIFIN, Department of Chemistrt

After the first and second world wars, thousands of tonnes of chemical warfare agents (CWAs) were dumped in the Baltic Sea. Recent studies have found CWA-related arsenical compounds accumulated in fish tissues. The potential effects of dumped chemical munitions in Baltic Sea marine biota are still poorly understood. To link the measured chemicals in the fish to biological effects, cytotoxicity of diphenylarsenic acid (DPA[ox]) an oxidation product of the chemical warfare agent Clark I/II, was studied using the rainbow trout liver cell line RTL-W1. Additionally, toxicity of diphenylarsine glutathione conjugate (DPA-SG), which is a metabolite of DPA[ox], was also studied. Cytotoxicity of the compounds was evaluated using the Neutral Red retention test (NRR), showing a LC_{50} value of 294 mg/L for DPA[ox]and 1.32 mg/L for DPA-SG, indicating that the glutathione conjugate of DPA[ox]is more than two orders of magnitude toxic than the DPA[ox] itself. The kinetics and metabolism of DPA[ox]were also studied by incubating the RTL-W1 cells in media with 100 mg/L DPA[ox] and measuring the CWA-related phenylarsenic compound taken up by the cells by ultra-high performance liquid chromatography connected to high resolution mass spectrometry (UPHLC-HRMS). Also, DPA[ox]concentration in the cell media was measured in order to compare the fate of DPA[ox]in cell media to intracellular DPA[ox]concentrations after 30 min, 1 h, 2 h, 3 h and 4 h exposure. Toxicity of trinitrotoluene (TNT), a conventional explosive found in many dumped conventional munitions, was studied with the same method, and the LC_{50}

for this substance was found to be 61 mg/L. These studies will elucidate the biological effects of dumped conventional and chemical munitions, and help in assessing the environmental and health risks posed by their continued presence and deterioration in the sea bottoms.

WE081

Industrial scale destruction of old chemical ammunition of the Great War on the western Front The hundred-year-old forgotten contaminations

H. Daniel, Bureau de recherches géologiques et minières (BRGM)

During WWI, ammunition had been used on an unprecedented scale. When hostilities ceased, huge ammunition dumps remained. Unexploded ordnances were collected on former battlefields too. There was an urgent need to dispose million tons of hazardous ammunition. New methods for safely breaking down chemical shells were then developed.. After defusing, the rounds were emptied by perforation when the toxic contents were liquid, by steam or hot-water washing-out for TNT explosive shells and by open-burning for both chemical and explosive shells. These processes caused severe top soil contaminations especially on former burning-grounds of chemical shell. Recent research has been conducted on 9 burning-grounds in France and Belgium. To this day, no vegetation grows at some locations due to extreme high grade of heavy metal (Zn, Pb, Cd,…), ranging for Zn from 10 to 100 g/kg, chlorinated and /or brominated dioxin & furan (1 000 to 4 000 000 ng/kg), and arsenic (2 to 110 g/kg) when arsenical "*Blue Cross*" shells loaded with the sternutators diphenylchlorarsine and diphenylcyanoarsine were open-burned. Inorganic arsenical compounds are associated with organic by-products produced by the oxidation (diphenylarsinic acid) or thermal decomposition (triphenylarsine, As-PAH like phenylarsafluoren) of CLARKs. Brominated dioxin, energetic compounds (TNT, nitronaphtalin) and thianes (impurities of yperit) have been measured too. High resolution geomagnetic measurements had been conducted on a site where 1,5 million old chemical shells have been destroyed during the interwar period near Verdun, leading to severe top-soil contamination, crops and meat destructions and the sequestration of the ground. Open-detonation pits and systems of burning trenches have been recognized and carefully probed. Exposure to site-specific contaminants through the consumption of foodstuffs produced locally on the considered site was unlikely to be a health concern. However, as for inorganic arsenic, given the presence of highly contaminated zones, it was suggested that cereals should not be grown on certain spots. These site, Spincourt, is an example of the ignorance of soil contamination left behind by WWI in land-use planning. Further research is needed to assess these forgotten contaminations and sites and theirs related environmental risks.

WE082

Assessing antimony (III) speciation with the technique AGNES

P. Pla-Vilanova, E. Companys, Universitat de Lleida and AGROTECNIO / Dep Quimica; J. Puy, Universitat de Lleida and AGROTECNIO; J. Galceran, Universitat de Lleida / Dep Quimica; M. Filella, Institute F.-A. Forel, University of Geneva / Institute FA Forel

The core of small-arm bullets contains Sb in a proportion around 2 to 10% (in weight). The leaching of Sb from any kind of munition might be a source of pollution, with potential toxicity since Sb is non-essential for living organisms. However, there is a serious lack of quantitative knowledge about its speciation (not only between the redox states III and V, but also between different chemical species of the same redox state) [1]. In the case of Sb(III), hydrolysis is so prevailing that species such as $Sb(OH)_3$ and $Sb(OH)_2^+$ are dominant in solution even at acidic pH values. This information, about which are the complexed species carrying Sb(III), could be essential to perform ecotoxicological studies going beyond the correlation between total Sb(III) concentrations and biological effects, given that bioavailability is often associated to the concentrations and/or fluxes of very concrete species. To address this issue, analytical techniques should be designed or adapted. AGNES is an electroanalytical technique which has been successfully applied to the determination of free-cation concentrations for metals such as Zn, Cd, Pb, In and Sn in a variety of systems (dissolution of nanoparticles, seawater, river water, soil extracts, etc.) [2]. Sb can also be tackled with AGNES, as Sb(0) accumulates in the amalgam until fulfilment of equilibrium (according to Nernst law) for judiciously chosen potentials. A novel calibration strategy allows to correlate a deposition potential with a ratio between the concentration of Sb(0) and that of $Sb(OH)_3$ for a given pH. This strategy, together with optimized parameters (deposition times, deposition potentials, stripping currents, etc.) and speciation results will be presented. References: 1. Toxicokinetics of Ag in the mealworm Tenebrio molitor exposed to different AgNP forms via food

Z. Khodaparast, University of Aveiro / Biology; C. van Gestel, Vrije Universiteit Amsterdam / Ecological Science; R.A. Verweij, Vrije Universiteit Amsterdam / Department of Ecological Science; S. Loureiro, Universidade de Aveiro / Biology

Application of sewage sludge onto agricultural land or the direct application of nanoagrochemicals can lead to exposure of soil and soil invertebrates to nanoparticles (NPs), with AgNPs being the most abundant NP type. To assess the risk of AgNPs, knowledge on the bioaccumulation of different forms of AgNPs in different terrestrial organisms is essential. The aim of this work was to determine the toxicokinetics of different AgNP forms in the mealworms *Tenebrio molitor*. Oat flakes, offered as food, were spiked with 100 mg Ag/kg dry food with 3-8 nm, 60 nm or 50 nm AgNPs, Ag_2S NPs (27 nm) and the ionic reference $AgNO_3$. Mealworms were kept on clean Lufa 2.2 soil and fed with the spiked food for a 21-day uptake phase and then transferred to clean soil and fed with clean food for a 21-day elimination phase. Three mealworms were collected at each sampling point (1, 3, 6, 9, 15, 21 days) for both phases. At each sampling time, animals and their molt (if they molted) were frozen individually (-20 ?C), dried, digested and analysed for Ag by graphite furnace Atomic Absorption Spectrophotometry. A one-compartment model with an inert fraction (F_i) was used to calculate the Ag uptake and elimination kinetics. The Ag toxicokinetics in mealworms exposed to different forms of silver via food showed no significant difference with uptake rate constant (k_1) values of 1.09, 1.74, 0.17, 3.12, and 0.25 g soil/g animal/day and elimination rate constant (k_2) values of 11.9, 14.5, 1.23, 19.5 and 2.42 day^{-1} for AgNPs 3-8 nm, AgNPs 60 nm, AgNPs 50 nm, Ag_2S NPs 27 nm and Ag^+, respectively. Moreover, Ag_2S NPs showed the lowest storage of Ag in an inert fraction (Fi = 0.01), while for AgNPs 3-8 nm, AgNPs 60 nm and Ag^+ the estimated Fi was similar at 0.7, 0.6 and 0.6, respectively, and for AgNPs 50 nm Fi was 0.3. The analysis of the mealworm molts showed that the amount of silver which can be eliminated by molting was quite high in case of Ag_2S NPs, with 71.8% of the body burden being found in the moult compared to those of AgNPs 3-8 nm, AgNPs 60 nm, AgNPs 50 nm and Ag^+, with 6.2, 4.1, 1.2 and 6.4 %, respectively. So, mealworms can excrete Ag by moulting, although the amount of Ag eliminated through moulting depends on the Ag form and its characteristics. The toxicokinetics in mealworms of different forms of Ag showed that different forms of Ag are handled in a different way by the organism.

WE084

The fate and effects of nano copper oxide to soil invertebrates

J. Velicogna, D. Schwertfeger, A. Jesmer, C. Beer, J. Kuo, R. Scroggins, Environment and Climate Change Canada / Biological Assessment and Standardization Section; M. DeRosa, Carleton University / Department of Chemistry; J. Princz, Environment and Climate Change Canada / Biological Assessment and Standarization Section

Metallic nanomaterials are increasingly used in commercial and manufacturing applications world-wide. Concern over the fate of these engineered materials in the environment has led to efforts to improve our understanding of fate and effects, and how they differ from metal ionic counterparts. Copper (Cu) nanomaterials are used for a wide variety of applications due to its conductive and anti-fungal properties. Engineered nano Cu materials are expected to be released to the environment ending up in the soil compartment either directly, through the leaching of nano Cu treated materials (e.g. treated lumber) or, indirectly through the application of contaminated biosolids to agricultural soils. The effects of nano copper oxide (nCuO) on earthworms (*Eisenia andrei*) and springtails (*Folsomia candida*) were evaluated through reproduction toxicity and bioaccumulation tests. A field collected agricultural soil was spiked either directly or through biosolid amendment with 40nm nCuO or, with $CuSO_4$. The fate of the nanomaterial was examined through measurements of test soils for: total Cu (using ICP-MS), Cu^{2+} ionic activity (using an ion selective electrode) and particulate Cu (using ICP-MS in single-particle mode, and TEM). By understanding the fate in the soils, we can better understand what form of Cu test organisms are exposed to and, hence the most likely cause for any observed effects.

WE085

Multiple sewage sludge application into soil - Fate and effect of nanosilver in an outdoor lysimeter study over 5 years

K. Schlich, Fraunhofer IME - Institute for Molecular Biology and Applied Ecology; M. Hoppe, German Federal Institute for Geosciences and Natural Resources / Groundwater and Soil; D. Rückamp, Federal Institute for Geosciences and Natural Resources; K. Hund-Rinke, Fraunhofer IME / Ecotoxicology

Nanomaterials (NM) will enter the environment via diverse pathways. Sewage sludge is repeatedly applied as fertilizer on farmland due to its high nutrient content. This may lead to a significant increase of NMs in soil over years. Our aim was to investigate the accumulation, plant uptake and additive effects due to multiple sewage sludge applications into soil for two years after a second application of Ag-NM via sewage sludge. In 2014, two concentrations of 1.8 and 7.0 mg Ag-NM/kg dry matter (dm) soil were applied via sewage sludge into the top 20 cm of lysimeter soil. The sludge was mixed into the top 20 cm to simulate ploughing. Over 3 years, the lysimeters were cultivated according to good agricultural practice. The effect on soil microorganisms was investigated as well as the fate of the NM in soil and the potential uptake into wheat, canola and barley (Schlich et al., 2017). No detectable horizontal displacement in combination with very low remobilization for both tested NM over 3 years was found indicating that the sludge applied NM remained nearly immobile in the pathway between soils and leachate. However, Ag uptake in the roots of wheat, canola and barley indicated that the chemical conditions in the rhizosphere induce Ag-NM remobilization from the incorporated sewage sludge even after three harvesting cycles. A constant inhibition of the soil microflora (ammonium oxidizing bacteria and substrate-induced respiration) was observed over 3 years at 7.0 mg/kg dm soil, while there was no effect at the lower Ag-NM concentration. Then, the experiment was continued for further 2 years. In accordance to the German Sewage Sludge Ordinance 5 tons of dry matter sludge can be applied on a hectare in 3 years. Therefore, after 3 years a new application of Ag-NM onto the lysimeter with an Ag-NM content of 1.8 mg/kg dm soil via sewage sludge was performed aiming in an Ag-NM content of 7.0 mg/kg dm soil. Only uncontaminated sludge was applied on the lysimeter, which already had an Ag-NM content of 7.0 mg/kg and onto the control lysimeter. After the application in April 2108, wheat was cultivated followed by bare fallow after the wheat harvest in October 2018. In regular intervals, the effect of the Ag-NM on soil microorganism was observed. In addition, the wheat plants were investigated for their Ag content in roots, shoots and ears. Once per month the leachate was collected and the Ag concentration was determined. Results until April 2019 will be presented.

WE086

Sorption of (nano)formulations difenoconazole in soil

J. Vasickova, D. Fojtová, Masaryk University / Faculty of Science, RECETOX; J. Hofman, Masaryk University, RECETOX / Faculty of Science, RECETOX; M. Kah, The University of Auckland / Department of Environmental Geosciences

Nanopesticides represent an emerging technological development that aims to improve the efficacy of existing pesticide active ingredients and/or to enhance their environmental safety profiles. Due to small size (nanometer size range), nanoformulations are expect to have significant impacts on the environmental fate of the active ingredient (a.i.). Sorption is one of the major processes that determine the fate, effects, efficacy and ecological risks of pesticides in terrestrial and aquatic environments process. The aim of this study was to evaluate the extent to which different formulations may affect the fate of difenoconazole in soil. Soil sorption of difenoconazole was measured for i) pure active ingredient, ii) commercially available formulation (particle size of 174 ± 7 nm), iii) formulation with polymer (565 ± 27nm), iv) formulation with conventional polymer (959 ± 55 nm). Standard batch equilibrium method (OECD no. 106, 2000) was applied to determine the fate properties of formulations in three agricultural soils. The experiment showed that there were differences upon comparison of the results obtained for the polymer (565 ± 27nm) and commercial formulation with that of the pure a.i. Pesticide formulation with polymer (565 ± 27nm) and commercial formulation yielded two fold higher soil distribution coefficients (Kd values) in all three soils relative to that of the pure a.i. Laboratory experiments showed that the nanoformulation could increase the measured sorption coefficients.

WE087

Investigations on release of nanomaterials from waste and sewage sludge incineration residues during deposition and agricultural use-comparison of pilot scale simulation and laboratory tests

B. Meisterjahn, Fraunhofer IME - Institute for Molecular Biology and Applied Ecology / University of Vienna, Department Environmental Geosciences; N. Schröder, Fraunhofer Institute for Molecular Biology and Applied Ecology IME / Ecological chemistry; D. Hennecke, Fraunhofer IME - Institute for Molecular Biology and Applied Ecology / Ecological chemistry; K. Hund-Rinke, Fraunhofer IME / Ecotoxicology; J. Oischinger, Fraunhofer Insitute for Environmental Safety and Energy Technology UMSICHT; V. Weiss, German Environmental Agency UBA

Engineered nanoparticles (ENPs) are used in consumer products such as textiles or paints. Thus, it can be expected that a considerable fraction will enter the waste stream, which means in most cases incineration and deposition of the incineration slag in landfills. Most of the sewage sludge in Germany is also incinerated, but the incineration ashes are frequently used in agriculture as fertilizer. Investigations with CeO_2-ENPs by Walser et al [1] showed, that nanoparticles are possibly not permanently bound to incineration residues and may become released. The aim of the present project was therefore to investigate the possible release of TiO_2-ENPs in two different scenarios: (i) pilot scale landfill simulation of ENP-amended domestic waste after incineration and (ii) simulation of agricultural use of ashes from ENP-amended sewage sludge after application to soil. For landfill simulation a special reactor was used which allows to set up conditions present in a real landfill. For agricultural use, the same system was used but for time lapsed seasonal simulation by repeated freezing / thawing of the material. Both simulations had a scale of about 1.5 m^3 and were periodically applied with artificial rain in order to obtain leachates. The leachates were analysed for total titanium-concentration (ICP-OES after digestion) and for the particle concentrations and size distributions by means of single particle ICP-MS (spICP-MS). For both scenarios, reference simulations without spiking of TiO_2-nanoparticles were run simultaneously. For the domestic waste landfill simulation, no significant release of titanium-containing nanoparticles was observed compared to the reference simulation, indicating that the added nanomaterials are strongly bound to the incineration slag. In contrast, in the simulation of agricultural use of sewage sludge ashes the observed release of nanoparticles in comparison to the control simulation was significant and even higher than could be expected from the amount of TiO_2 spiked. The results from the simulation experiments could be reproduced with the same materials in standard laboratory soil elution experiments according to DIN 19528. Processes and transformations of engineered TiO2 nanoparticles in aquatic and terrestrial natural environments

G. Quaranta, Université of Strasbourg / CNRS / IPHC; A. Schulz, University of Strasbourg CNRS / LHYGES/EOST; S. Lawniczak, Universty of Strasbourg / LHYGES

During the production of NPs TiO2 by the sulfate process (necessary to obtain the anatase form) releases occur in the last stages of manufacture and more particularly during the steps of washing, neutralization, filtration, atomization / calcination and grinding / sieving titanium dioxide. The industrial process generates effluents that may contain TiO2 NPs that are sometimes released directly into natural water courses, thus affecting water and sediments. The soils can be impacted by particles from emissions and redeposited after transport by wind. The fate of these nanoparticles is strongly related to their intrinsic characteristics. Once deposited by winds and precipitation or emitted directly to soils and water, NPs TiO2 form aggregates: their important surface area induces the presence of many reactive sites. This characteristic leads to an instability of these compounds which generates aggregation processes: homoaggregation, containing only agglomerates of NPs TiO2 or heteroaggregation, containing agglomerates of NPs TiO2 and particles of the natural environment. These processes are governed by different parameters of the physical environment where NPs TiO2 are found (pH, ionic strength, percentage of organic matter, presence of other chemical compounds) and parameters specific to nanoparticles (size, zeta potential, concentration). It is therefore essential to acquire information and better knowledge on the behavior of NPs TiO2 in the environment in order to evaluate their fate in the different environmental compartments. For this purpose, it requires firstly to detect and quantify TiO_2 NPs in water, soil and sediment near a production site of TiO_2 NPs in Vieux-Thann (68) and secondly to determine total titanium concentrations in soil, water and sediment samples by ICP-AES. The results show that water and sediment samples located near and downstream of the site production are 2,5 to 20 times more concentrated than the upstream point (used as a reference) which imply an impact coming from the production site. However, soil samples are only 1 to 1.5 times more concentrated than the geochemical background.

WE089

Impacts of pristine AgNPs and Ag2S-NPs on the growth and reproductive success of the pond snail Physa acuta

C. Pinheiro, University of Aveiro; S. Goncalves, Department of Biology & CESAM - University of Aveiro / Department of Biology and CESAM; I. Lopes, University of Aveiro / Department of Biology & CESAM, 3810-193 Aveiro; S. Loureiro, Universidade de Aveiro / Biology

Due to its wide use in antibacterial products, silver nanoparticles (AgNPs) end up in wastewater treatment plants (WWTPs) being discharged into the aquatic environment. In WWTPs, AgNPs undergo physical-chemical transformations, which modify their properties. It is crucial to consider such transformations when assessing their impacts to aquatic organisms. The freshwater snail *Physa acuta* was used to assess the potential toxic effects of pristine AgNPs and Ag_2S-NP, which simulate the transformation underwent in WWTPs, and to compare their toxicity. Chronic tests were performed to assess effects on survival, shell length, reproductive success (expressed as cumulative number of egg clutches and eggs per individual) and intrinsic rate of population increase. Both NPs caused mortality no higher than 20% at the tested concentrations. Exposure to pristine AgNPs caused a decrease in the shell length at the highest tested concentration (600 μg/L) while Ag_2S-NPs caused an increase in shell length at 300 μg/L. Pristine AgNPs caused a decrease in the clutch production and cumulative number of egg per individual with increasing concentrations, while Ag_2S-NPs had no effects on the cumulative number of eggs per individual and a beneficial effect on clutch production. Exposure to pristine AgNPs resulted in a decrease in the intrinsic rate of population growth at the highest tested concentrations (300 and 600 μg/L). Snails exposed to Ag_2S-NPs showed an increase in the intrinsic rate of population growth only at 37.5 μg/L. The frequency of egg abnormalities, used as an additional endpoint, was more responsive to both NPs than other endpoints such as cumulative number of egg clutch per snail. Polyembryony and eggs with atrophied albumen were the most frequent egg abnormalities. These type of egg abnormalities can provide additional information about physiological pathways disturbed by different Ag particulated forms. Besides, our results suggest that egg abnormalities are a more sensitive endpoint when compared to the classical

reproductive endpoints commonly assessed in toxicity tests with aquatic snails.

WE090
Multiple effects of elevated temperature and acidification on accumulative dynamics of copper nanoparticles in freshwater fishes
W. Chen, Kaohsiung Medical University / Dept Biomedical Science and Environmental Biology; Y. Lu, Kaohsiung Medical University / Dept of Biomedical Science and Environmental Biology; Y. Zhang, Kaohsiung Medical University
The potential risk to freshwater ecosystems posed not only by nanomaterial contaminant but also by temperature and acidification. To date, there is a lack of knowledge related to combined effects of relevant environmental change and copper nanoparticles (CuNPs)in freshwater ecosystems and their potential impact on freshwater organisms. This study examined effects of increased temperature and acidification on accumulation and depuration of CuNP in embryo and larvae of medaka (*Oryzias latipes*) and larvae tilapia (*Oreochromis niloticus*). Our findings indicated that high acidification appeared to be a major driver in increasing CuNPs accumulation of medaka embryo, whereas increased temperature had antagonistic effect against acidification on CuNP accumulation. However, there was no difference of Cu accumulation on medaka larvae among conditions of environmental changes in both uptake and depuration exposures. For tilapia, we also found slowly decreased the Cu depuration with high temperature after 1-d depuration exposure. The conditions of moderate acidification with moderate temperature as well as high acidification with high temperature slowly decreased Cu accumulation of tilapia, compared to control condition. It revealed the additive effects of elevated temperature and acidification on Cu depuration of tilapia. Differential species and life stages displayed varying level of CuNPs accumulation in response to the combined temperature and acidification. Our study demonstrated that the combined environmental changes may not lead to adverse effect of CuNPs on aquatic species. We conclude that acidification is a major driver than temperature in increasing the accumulation of metal nanoparticle in freshwater fish.

WE091
Toxicokinetics of pristine and aged silver nanoparticles in freshwater benthic organisms: the role of exposure route
P. Silva, Universidade de Aveiro / Biology Department and CESAM; C. van Gestel, Vrije Universiteit Amsterdam / Ecological Science; R.A. Verweij, Vrije Universiteit Amsterdam / Department of Ecological Science; S. Loureiro, Universidade de Aveiro / Biology
Nanomaterials (NMs) can suffer several physico-chemical changes during their life-cycle. When released into the environment, NMs may reach biological receptors in unpredictable forms, which can determine their fate through different uptake routes. Moreover, organisms can also act as bio-reactors and induce changes on NMs during internal processing. In order to understand and assess NM bioavailability, ways of uptake and elimination and biological fate, it is necessary to conduct toxicokinetic modelling studies. In freshwater systems, benthic organisms can be exposed to NMs through water and sediment and therefore different routes and rates of NMs are expected. The present study aimed at determining the toxicokinetics of silver nanoparticles (Ag-NPs), in their pristine and aged form, through different exposure routes, in the freshwater benthic organisms *Physa acuta* (pond snail) and *Dugesia tigrina* (planarian). Bioaccumulation assays were performed with three pristine Ag-NPs of different sizes (3-8 nm, 50 nm and 60 nm), a simulating aged form (Ag_2S-NP, 27 nm), and $AgNO_3$ as ionic control. Exposures were through 1) contaminated aqueous medium; 2) contaminated aqueous medium and clean sediment; 3) contaminated sediment and clean aqueous medium. In all experiments, organisms were exposed to contaminated medium during the uptake phase and then transferred to clean medium for the elimination phase. Organisms were sampled throughout the tests and total body Ag concentrations were analysed by graphite furnace atomic absorption spectrometry. Toxicokinetics of Ag were derived by one-compartment models. Results revealed higher uptake rates and bioaccumulation factors (BAF) for the snails, while planarians presented, in general, low uptake rate constants (k1) and low BAFs. Planarians showed the highest uptake rate for the aged form (although with lower k1 than the snails) in the exposure with contaminated water and clean sediment. Snails exhibited similar uptake rates between exposures through contaminated aqueous medium only (no sediment) and contaminated aqueous medium with clean sediment, being higher for ionic Ag and 60 nm Ag-NP. However, for Ag_2S-NPs, the snails showed one of the highest k1 values in the exposure with contaminated aqueous medium (no sediment), while for the exposure with contaminated aqueous medium and clean sediment they presented one of the lowest k1. This suggests that exposure routes may have a determining role on the uptake rates of these NPs.

WE092
Zinc oxide nanomaterials toxicity to Daphnia magna. Effect of particle coatings on immobilization, reproduction and body size.
T. Chen, Heriot Watt University; Z.A. Gajda-Meissner, R.S. Idriss, Heriot Watt University / Institute of Life and Earth Sciences; D. Boyle, University of Plymouth / School of Biological and Marine Sciences; T.F. Fernandes, Heriot-Watt University / Centre for Marine Biodiversity and Biotechnology, Institute of Life and Earth Sciences
Zinc oxide nanomaterials (ZnO NMs) have remarkable optical, physical, and antimicrobial properties, which result in their use in a wide range of applications such as biosensors, cosmetics, drug-delivery systems, sunscreens, biocides. In general, the purposes of surface coating on nanomaterials (NMs) are: extending their applications, changing the properties, or reduce toxicity (safe-by-design). In this study, the ecotoxicity of triethoxycaprylsilane coated ZnO NMs (152 nm) and uncoated ZnO NMs (70-90 nm), obtained from the Joint Research Centre of the European Commission, were studied using *Daphnia magna* as model species. The Acute Immobilisation Test (OECD 202) and the Reproduction Test (OECD 211) were employed in this study. The parent organisms were cultivated with 16 hours light/ 8 hours dark lighting cycle and fed with alga *Chlorella vulgaris* daily. Neonates aged less than 24 hours were used in the acute experiments. For the preparation of the ZnO NMs suspensions, the protocol from the Nanogenotox project was followed and the initial concentration of ZnO NMs was 2.56 mg/mL. The results indicate that uncoated ZnO NMs and coated ZnO NMs all revealed acute toxicity toward *D. magna*. The 48-hours EC50 values for uncoated and coated ZnO NMs were in the similar scale, around 2.3 to 3.5 mg/L. However, in the chronic reproduction test, uncoated ZnO NMs showed higher mortality than coated ZnO NMs. With the concentrations ranging 180, 300, 500 to 840 µg/L, the parent *D. magna* mortality was 10%, 10%, 30%, 70% in the coated ZnO NMs group, respectively. In contrast, it was 60%, 50%, 90%, 100%, respectively, in the uncoated ZnO NMs group. Furthermore, in the coated ZnO NMs group, neonates per parent daphnia and the body size in concentrations 180, 300, 500 and 840 µg/L were significantly lower compared to the control group; there was also a clear trend showing that uncoated ZnO NMs exposures led to a decreasing number of neonates per parent daphnia. Based on the present data, it is suggested that coated ZnO NMs are less toxic than uncoated ZnO NMs toward *D. magna* in longer-term exposures. It is suggested that further studies, including more replicates and other aquatic species, should be carried out. The final goal of this study is to continue to support nanosafety, working closely with industry, which will benefit both environment and human health.

WE093
The effects of ageing on fate and toxicity of coated silver nanoparticles to freshwater alga Raphidocelis subcapitata
S. Lekamge, RMIT University / School of Science; A.F. Miranda, School of Science / School of Science; C. Trestrail, B. Pham, A.S. Ball, R. Shukla, D. Nugegoda, RMIT University / School of Science
The fate and transformation of AgNPs in the aquatic environment together with their impacts on organisms remain a research area requiring further study, given the increasing release of AgNPs into the environment. In this study, effects of ageing on the fate and behaviour of coated AgNPs; tyrosine (T-AgNP), epigallocatechin-gallate (E-AgNP) and curcumin (C-AgNP), in the algae medium and on the sub-lethal effects in the freshwater alga, *Raphidocelis subcapitata* were studied. The stability of the AgNPs was evaluated by monitoring surface plasmon resonance, zeta average hydrodynamic diameter, zeta potential and dissolution of the NPs over 32 days. Results indicated that the transformation of all three types of AgNPs occurred during the incubation, while coating-specific effects were observed. The presence of the three types of AgNPs resulted in increased ROS formation in algae compared with the control ($p < 0.05$) while aged T-AgNPs and C-AgNPs induced excessive ROS generation compared with the fresh counterparts. Increased ROS levels caused increased lipid peroxidation in the treatment groups exposed to both fresh and aged NPs while the TBARS levels were higher in algae exposed to aged AgNPs. The observed increase in CAT activity of algal cells was attributed to early stress responses induced by excessive intracellular ROS generation while the CAT levels were higher in the aged NP treatment groups in line with the increased ROS levels. It can be concluded that AgNPs have a negative effect on aquatic algae, as manifested by the increased ROS levels and lipid peroxidation while antioxidant enzymes such as CAT are activated to neutralize the oxidative damage. Overall, the results suggest that the ageing and coating of AgNPs have major impacts on AgNP transformation in media and their effects to algae.

WE094
Bioaccumulation of radiolabelled weathered multi-walled carbon nanotubes in various aquatic organisms: water and dietary exposure
I. Politowski, RWTH Aachen University / Institute for Environmental Research; M.P. Hennig, RWTH Aachen University; F. Wittmers, A. Schaeffer, RWTH Aachen University / Institute for Environmental Research
Carbon-based nanomaterials like carbon nanotubes (CNT) are incorporated in various consumer plastic products. During production processes and after usage they finally enter the environment. Due to environmental complexity, fate of CNT might be altered by various biotic and abiotic influences. Herein, radiolabelled multi-walled carbon nanotubes irradiated by simulated sunlight (65 W/m^2; 3 month, ^{14}C-wMWCNT) were used in bioaccumulation studies considering bioconcentration (water exposure) and biomagnification (dietary exposure). The primary producers *P. subcapitata* and *C. reinhardtii* and the primary consumer

Daphnia magna were chosen as testorganisms. In tests on bioaccumulation of wMWCNT (100 μg/L) in green algae the calculated log BCF for *C. reinhardtii* and *P. subcapitata* after 24 h was 4.1 and 3.0, respectively. The higher bioconcentration of one magnitude in *C. reinhardtii* can be explained by the different shape or size of algae cells and the difference in exudate components. In a second experiment, CNT-loaded algae (72 h) were fed to *D. magna* for dietary exposure and results were compared to water exposure (100 μg wMWCNT/L). In water exposure scenario, maximum uptake was reached after 19 h with 7.1 ± 1.5 μg wMWCNT/mg dw. In the following 53 h, a decrease in body burden was observed. The maximum amount of CNT uptake during dietary exposure was already reached after 2 h. Data revealed a 100-fold lower uptake of 0.07 ± 0.01 μg wMWCNT/ mg dw in comparison to water exposure. The calculated log BCF for water exposure was 5.2. At first sight this indicates a really high bioaccumulation potential for CNT in water fleas, but also gut accumulated CNT were included in this amount. To determine elimination a second test was constructed, i.e., the influence of presence and absence of food was examined. After an uptake phase of 24 h, daphnids were placed into fresh medium and elimination over 48 h was measured. It could be observed, that in presence of food source elimination processes were significantly faster than without food. Results show, that the amount of CNT taken up is eliminated almost completely after a certain time which indicates, that MWCNT appear to be substances with low or no concern for bioaccumulation. **Acknowledgements** The work is supported by the European Project NANO-Transfer that receives funding from the Bundesministerium für Bildung und Forschung (BMBF) under agreement with the FP7 ERA-NET SIINN.

New challenges to evaluate potential risk of nanoscale copper phthalocyanine in the aquatic environment

C. Pang, DTU (Technical University of Denmark) / Department of Environmental Engineering; A. Baun, Technical University of Denmark DTU

Nanoscale copper phthalocyanine (n-CuPc) is a pigment widely used in paints to enhance automobile coatings and make colors transparent and more appealing to users. This application implies high probability of end-of-life release during recycling and/or after disposal, which may lead to environmental exposure and risks. However, assessing potential environmental and human health risks of n-CuPc is very challenging as new science at the interface of biological system and nanomaterials is emerging only now and sufficient and reliable risk data are often lacking. During the product life cycle, interaction of n-CuPc with the environment changes significantly their physical and chemical properties thus affecting exposure and risk. Even though (eco)toxicity of n-CuPc has been evaluated extensively, the testing was conducted under assumption that material is stable in the environment and no nano-specific transformation properties were addressed in the test design. Therefore, the old testing protocols on n-CuPc may not result in a mechanistic understanding of the induced (eco)toxicity in nano-form. To understand the knowledge gaps of n-CuPc behaviour in the aquatic environment, the biodynamic of n-CuPc in *Daphnia magna* was conducted in our laboratory. The age of 5 days' *D. magna* was exposed in M7 medium containing n-CuPc (0.1mg/L). The *D. magna* was sampled at 1 h, 4 hrs, 8 hrs, 16 hrs and 24hrs to analyze the bioaccumulation of n-CuPc by ICP-MS. After 24 h, *D. magna* was transferred to M7 media for n-CuPc depuration. *D. magna* was sampled at 1 h, 4 hrs, and 24 hrs to analyze n-CuO amount in *D. magna*. The biokinetics results show increased uptake of n-CuPc with the exposure time within first 16 hrs and saturation at 24 hrs. n-CuPc can not be depurated in *D. magna* in 24 hrs. Our results are not consistent with the previous test data which showed no n-CuPc bioaccumulation in environment. The difference in the results may be due to the different methods of n-CuPc suspension preparation in media compare to the old protocols and the n-CuPc specific physical-chemical properties which traditional testing protocols were not detecting. Our study provides evidence that n-CuPc show complete different biokinetics as compared to the testing protocols used before. A new protocol for re-evaluation of potential exposure and hazard of n-CuPc in the aquatic environment is urgently needed to ensure safe use of n-CuPc in growing market applications.

WE096

Toxicity mitigation by N-acetylcysteine and photo-induced toxicity of zinc oxide nanoparticles on a bacterivor nematode: Panagrellus redivivus

L.V. Kiss, A. Seres, P. Nagy, Szent István University / Animal Sciences and Ecology

Nanoparticles have new physical and chemical properties as a result of their alteration in size, therefore they have to be particularly well characterized with several analytical techniques and with extensive biological research. Toxicity of ZnO particles (with 15 and 140 nm average particle size) to *Panagrellus redivivus* was examined under dark condition (in thermostat) versus under simulated solar UV radiation (in Plant Growth Chamber). N-acetylcysteine was used in toxicity mitigation assay to elucidate the importance of dissolved zinc ions as well as phototoxicity in ZnO toxicity. ROS generation and particle dissolution were also measured under both irradiation conditions. Both ZnO particles toxicity increased under solar UV radiation. Toxicity mitigation by N-acetylcysteine under dark and solar UV radiation conditions proves to clarify the role of particle dissolution and ROS generation in nanoparticles toxicity. After the mitigation of the toxic effect of dissolution and phototoxicity, there was still mortality in the higher concentrations of the 15 nm ZnO particles. We may conclude the nanorelevant toxic properties, like increased surface area, particle size or morphology were also playing a role in toxicity mechanism.

WE097

The ecotoxicological impact of titanium dioxide nanoparticles on the fish kairomone induced anti-predator defence in Daphnia magna

S. Hartmann, University of Siegen, Institute of Biology / Department of Chemistry and Biology; A. Beasley, The University of Manchester; K. Witte, University of Siegen / Department of Chemistry and Biology

In the last decade, the production volume of manufactured nanomaterials (MNMs) has dramatically increased due to their widely use in common products. Because of the bright white pigment, titanium dioxide nanoparticles (TiO_2NPs) are one of the most industrially used MNMs and are applied in daily items such as sunscreens, toothpaste, food and also in paints or coatings. The ecotoxicity of TiO_2NPs to the freshwater organism *Daphnia magna* is well investigated. The interaction between NP-exposure and one important mechanism of water fleas, the anti-predator defence, however, has not been studied yet. It is known that daphnia are able to produce offspring with longer spines or characteristic helmets as a phenotypic response to kairomones released from fish. The resulting increase in body size allows the daphnia to defend themselves against predators in their natural environment. As a key species in the food chain of the aquatic environment, daphnia are of great important for fresh water systems. Their ability to grow adequate defensive structures is, therefore, necessary to prevent an ecological imbalance in the freshwater environment. In this study, we investigated the ecotoxicological impact of TiO_2NPs (NM-105) on the anti-predator defence response in daphnia by chronically exposing *Daphnia magna* to fish kairomones from the tropical freshwater fish *Danio rerio* in combination with different nanoparticle concentrations. Following the OECD guideline No. 211, the experiment was performed over 21 days with a daily water change to ensure a high concentration of fish kairomones. As endpoints, we measured the body length and the tail spine length after each moult of the test animals and juveniles and counted the number of offspring.

WE098

Bioavailability and Bioaccumulation of Silver Nanoparticles in the Rainbow Trout Oncorhynchus mykiss

L. Hermsen, R. Zeumer, S. Kühr, Fraunhofer IME - Institute for Molecular Biology and Applied Ecology / Bioaccumulation and Animal Metabolism; B. Knopf, IME Fraunhofer / Environmental Specimen Bank and Elemental Analysis; B. Meisterjahn, Fraunhofer IME - Institute for Molecular Biology and Applied Ecology / University of Vienna, Department Environmental Geosciences; R. Kaegi, Eawag - Swiss federal Institute of Aquatic Science and Technology / Process Engineering; C. Schlechtriem, Fraunhofer IME / Department Bioaccumulation and Animal Metabolism

Due to the increasing use of silver nanoparticles (AgNPs) in the production of various products, the risk of AgNPs being released into the environment rises. Even though AgNPs are mostly retained within wastewater treatment plants (WWTP), a small fraction of predominantly transformed nanoparticles enters the aquatic environment. Besides the numerous studies on ecotoxicological effects, information on the transfer, bioavailability and bioaccumulation of AgNPs in the aquatic food chain is essential for risk assessment. The aim of this study was to investigate bioavailability and bioaccumulation of waterborne and dietary AgNPs in the rainbow trout *Oncorhynchus mykiss*. Several model WWTPs were conducted according to OECD Guideline 303A. The effluents containing AgNPs (present or supplemented manually) were compared to pristine AgNPs and used to perform a bioconcentration study with *O. mykiss* according to OECD Guideline 305. Fresh zooplankton was collected in a fishpond in southern Germany and enriched with pristine AgNP. The loaded plankton was filtered, frozen, freeze-dried and processed into agar pellets, which can be eaten by fish. The resulting fish food was stable and displayed a homogenous AgNP distribution. The agar pellets were fed to juvenile *O. mykiss* in a biomagnification study according to OECD Guideline 305. Tissue concentrations during uptake and elimination in *O. mykiss* exposed to AgNPs via water or food were investigated by quantitative inductively coupled plasma mass spectrometry (ICP-MS). Enriched plankton samples were analysed by high-resolution transmission electron microscopy (TEM) with energy dispersive X-ray (EDX). For waterborne AgNPs present in or supplemented to WWTP effluents no significant uptake into the carcass of the test organisms could be detected. However, exposure to pristine AgNPs was leading to the accumulation of silver in fish tissues presumably driven by the uptake of silver ions released by the AgNPs. Biomagnification studies showed that pronounced silver concentrations could be found in the digestive tract. However, only a limited biomagnification of silver could be detected.

WE099

Tissue distribution of radiolabeled 110mAg nanoparticles in fish

M. AL SID CHEIKH, University of Plymouth / Marine sciences and engineering; C. Roleau, Peches et Oceans Canada; D. Bussolaro, C. Ribiero, Universidade

Federal do Paraná / Departemento de Biologia cellular; E. Pelletier, University of Quebec, Rimouski / ISMERUQAR
This work presents the first complete tissue distributions of dissolved (Ag_I) and silver nanoparticles (20 nm, Ag_0NPs_{20}) in fish (Arctic charr, *Salvelinus alpinus*). The distributions are provided for fish exposed to three different treatments including intravenous (IV), dietary and waterborne. Quantitative whole-body autoradiography (QWBA) analyses obtained on high-resolution images reveal distinct silver distribution patterns according to the treatments and the forms. The IV exposures showed that $AgNPs_{20}$were mainly located in bile and kidney after 8 d, while $Ag_I$was distributed through the whole body and reached particular tissues such as bones, eyes, skin, liver, spleen, kidney, and intestine. The Ag_0NPs_{20}distribution with the dietary exposures suggests some dissolution occurred within fish organs. We suggest that dissolved silver (i.e. from $Ag_I$and Ag_0NPs_{20}) could precipitate as chloride, sulfide or selenide and be incorporated in bones during the growth. As such, it is difficult to state if silver cross biological barriers in a nanoparticular form. Finally, the waterborne exposures revealed that the gills can capture Ag_0NPs_{20}in small quantity, implying that the stability of Ag_0NPs_{20}in water is critical.

WE100
Histopathological effects of silver ions and nanoparticles on zebrafish (Danio rerio) spleen and liver morphology during short time toxicity test
H. Szudrowicz, J. Lesiak, E. Latoszek, Warsaw University of Life Sciences / Department of Ichthyobiology Fisheries and Aquaculture Biotechnology; J. Frankowska-Łukawska, Warsaw University of Life Sciences / Department of Botany; M. Kamaszewski, T. Ostaszewska, Warsaw University of Life Sciences / Department of Ichthyobiology Fisheries and Aquaculture Biotechnology
Despite the fact, that nanotechnology is rapidly growing branch of industry, the toxicity of nanoxenobiotics has not been well understood yet. The aim of the study was to investigate influence of nanoparticles and silver ions on the morphology of zebrafish (*Danio rerio*) spleen and liver. Fish at the age of 5 months were exposed for a week to aqueous solutions of silver nanoparticles at concentrations of 0.01, 0.05, 0.1, 0.5, 1.0 and 2.0 mg/L (AgNP groups) or aqueous solutions of silver ions at concentrations of 0.01 and 0.05 mg/L (Ag + groups). In the control group fish were kept in water without the addition of xenobiotics. All the animals were fed *Artemia salina* and commercial *ad libitum*. On the last day of the experiment, the fish were anaesthetized in MS222, fixed in glutaraldehyde to assess the ultrastructural changes in hepatocytes or in Bouin's solution and then subjected to a standard histological procedure. Obtained histological slides were stained with the hematoxylin/eosin methods to analyze liver and spleen morphology, AB/PAS to analyze deposition of lipofuscin in macrophages, and Perl to assess the deposition of hemosiderin in macrophages. On the last day of the experiment, survival rate was close to 100% in the all groups, except Ag+ 0.05mg/L. Microscopic analysis did not show any histopathological changes in liver and spleen fish from the control group. The area occupied by the lipid vacuoles in the cytoplasm of hepatocytes in liver was higher with increasing concentrations of studied nanoparticles and silver ions. In liver macrophages were not observed. In the spleen parenchyma fish from the control group no deposition of macrophages was found. In the groups exposed to the higher concentration of tested xenobiotics, the area occupied by macrophages forming the melanomacrophage centers in the spleen increase. The largest area of melanomacrophage centers (statistically significant) were found in the spleens of the fish exposed to AgNP 2.0 mg/L. In addition, intensive deposition of lipofuscin and hemosiderin was observed in melanomacrophage centers fish from the Ag + 0.05mg/L and AgNP 2.0 mg/L groups. The obtained results indicate that the increase concentration of xenobiotics may be affected on disturbance of homeostasis, activation of the immune system and deposition of lipofuscin (indicator of fatty acids peroxidation) and hemosiderin (reservoir of iron ions) in macrophages.

WE101
Toxicity evaluation and antioxidant activity of caffeic acid-loaded mesoporous silica nanoparticles
T. Andreani, Centre of Investigation in Chemistry (CIQUP), Faculty of Sciences, University of Porto, Portugal; V. Nogueira, Faculty of Sciences and CIIMAR - Porto University; C. Martins-Gomes, A. Silva, University of Trás-os-Montes and Alto Douro; R. Pereira, Faculty of Sciences of University of Porto Portugal; C. Pereira, Centre of Investigation in Chemistry CIQUP Faculty of Sciences University of Porto Portugal
The nanoencapsulation is an excellent strategy to increase the solubility, stability and bioavailability of antioxidants, such as caffeic acid (CA). Therefore, the aim of this work was to synthesize and evaluate the effect of mesoporous silica nanoparticles (MSiNP) and MSiNP coated with polyvinyl alcohol (MSiNP-PVA) loaded with CA on the microalgae *Raphidocelis subcapitata* growth and on Raw 264.7 cells viability, as well as to evaluate the antioxidant activity of CA released from nanoparticles. MSiNP were synthesized using tetraethyl orthosilicate (TEOS) as precursor, N-cetyl-trimethylammonium bromide (CTAB) as porous template and NH_3as catalytic agent. Coating of MSiNP was made using a solution of PVA (60 000 5%, w/v). For algae assay, stock solutions of MSiNP were prepared in algae culture medium and added to algae inoculum into microplate and maintained under photoperiod conditions during 72h.The cytotoxicity of the samples was evaluated by comparing the viability of non-exposed Raw 264.7 cells with exposed cells to different concentrations during 48h using AlamarBlue method. The antioxidant activity of CA released from nanoparticles was evaluated by nitric oxide (NO) and (2,2′-azino-bis (3-ethylbenzothiazoline-6-sulphonic acid (ABTS) radical assays. MSiNP-PVA reduced the algae growth in comparison to the control group. However, no toxic effects were observed when Raw 264.7 cells were exposed to nanoparticles. The NO scavenging activity of CA released from MSiNP was higher than that released from MSiNP-PVA at highest concentrations. However, in ABTS assay, no differences were observed in the antioxidant effect of CA between the results with MSiNP and MSiNP-PVA and the nanoparticles increased the scavenging capacity of CA with concentration. Data showed that the antioxidant activity of CA released was not affected by nanoencapsulation at least in NO radical assay. In general, MSiNP and MSiNP-PVA are biocompatible materials and their effect can vary depending on the test species.

Investigations on the uptake and fate of nanostructural polystyrene in the fresh water mussel Corbicula fluminea
S. Kühr, Fraunhofer IME - Institute for Molecular Biology and Applied Ecology / Bioaccumulation and Animal Metabolism; B. Meisterjahn, Fraunhofer IME - Institute for Molecular Biology and Applied Ecology / University of Vienna, Department Environmental Geosciences; N. Schröder, Fraunhofer Institute for Molecular Biology and Applied Ecology IME / Ecological chemistry; I. Hering, Fraunhofer-Institut für Molekularbiologie und Angewandte Oekologie IME; B. Knopf, IME Fraunhofer / Environmental Specimen Bank and Elemental Analysis; D. Volker, German Environment Agency; K. Schwirn, German Environment Agency - UBA; C. Schlechtriem, Fraunhofer IME / Department Bioaccumulation and Animal Metabolism
Polystyrene is one of the mostly used type of plastic and could enter the environment by direct release from industrial products during their usage as well as by their disposal. In the environment, those macro- and microplastics could undergo weathering through biological degradation, mechanical erosion and UV radiation and could thus be transformed into nanoplastic particles. Most nanoparticles (NPs) tend to sediment in water and are supposed to be primarily taken up by benthic species in aquatic ecosystems. Different studies have shown that mussels are able to ingest and to incorporate NPs suspended in water. By this the NPs may bioaccumulate in this organisms and thereby enter the food chain at a very low trophic level leading to potential further biomagnification. The filter feeding freshwater bivalve *Corbicula fluminea* was used to investigate the uptake of nanostructural polystyrene (nPS) from the water. By the use of fluorescent nPS and fluorescence microscopic analysis we were able to investigate the uptake, localisation and elimination of the nPS in the soft body of *C. fluminea* after different exposure and depuration times. During the exposure period the nPS induced a high filtration activity resulting in a strong production of (pseudo-)feaces, whereby the feaces showed a strong fluorescence intensity. Also the soft tissue of the mussel showed a high strength of fluorescence after 24 hours of exposition with different intensities for the different compartments like the mantle, the foot, adductor muscles and the viscera (including the gills and the digestive system). The results indicate that the particles are ingested, are temporarily adsorped to the tissue surfaces, finally pass the digestive system without being incorporated into the organisms tissues and are obviously not bioavailable for mussels. A rapid and effective elimination of the nPS was observed after 24 hours of depuration.

WE103
Condition dependent aging of nanosized titanium dioxide influences copper toxicity towards the water flea Daphnia magna
R. Roy, University of Koblenz-Landau / Institute for Environmental Sciences; S. Lüderwald, Universität Koblenz-Landau / Institute for Environmental Sciences; A. Alawi Ahmed Maknoon, University of Koblenz-Landau / Institute for Environmental Sciences; G. Metreveli, University of Koblenz-Landau; R. Schulz, University of Koblenz-Landau / Institute for Environmental Sciences; M. Bundschuh, Institute for Environmental Sciences University of Koblenz-Landau / Department of Aquatic Sciences and Assessment
Nanosized titanium dioxide ($nTiO_2$) has wide applications in consumer products and is inevitably released into the environment including freshwater bodies. During their aquatic life cycle, $nTiO_2$ may interact with natural organic matter (NOM) affecting ecotoxicological consequences of co-occurring chemical stressors such as heavy metals. The ecotoxicological consequences of these interactions are influenced by various factors including aging duration of $nTiO_2$ in the environment complicating a valid risk prediction. The present study aimed at assessing the influence of $nTiO_2$-aging conditions on the toxicity of copper (Cu) for various aging durations under freshwater conditions using a factorial test design. The test design crossed two $nTiO_2$ levels (0.56 versus 2.57 mg/L) with two levels of NOM (0 versus 8 mg/L TOC) and seven nominal Cu concentrations (ranging from: 0 – 1536 µg/L) for a duration of 0, 1, 3 and 6 days, while two types of aging conditions were realised. The Type 1 aging condition was characterised by aging of $nTiO_2$ along with Cu and in a combination with NOM while the Type 2 aging condition included aging of $nTiO_2$ in a combination with NOM and Cu was freshly added to the aged dispersion prior to the exposure of the test

organism, i.e. *Daphnia magna*. The actual toxicity experiment followed the OECD 202 guideline. The results of the experiments applying the aging condition of Type 1 showed that irrespective of the aging duration (excluding 0 day aging), the presence of 2.57 mg/L $nTiO_2$ elevated Cu toxicity by ~ 2-fold as compared to an unaged Cu solution. In contrast to this, the presence of NOM in combination with 2.57 mg/L $nTiO_2$ showed a 2-fold reduction in Cu toxicity. The elevation or reduction in Cu toxicity in presence of 0.56 mg/L $nTiO_2$ in combination with NOM showed a similar trend but were often statistically not significant. In the case of the Type 2 aging condition, the presence of 2.57 mg/L $nTiO_2$ reduced Cu toxicity by ~ 2-fold while the reduction in Cu toxicity in presence of 0.56 mg/L $nTiO_2$ was by trend again comparable but not statistically significant. In addition, the presence of NOM in combination with 2.57 mg/L and 0.56 mg/L $nTiO_2$ diminished Cu toxicity up to 3-fold and ~ 2-fold, respectively. In consequence the present study shows that both presence of NOM and Type 2 aging condition assist $nTiO_2$ to alleviate Cu induced toxicity.

WE104

Estimating the distribution of TiO2, CeO2, ZnO and SiO2 nanoparticles with various forms when released to waste water treatment plant through sewers

K. Kim; J. Park, KIST Europe / Environmental Safety Group; D. Lee, Seoul National University / Environmental Planning Institute Graduate School of Environmental Studies; S. Kim, H. Jeon, KIST Europe / Environmental Safety Group

In recent years, there have been many challenges in developing environmental exposure model for estimating behavior of engineered nanomaterial (ENMs) as the production and use of ENMs increase. Most developed models are based on the assumption that ENMs release into the environment as their pristine forms and also remain in that state throughout their life cycle. However, it is reported that physical or chemical transformations of ENMs are inevitably occurred during their life cycle. Therefore, it is very important to predict the fate and transport of the ENMs in the intermediate pathway and it is also significant to estimate distribution of various forms of ENMs before releasing to environment. These results should be incorporated into exposure models as input data of emission amounts in order to improve reliability of predicted environmental exposure values. In this study, we compare the behaviors of the four kinds of engineered nanoparticles (ENPs): TiO_2, CeO_2, ZnO and SiO_2 when flowing in the sewers and the proportion of the forms of each ENPs before flowing into waste water treatment or natural water by using SWNano model. The SWNano (Sewer Water Nano) model was developed to predict behavior of ENPs in sewer system, which is representative intermediate pathway between emission and water compartment. And it was confirmed in our previous study that heteroaggregation process of TiO_2 ENPs with SPMs in sewage was the most influential process and rate of heteroaggregation was determined according to various conditions such as properties of sewage, ENP and sewer. In order to assess the behavior and the forms of not only TiO_2 ENPs but also other kinds of ENPs in the sewer, the physicochemical properties of these four ENPs such as size and zeta potential, etc. were obtained through experiment. Particularly, the size of ENPs were measured by using three equipment: SEM, DLS and SP-ICP since the size of ENPs is major factors in aggregation process. Attachment efficiency of ENPs were estimated by implementing empirical values of ENP properties to XDLVO theory. The model predicted that how difference in physicochemical properties of ENPs affected temporal concentration changes and proportion of released forms, although heteroaggregation is a major determinant of behavior in sewer for all ENPs. Furthermore, expansion of various types of ENPs in SWNano model represent that SWNano model can be a good candidate for a exposure assessment tool of ENPs.

WE105

Toxicity of novel nano-based sensors for early detection of corrosion on marine organisms

R. Martins, Department of Biology, University of Aveiro / department of Biology & CESAM; J. Figueiredo, University of Aveiro / Biology; A. Sushkova, T. Galvão, M. Wilhelm, University of Aveiro / Department of Materials and Ceramic Engineering, CICECO; A.M. Soares, University of Aveiro / department of Biology & CESAM; J. Tedim, University of Aveiro / Department of Materials and Ceramic Engineering & CICECO; S. Loureiro, Universidade de Aveiro / Biology

Corrosion is an environmental and economic global problem. The regular monitoring of corrosion in maritime structures is critical due to safety reasons. However, current monitoring techniques are destructive, complex, expensive and do not provide real-time information regarding the structure's integrity. The MarTERA project "SMARTAQUA" (ERA-NET cofund scheme of H2020) is focused in the development of nanolayers that can be applied directly on maritime steel structures, to provide eco-friendly, low-cost and real-time detection of corrosion degradation. This will be achieved by incorporating smart nano-structured sensors containing active compounds that can detect the presence of specific triggers associated to the beginning of corrosion (e.g. pH changes or presence of chlorides or Fe^{3+}), for instance, by changing its colour. Layered double hydroxides (Mg-Al LDH) and hollow silica mesoporous nanocapsules (SiNC) were used as nanocarriers of potassium hexacyanoferrate ($Fe(CN)_6$) and phenolphthalein (PhPh), respectively. As far as we know, effects of Mg-Al LDH and PhPh in marine organisms are scarcely (or not yet) studied while hollow SiNC and $Fe(CN)_6$ are reported to exert deleterious effects in some marine organisms. Therefore, the present study aimed at assessing the acute and short-term chronic effects of both novel nanomaterials (LDH-[$Fe(CN)_6$]; SiNC-PhPh), together with the unloaded nanocarriers (Mg-Al LDH; SiNC) and the active ingredients ([$Fe(CN)_6$]; PhPh). Exposure tests were carried out using the green microalgae *Tetraselmis chuii* and the crustacean *Artemia salina* following the OECD 201 (2011) and ASTM E1440-91 (2012), respectively, with minor adaptations. Exposure concentrations range varied according to the species and tested compound. All materials were structurally and morphologically characterized. Engineered nanomaterials and both free sensing compounds exhibited no acute toxic effects in *A. salina* (NOEC=100 mg/L). Nevertheless, all tested compounds, apart from Mg-Al LDH, caused significant growth inhibition on *T. chuii*. NOEC values ranging from 3.25 to 5 mg/L were calculated for PhPh, SiNC-PhPh and SiNC, while NOEC of [$Fe(CN)_6$] was half than its nano-form (1.25 mg/L). Although the proposed nano-based solutions are marginally less toxic than the free sensors, it is recommended the implementation of safer-by-design strategies to promote a decrease in their current toxicity (e.g. substitution of surfactants).

WE106

Toxicity of the C60 to marine macroalgae Gracilaria caudata (Gracilariales, Rhodophyta)

L.R. Diniz, Universidade de Sao Paulo / Bioquimica; C. Alves-Lima, L.Z. Villela, University of São Paulo USP; P. Colepicolo, University of São Paulo USP / Biochemestry

In recent years, the increasing application of nanomaterials (NMs) in various areas as industrial and household, contributes to the growth of the global economy. However, the fate and effects of these nano contaminants have attracted the attention of the scientific community, as these compounds are likely to cause adverse effects, even at low concentrations, they can cause potential risks to exposed organisms to the environment and to human health. The fullerene C_{60}, the object of interest in this study, was discovered by Kroto et al. (1985), as an allotropic form of carbon, being a relevant molecule with respect to the production, scientific interest and engagement in the research due to its physical and chemical characteristics and properties that are intrinsic, such as size, surface area and agglomeration/dispersion capacity. This nanoparticle has a potential environmental risk due to the propensity to affect the rate of absorption and toxicity of other environmental contaminants, which enhances the deleterious effect of these mixtures on exposed organisms. This study aims to investigate the effect of C_{60} under the marine macroalga *Gracilaria caudata J. Agardh*, red macroalgae of the Rhodophyta family, which grows naturally along the entire Brazilian coast, being distributed from the state of Maranhão to Santa Catarina. The *G. caudata* macroalgae is important for industries that extract from them a gum called Agar, which is widely used in the food industry, pharmaceuticals, cosmetics, agriculture, and fertilizers. However, the exposure of this macroalgae to contaminants has serious implications and may potentially represent an entry of contamination into the chain through its direct consumption by organisms at higher levels. In this work, to measure the growth rate at a laboratory scale, it was applied an accessible, and sensitive method that uses imaging described by Alves-Lima et al. (2018), with adaptations. The stock solution of the fullerene will be diluted in seawater to the desired concentration. A preliminary test will be done in a geometric series of 5 concentrations, to determine the concentration range, delimited by the lowest and highest concentration of inhibition. This interval, in turn, will be used in the preparation of the definitive test. The Inhibition Concentration (IC50) of the algae growth will be determined.

WE107

Reactivity of ZnO nanoparticles in synthetic saliva: dissolution and transformation driven by phosphate

J. Galceran, Universitat de Lleida / Dep Quimica; C.A. David, F. Quattrini, J. Puy, C. Rey-Castro, Universitat de Lleida and AGROTECNIO / Dep Quimica

The use of ZnO nanoparticles (nZnO) in personal care products, dentistry, food packaging, etc. raises a potential concern about the ensuing oral exposure. As point of entrance to the gastrointestinal tract, the oral cavity represents a compartment of major interest for studies of risk assessment of nanomaterials. Once in contact with saliva, nZnO may undergo –among others- chemical and physical transformations which include dissolution (to produce the free ion) and reaction (for instance, with phosphate anions). The fate and speciation of the introduced Zn will depend on all these transformations. Conventional techniques such as ultrafiltration (UF) combined with inductively coupled plasma mass spectrometry (ICP-MS) exhibit some limitations which can be overcome by the electroanalytical technique AGNES (Absence of Gradients and Nernstian Equilibrium Stripping) [1]. This technique has successfully shed light on the kinetics and thermodynamics of nZnO dissolution in various media [2-3] as well as on the relevance of nZnO dissolution for toxicity tests *in vitro* [4]and *in vivo* [5]. One advantage of AGNES is that there is no need of a separation step. This presentation will focus on the study of nZnO evolution in contact with synthetic human saliva with several techniques, including AGNES. The key role of phosphate will be highlighted in the kinetic and thermodynamic results. For instance, in the presence of phosphates, nZnO dissolve at a reduced speed in comparison with the dissolution rate of nZnO in non-complexing solutions of the same ionic strength. Solubility of nZnO in saliva determined by AGNES titrations will be presented. AGNES methodology compares favourably with data obtained by ultrafiltration and inductively coupled plasma mass spectrometry (UF-ICP-MS) in terms of speed, reproducibility and access to the free metal ion concentration. WE108
Transformation/dissolution of cobalt nanoparticles in biological media - influence of adsorbed biocoronas of amino acids, polypeptides and proteins
N. Mei, KTH royal Institute of Technology
This study focuses on the interactions between cobalt (Co) nanoparticles (NPs) and biomolecules in phosphate buffered saline (PBS) to understand how the adsorption of biomolecules influences the dissolution characteristics. Amino acids with different functional groups (*i.e.* lysine, glutamine, glutamic acid and cysteine), oppositively charged polypeptides (poly-lysine and poly-glutamic acid) and proteins (lysozyme and mucin – relevant for the inhalation route) were selected to investigate how the different properties of the biomolecules influence the surface reactivity of Co NPs. This was accomplished by employing different analytical techniques and electrochemical tools. From this study it can be concluded that the smaller biomolecules (the amino acids) do not adsorb on the Co NPs in PBS, whereas adsorption takes place for the larger biomolecules (polypeptides and proteins). This can be explained by the high affinity between Co NPs and phosphate ions in PBS, which results in the formation of Co-phosphate compounds on the surface that hinders the adsorption of the small amino acids. For the larger biomolecules, the driving force of adsorption is higher due to an entropic gain (*i.e.* increase of the free energy) originating from the exchange of small molecules (*e.g.* water and counter ions) from the Co NP-biomolecule interface. The formation of Co-phosphate at the Co NP surface reduces the protective properties of the surface oxide of the Co NPs, as evident from a reduced open circuit potential (OCP) value (reduced nobility). Except for cysteine, adsorption of the biomolecules had minor influence on the dissolution of Co NPs compared to dissolution in PBS only, though some kinetic differences were observed. Enhanced dissolution in the presence of cysteine is believed to be associated to the relatively high affinity between cysteine and Co-ions in solution, reactions that chemically drive the dissolution process. The adsorption of the larger biomolecules initially (< 4 h) resulted in reduced Co dissolution, but did not influence the long term behavior. The dissolution of the Co NPs in biomolecule-containing PBS solutions was very fast, with 35-55% of the Co NPs dissolved within one hour in the amino acid-containing solutions, and 15-40% in the polypeptide and protein solutions, similar to findings in PBS only. The results indicate that Co NPs will readily dissolve and only exist as NPs for limited time periods at biological conditions, *e.g.* in the human lung.

WE109
The standard development of nanoparticle exposure assessment through SP/ICPMS equipment
J. Park, KIST Europe / Environmental Safety Group; K. Kim; H. Jeon, S. Kim, KIST Europe / Environmental Safety Group
The development of nanotechnology, particularly of nanoparticles, is having a revolutionary effect in science and technology. It is important to develop with suitable physical and chemical properties of nanoparticles. Otherwise, it receives unexpected adverse effects (e.g. ecotoxicological) which can be caused by the special properties of the nanoparticles. So there is requiring a study on the safety and the risk of the nanoparticles as well as the development of nanotechnology. In recent years, toxicity assessment method using nanoparticle in stable suspension has been emphasized in safety evaluation of nanomaterials. The nanoparticles dispersed in the aqueous solution have the possibility of creating an artifact that does not reflect the state of the dispersion aqueous solution. Confirmation of the conditions for measuring the size and size distribution reflecting the state of the dispersion aqueous solution is fundamental to reliable nanomaterial characterization. In addition, this characterization is needed to design environmentally appropriate toxicity studies and risk assessments. In this work, the size and size distributions of liquid suspension containing well-dispersed standard nanoparticles are measured by single particle inductively coupled plasma-mass spectrometry (SP/ICP-MS). The advent of SP/ICP-MS has helped advance the field of nanometrology, specifically at concentrations and in matrices that are environmentally relevant. SP/ICP-MS is a technology that can be applied to metal nanoparticle analysis of 20 nm or more. The required concentration in the sample has the advantage that it can be analyzed sufficiently below the ppt level. The size distribution measurements of particles are made using variety certified reference materials (CRM). These were compared with certificate values. And we have found reliable measurement conditions through repeated measurement. Through these results, the new environmental fate and exposure model of nanoparticle in different matrices can be developed through these results which contains relationships between agglomeration rates, primary size, and surface charge of the nanoparticle and the matrix.

Improving Decision Support for Sustainability Going beyond Standard LCA (P)

WE111
Using customised agricultural LCA tools in research projects: reconciling ease of use and flexibility. The case of cropping system modelling
J. Auberger, C. Malnoë, J. Aubin, INRA / UMR SAS, INRA, AGROCAMPUS OUEST, Rennes; L. Nitschelm, INRA-Agrocampus Ouest / UMR SAS; H.M. Van der Werf, INRA / UMR SAS, INRA, AGROCAMPUS OUEST, Rennes
Customised agricultural LCA tools are increasingly popular, because they simplify LCA studies of agricultural production systems. These tools are easier to use than generalist LCA tools and reduce the risk of errors. However, compared to more generalist LCA tools, customised LCA tools are less flexible, and it is harder to tackle new research questions, that were not anticipated during the design of the tool. This study shows that customised LCA tools can be used to address new research questions, provided that they are adapted to them. The customised LCA tool MEANS-InOut was developed in a "product-oriented" way, to answer the question "What are the resources needed and the emissions due to the production of the agricultural product X?" This question resulted for crops in the scope definition: one product, on one field, for one year. LCA studies considering a single crop are challenged by agronomists, because interactions among crops within the rotation, which are a key factor for cropping system design, are largely ignored. The ACV Bio project has the ambition to address this question. In a cropping system view, the scope of the system is: several products, on one field, for several years. MEANS-InOut has been chosen as the tool to create LCIs in this project A cropping system is defined as the crops, crop sequence and management techniques used on a field over a period of years. It could be represented as the aggregation of the crops composing it. Considering this, no adaptation of LCI modelling is necessary. However, this approach does not take into account the interactions among the crops. The need for methodological and tool adaptations to assess the effects of the interactions among the crops of a cropping system was recognised in the planning of the ACV Bio project. Agronomists and tool developers worked together to adapt MEANS-InOut to the study of a cropping system as whole. These adaptations profoundly changed the data entry forms, emissions models and export functions. It also allowed automatic consistency controls and improved the tool usability. This case-study shows that a customised agricultural LCA tool can be used to answer a new research question, provided that the tool has been initially designed to be adaptable and that time and resources for the adaptation of the tool have been planned in the project. Strong interactions between scientists, users and tool developers are key to deliver tools, adapted to the need of users.

WE112
Integrated Life Cycle Analysis and Multi-level Energy Systems Modeling
E. Gencer, Massachusetts Institute of Technology; S. Torkamani, ExxonMobil Research and Engineering; F. O'Sullivan, Massachusetts Institute of Technology
The global energy system is undergoing a major transformation facing the dual challenge of meeting increasing energy demand while reducing greenhouse gas emissions. This change is characterized by the convergence of power, transportation, and industrial sectors, and the surge of multi-sectoral integration. Understanding the implications of these dynamics is challenging and requires a holistic approach to provide systems-level insights. To address this need, we have developed a systems-level life cycle analysis (LCA) framework that is designed to explore the emissions impacts of relevant technological, operational, temporal and geospatial characteristics of the evolving energy system. The underlying analytical engine includes the cradle-to-grave life stages of major energy conversion routes and covers more than 900 individual pathways. Detailed process simulation capabilities have been incorporated for in-depth analysis of greenhouse gas emission sources such as power plants and selected chemical conversion pathways. In addition to performing conventional LCA, we have implemented models for vehicle fleet and electric power systems to analyze systems-level interactions. By executing the analysis with embedded fleet models, we can establish a basis for the accurate assessment of the life cycle implications arising from complex system-level restructuring. The presentation will focus on the modeling methodology and the results of case studies.

WE113
Life cycle assessment, eco-design and recyclability of infrastructure integrated flexible thin film solar cells
J. Mahaux, HELMo-CRIG
Public infrastructure represents a huge area of built environment that can be used

for renewable energy generation by integrating solar cell materials into road pavements and road furniture. As electric driving is rapidly developing, and the use of intelligent traffic control systems is growing, an increasing amount of this infrastructure produced energy can be used locally. Moreover, it can enhance secure operation of critical control systems independent of external power failures, and on remote locations local energy generation can be more cost effective. Promising demonstrators have already been realized where crystalline solar cells are incorporated into bicycle paths, roads, smaller demo projects and sound barriers. However, costs of such systems are still high, not only because they have not yet developed towards the stage of standard high-volume products, but also because they are based on brittle silicon solar cells in the form of small tiles. These require severe mechanical protection and much assembly. This project aims to reduce cost by using flexible (and thus less breakable) thin film solar sheets, and by more effective integration of long lengths of these into public infrastructure. As a result, large scale durable electricity generation without additional land use will be enabled close to point of use. In order to ensure and support the environmental sustainability of renewable energy generation with infrastructure integrated thin film solar cells, a comparative life cycle assessment is performed. The considered incumbent technology is crystalline silicon solar cells while several emerging flexible thin film technologies are investigated: CIGS, CdTe and perovskite solar cells. Direct partnership with research centers and companies developing the emerging technologies enables the collection of as many site or laboratory specific data as possible. On the other hand, the main data sources for silicon solar cells are existing databases. Prospective efficiency models, that will be adapted throughout the project, are used to investigate multiple scenarios. As industrial scale development is not yet reached, the impact assessment results can therefore be used for recommendations on eco-design of the infrastructure integrated thin film solar cells, the recycling process to adopt and future development needs. This project is supported by the Interreg V-A Euregio Meuse-Rhine program.

WE114

Life Cycle Environmental Impacts of Synthetic Diamond Production

A. Furberg, Chalmers University of Technology; R. Arvidsson, Chalmers University of Technology / Environmental Systems Analysis; M. Larsson, M. Zachrisson, K. Fransson, RISE Research Institute of Sweden; S. Molander, Environmental Systems Analysis, Chalmers University of Technology / Energy & Environment

Synthetic diamond is a superhard material found in applications such as cutting and grinding of rocks, minerals, metals and plastics, but also in windows and lenses in analytical equipment. Since the 1950s, when the synthesis of diamond via the high-pressure high-temperature (HPHT) synthesis was introduced, the use of synthetic diamond has gained increasing importance within industry, for example in cutting processes. Today, synthetic diamond dominates the industrial diamond use over its natural counterpart and the production is mainly via HPHT synthesis. Chemical vapor deposition (CVD) synthesis is also applied but to a lesser extent due to various technological issues, including the tendency of CVD diamond coatings to wear and tear in tooling applications. Nevertheless, a lot of research exist in the area of synthetic diamond film production via CVD synthesis addressing technological issues and CVD diamondhas been described as the potential facilitator of a new diamond age. In the strive for sustainable production, it is important to investigate the environmental impacts associated with various products and life cycle assessment (LCA) is commonly applied for this purpose. Until now, however, no study has conducted LCA of conventional synthetic diamond production via HPHT synthesis and so far, only laboratory-scale LCA results have been presented for one CVD synthesis alternative. The aim of this study is to conduct a cradle-to-gate LCA for synthetic diamond production both via the conventional HPHT synthesis and the potentially emerging CVD synthesis. For the latter route of synthesis, prospective (or ex ante) LCA was conducted and a predictive scenario was constructed focusing on microwave CVD. Future scenarios were constructed, e.g. by modelling the background energy system both using a fossil-based mix, representing the currently dominating Chinese production, and a renewable energy mix in an explorative scenario. A comprehensive uncertainty analysis was furthermore conducted for the included parameters. Environmental impacts were compared between the two routes of synthesis and hotspots in synthetic diamond production identified. The results from this research can be applied as a foundation for further LCA studies of synthetic diamond products.

WE115

Use of LCA methods for organisational decision-making. Case study of the Organisation Environmental Footprint (OEF) and the Nordic Swan Ecolabel in the retail sector

H.H. Salo, Finnish Environment Institute, SYKE

The Organisation Environmental Footprint (OEF) methodology aims to outline specific, prescriptive methodological standards to be used in the European Union in order to assess the environmental impacts of organisations. It should be a multi-criteria, life-cycle-based approach that considers all organisational and related activities across the supply chain, provides for reproducibility and comparability over flexibility, and ensures physically realistic modelling. In this study we compared the OEF methodology to the approach of the Nordic Swan Ecolabel. The Swan, established in 1989, is well-known within the Nordic market and grants a license for the best performing products or services in a particular category, using existing LCAs and life cycle thinking based methods as sources for the environmental aspects focused. There are differences between OEF and Swan in the way the functional units and reference flows are defined. The Swan uses shares of sales, number of products available and sales in local currency. OEF measures the quantitative amounts produced and eventually consumed based on sales and losses occurring at the retailer, together with the environmental impacts of each product. OEF analysis is an aggregation of all the products of an organisation, which for the purposes of the Organisation Environmental Footprint Sector Rules (OEFSR) is a virtual, average retailer in the EU market. OEF also measures the energy consumption of the store and its impacts. The OEF shall include all upstream impacts, and some downstream ones if possible. The Swan includes only aspects related to production and use of goods sold in the shop and waste production and sets its system boundaries based on relevance, potential and steerability of the label. From a retailer's point of view, both the schemes act more as environmental management systems than as a way of external communication and gaining added value in the market. As opposed to the Swan, OEF does not set any requirements for performance levels. Therefore, it could be easier for the store to adopt, but on the other hand, it does not indicate good performance externally like the Swan does. Thus, OEF would be a helpful tool to gain a broad information basis, based on multiple environmental criteria and including upstream activities. It is time to consider using OEF in the criteria development of type 1 ecolabels like the Swan, and as an information basis for the environmental management systems of organisations.

WE116

Evaluating climate change pathways through a building's lifecycle based on dynamic impact assessment metrics

K. NEGISHI, CSTB; L. BARNA, INSA Toulouse / LISBP; Y. PIGNE, Universite du Havre; T. NAVARRETE GUTIERREZ, Luxembourg Institute of Science and Technology; N. SCHIOPU, A. LEBERT, CSTB; T. Gibon, Luxembourg Institute of Science and Technology (LIST) / Environmental Research and Innovation; E. POPOVICI, Luxembourg Institute of Science and Technology / ERIN; E. Benetto, Luxembourg Institute of Science and Technology (LIST) / Environmental Research and Innovation

A current practice of Life Cycle Impact Assessment (LCIA) uses a finite analytical horizon time and steady-state modelling conditions to provide traditional characterization factors. Metrics for dynamic environmental assessment and its computational tool have recently been proposed as an alternative solution to overcome these limitations dues to lacking of time dimension in LCA, precisely for climate change and toxicity impact categories (A. Shimako et al., 2017). As a building system has a very long lifetime, a framework of dynamic LCA method specific to the building sector was recently proposed by K. Negishi et al. (2018), allowing supporting the sustainable building design by calculating environmental burdens and the associated impacts on climate as temporal functions. The main purpose of this study is to identify building-related industrial sectors as hot spots with the aim to introduce an effective policy instrument of GHG mitigation actions for building's stakeholders. The dynamic LCA methodology is applied to a testbed case on a French building. This advanced dynamic approach is performed by integrating parameters that differentiate temporally LCI and LCIA and by combining traditional and new LCA tools (e.g. matrix-based LCI modeling method, database, allocation method, etc.). In this work were evaluated by dynamic LCA environmental impacts of 10 categories of construction products and compared with conventional LCA results in order to see how dynamic LCA would complete conventional LCA and support decision makings. The graphical representation of dynamic LCA results as a function of time provides important features proposing the proper consideration of essential information for time periods encompassing the lifetime of the studied system. Following anthropogenic activities over time, the dynamic profile of impacts allows making an appropriate decision at each occurrence of environmental burdens. Through the case study, it is shown that the complete dynamic LCA framework can be successfully applied to a building system considering system evolutions over time. The main findings from this work are that temporally distributed emissions give a completely different perspective of impacts and the dynamic metrics show the importance of setting targets for mitigation efforts concerning long-term emissions such as construction products requiring recurrent replacement to attain our objective of limitation of the global warming.

WE117

Sustainability performance of emerging upcycling applications of silanized fly ash reinforced polymer composites from WtE (Waste to Energy) plants

k. shanmugam, Umea University / Chemistry; V. Upadhyayula, Umea University / Chemistry Department

WtE (incineration of municipal solid waste for energy recovery) is a sustainably preferred waste management strategy compared to landfilling. This energy is utilized to meet municipal and/or industrial electricity and heat demands of the society. Bottom and fly ashes are two important byproduct streams of WtE incineration plants. Bottom ashes are non hazardous in nature because of their lower heavy metal concentration and being increasingly used as secondary construction material .On the other hand, fly ash from WtE plants is hazardous and European Union mandates its disposal in hazardous waste landfills. Potential avenues for recycling fly ash can be classified into three types: (a) separation methods (b) solidification/stabilization and (c) thermal methods, which are used in construction industry (asphalt filler, cement clinker etc.). Although recycling fly ash is encouraging, its value as a secondary (i.e. recycled) material in the economy is not significant. Recycling of secondary materials derived from waste streams into avenues with high economic importance is strongly recommended according to principles of circular economy. This study evaluates sustainability performance of three emerging upcycling applications of silanized fly ash reinforced polymer composite (immobilization of heavy metals in ash and up scaled as filler reinforcement in thermoplastic and thermoset polymers) as: (a) thermal insulating false ceiling roof that potentially reduces air conditioning load of a building; (b) lightweighted automotive parts that improves fuel economy of an automobile; and (c) as a coating for protection of mild steel from atmospheric corrosion. The sustainability performance of these applications is determined in two steps. Firstly, their environmental performance is evaluated using a life cycle assessment (LCA) study. Secondly, a screening level life cycle costing analysis is performed by including environmental externality costs (or savings) that are quantified based on LCA results. The assessment is aimed to improve understanding on sustainable benefits and implications of silanized MSW fly ash reinforced polymers considering their properties of thermal insulation, mechanical strength and corrosion resistance. The outcome of this work offers critical insights to multiple stakeholders, such as local municipalities operating WtE incineration plants, venture capitalists with stakes in promoting sustainable innovations and technologists of the field.

WE118

Life Cycle Assessment of Added Value Compounds Production with Microalgae

C. Onorato, Karlsruhe Institute of Technology (KIT) / ITAS; C. Rösch, Karlsruhe Institute of Technology, KIT / Institute for Technology Assessment and System Analysis, ITAS

Microalgae are an alternative to produce sustainable fuel, food and high-value compounds such as carotenoids and terpenes for nutraceutical supplements and cosmetics. Algae production is focusing on these high-value compounds, as their selling price can guarantee the return on investment and they are bio-based ingredients. Against this background, the EU-project ABACUS was developed. Within this research project, we are assessing the environmental impacts of the technologies applied to produce carotenoids and terpenes by Life Cycle Analysis (LCA) methodology. We investigated the impact of algae cultivation on the LCA results by comparing the three most relevant photobioreactors (PBR) available on the market: the flat panel airlift (FPA), the horizontal tubular unilayer PBR (HTU-PBR) and the green wall panel (GWP). We also started to analyze the downstream processes (harvesting and extraction) and then we studied the influence of the characteristics of the PBR location by carrying out a sensitivity analysis for both indoor and outdoor cultivation in different European regions. Our preliminary LCA results based on data from pilot scale production indicate that location has a significant impact due to different algae productivities and energy demand for lighting, heating and cooling. We found that in particular for indoor systems, the electricity consumption is the main contributor to the GWP and that the related impact would decrease significantly if the share of renewable energy would increase. Moreover, our results indicate, that a crucial issue for assessing the algae technology is that processes at laboratory and pilot scale are not optimized and unfavorable LCA results are due to a poorly designed system. For this reason, we tried to develop together with engineering experts an upscaling methodology applicable for the different cultivation systems. Already with our first LCA results, we could successfully start to exchange ideas and advise our industry partner. We found that the results of our sensitivity analysis helped technology developers to understand to which extent the different stages of the process influence the results and how the environmental impacts could be reduced by changing the system configuration or energy sources. The results are based on the project ABACUS, which receives funding from the Bio-Based Industries Joint Undertaking under the European Union's Horizon 2020 research and innovation program (Grant Agreement N° 745668).

WE119

Use of life cycle assessment in process development of a catalytic fast pyrolysis method for bio-oil production

K. Fransson, K. Wilson, RISE Research Institute of Sweden

To meet future demands of energy from non-fossil sources, biofuels has been pointed out as important. To generate liquid fuels from biomass, fast pyrolysis is one of the most promising technologies. However, the produced pyrolysis oil may have several major drawbacks which suppress its application for power and heat generation or transportation fuels. These are: high oxygen, water and water-soluble (acids) contents which affect negatively the acidity (corrosion effect), miscibility with petroleum-based fuels (separation of fractions), chemical stability (aging), high viscosity and low energy density. In the EnCat project, a new process is developed that will make it possible to use both woody biomass and biomass residues from agriculture for production of bio-oil via pyrolysis. The drawbacks mentioned above will be avoided through a novel biomass pre-treatment step followed by pyrolysis in a reactor making use of deoxygenation catalysts. Simultaneously, CO_2 will be captured with sorbents and hydrogen will be produced. After cleaning, the oil vapours will be mildly hydrogenated to produce a high-quality bio-oil. Life cycle assessment was implemented early in the process development process as a method to identify environmental hotspots. Also, which applications for combustion of bio-oil that might be the most suitable in order to optimize overall environmental effects were identified. It was found that one hotspot was the pre-treatment step and from the LCA results, it was suggested that further process development of the pre-treatment step was focused on chemical and water recovery. Another hotspot of the process was catalyst use. Therefore, an advice for the researchers developing the process was to work on regeneration of the catalyst.

WE120

Integrating future background scenarios for prospective LCA - method and case study on the German energy system

T. Junne, German Aerospace Center / Systems Analysis & Technology Assessment; M. Saiger, LCS Life Cycle Simulation GmbH; J. Buchgeister, S. Simon, German Aerospace Center / Department of Energy Systems Analysis; T. Naegler, German Aerospace Center / Energy Systems Analysis

Highly detailed bottom-up energy system models are often used for evaluating future energy system configurations from an infrastructural and systematic perspective. However, the integration of environmental impacts next to directly emitted CO2 into those models is largely missing. Albeit, it would offer the opportunity to identify highly detailed system configurations that are both cost-efficient and ecologically sustainable from a broader perspective. In order to ensure the holistic assessment of the ecological sustainability of systems, life cycle assessment (LCA) appears to be the most important and appropriate instrument/methodology. While LCA is based traditionally on static life cycle inventory (LCI) models (e.g. based on today's energy mix), we develop a general framework for deriving prospective LCI-based impact coefficients for energy technologies (electricity, heat, synfuels, mobility) from a detailed bottom-up LCI. The framework a) breaks down LCI coefficients into the life cycle phases of construction, operation and decommissioning and thus enables the allocation of environmental impacts construction, operation, and end-of life to the individual model years and b) integrates global background scenarios for power generation into the life cycle assessment of energy system relevant technologies, resulting in strong changes of specific environmental impacts in some impact categories. c) The framework furthermore allows analysing the demand for critical minerals for future energy technologies (not on a life cycle basis). The modelling framework is applied to transformation paths of the German energy system up to 2050. Expected results show that the climate friendly (with respect to direct emissions) transformation of the energy system will result in decreasing environmental impacts in some impact categories (such as human health), but increase environmental impacts in others (such as resource demand, in particular with respect to land use and critical minerals).

WE121

Scaling-up techniques used in prospective life cycle assessment of chemical technologies - a review

N. Tsoy, CML Leiden University / CML; J. Guinee, University of Leiden / Institute of Environmental Sciences CML; B. Steubing,

Life Cycle Assessment (LCA) has been successfully used as a framework for the environmental assessment of mature chemical technologies. However, applying LCA to novel technologies is a challenging task. One challenge is that LCA is performed to assess emerging technologies being developed at the laboratory/pilot scale and these technologies are not yet commercially available. The industrial scale processes differ from those at the laboratory/pilot scale. By having complex equipment and sophisticated features, e.g. heat recovery systems and waste recycling loops, the industrial processes are more efficient than the laboratory/pilot scale processes. The issue is that for the emerging technologies no industrial scale data exists, which is necessary for conventional LCA. In some cases, the lack of industrial scale data is resolved by using scaling-up techniques. Here, we present a review of the scaling-up techniques applied in prospective LCA of the chemical technologies. The aim of the study is to review the scaling-up methods and classify them into groups. Different name variations for LCA of emerging technologies were used as the keywords in the literature search using Web of Science and Scopus academic search engines, e.g. "prospective LCA", "ex-ante LCA", and "anticipatory LCA". The number of the LCA publications relevant to this study was 53. The titles and the abstracts of those works were screened, and 15 prospective LCA studies were selected. Different scaling-up methods were applied in these LCA works, e.g. the use of scenarios based on thermodynamic calculations, proxies from the technologies at the industrial scale and the use of the optimization software, e.g. Aspen. The review work is ongoing, and in the next step the common features of those scaling-up techniques will be identified and then the methods will be classified into groups. The results of this review work could be used by the LCA practitioners aimed to scale-up new chemical technologies in prospective LCA. **Keywords:** review, prospective LCA,

emerging technology, scaling-up, optimisation

WE122

Life Cycle Assessment in support of the benchmarking of metals production techniques: approaches for dealing with multifunctionality and implications for decision-making

F. Lai, F. Laurent, J. Villeneuve, Y. Menard, BRGM / Waste and raw material unit

The demand for metals is expected to follow an exponential increase in the years to come to satisfy an ever-growing market for manufactured goods. In the meantime, the depletion of metals-rich deposits requires to develop new beneficiation and extraction processes in order to recover metals from low-grade/complex ores (e.g., hydrometallurgical processes such as bioleaching). In addition to technical and economic performances, the environmental sustainability of such new techniques must be assessed. For this purpose, Life cycle assessment (LCA) is a widely accepted tool that also allows comparison of different options. Nevertheless, such comparison is not always straightforward, since the recovery of metals from polymetallic ores results in the production of several metals of interest, thus raising multifunctionality issues. The ISO standards describe different allocation criteria/substitution approaches to deal with multifunctionality in LCA, which can lead to significant differences in impact assessment (LCIA) results. The goal of this study is to compare and discuss the different approaches for solving multifunctionality in the context of techniques benchmarking through a LCA case study. Two hydrometallurgical routes have been considered: atmospheric leaching and pressure leaching. The processed materials are two samples from a same bulk concentrate that eventually yield three metallic co-products: copper, zinc and lead. As copper is assumed to be the main metal in this case, the functional unit has been set as “the production of 1 ton of copper”. The system boundaries include the leaching step and the downstream recovery of the three metals. To apportion the environmental burden to the copper (with respect to the functional unit), five multifunctionality-solving scenarios have been implemented in accordance with the ISO 14044: (i) partial subdivision combined with mass allocation; (ii) substitution by system expansion; (iii) mass allocation; (iv) economic allocation and (v) allocation to the main metal (i.e. copper). The discrepancy in LCIA results with respect to the five scenarios confirms that the choice of the allocation/substitution rules implemented affect the LCA conclusions. This should be studied through sensitivity analysis during the life cycle interpretation as it can strongly influence the subsequent decision that is to be supported by the LCA.

WE123

Sustainable concrete through CO2 mineralisation: an environmental analysis of the different available options

A. Di Maria, KU Leuven / MTM; R. Snellings, Flemish Institute for Technological Research VITO / Sustainable Materials Management; L. Alaerts, KU Leuven / Department of Materials Engineering; M. Quaghebeur, Flemish Institute for Technological Research VITO; K. Van Acker, KU Leuven / Materials Engineering

Portland cement (PC) is the most used binder in concrete production, and it is responsible for 8-10% of the global anthropogenic CO_2 emissions. PC is also accountable for 74-81% of the carbon footprint of concrete. Therefore, substantial climate impact reductions for concrete will require eco-innovation at the cement level. Today, one of the most promising technology to reduce PC production is its substitution with industrial by-products. However, by-products availability is rather constrained. Therefore, future sustainable cements must rely on a wider variety of solutions, and the construction sector will have to be more diverse and tailored to local resources, depending on the availability of secondary raw materials from different industrial plants. In this context, mineral carbonation represents a promising option to both mitigate atmospheric greenhouse gas concentrations and to produce sustainable concrete. A suitable class of materials for carbonation are alkaline slags generated as by-products from stainless steel production industry, so-called stainless-steel slags (SSS). The study focuses on the carbon footprint of new concrete made through mineral carbonation of SSS. Three examples of SSS carbonation process are analysed, each using a different source of CO_2: flue gas from the steel industry, in which CO_2 is separated through a cryogenic process biogas from anaerobic digestion, in which CO_2 is separated through membranes waste gas from ammonia production, in which CO_2 is separated through chemical absorption The produced carbonated concrete is equivalent in performance to traditional PC-based, non-reinforced concrete products on the market. By using the life cycle assessment methodology, the study describes the environmental performances of carbonated concretes made using different sources of CO_2 and highlights the environmental hotspots of carbonated concrete compared to traditional PC-based concrete. The carbonated concrete presents lower total CO_2-equivalent emissions compared to the traditional PC-based concrete. Membrane separation of biogas is the technology presenting the lowest CO_2-equivalent emissions. Regardless of the CO_2 source, all considered carbonated concretes serve as CO_2 storage, since the CO_2-equivalent emitted during their production is lower than the CO_2 uptake. Therefore, the environmental results show the potential for the carbonation process to reduce the climate change impact of traditional concrete production.

WE124

Manufacturers' data vs literature data - a comparison of LCI and LCA results for wood-burning residential heating systems

D. Rixrath, Forschung Burgenland GmbH; C. Wartha, University of Applied Science Burgenland; M. Enigl, Bioenergy 2020 GmbH; G. Piringer, University of Applied Sciences Burgenland / Dpt. Energy and Environmental Management

Life Cycle Assessments (LCA) can help companies to improve their products to become more sustainable. The quality of LCA results is critically dependent on the quality of inventory data, but in LCA practice, secondary data sources are often used where primary data would be appropriate. Using the example of biomass heating systems, this study contrasts LCA results from primary data that were directly collected from manufacturers with those obtained from the ecoinvent database as a source of secondary data. Three approaches are compared: 1. Secondary data only: The exclusive use of unchanged ecoinvent data for both combustion and infrastructure manufacturing impacts. 2. Hybrid primary/secondary data: Some combustion emissions and manufacturing inventory from manufacturers’ data; other combustion emissions retained from suitable ecoinvent data sets. 3. Primary data only: no supplemental ecoinvent data are used, only the manufacturers’ infrastructure and emission data. The assessment was done for a log wood stove (8kW_{th} nominal power) and a wood pellet boiler (20kW_{th} nominal power). The idea was to collect as much data from manufacturers as possible on stove and boiler production and for the combustion emissions. Two companies provided bills of materials used in stove and boiler production and some emission measurements during the operation (practice-oriented, realistic test conditions obtained from literature). For secondary data and upstream processes, the ecoinvent database versions 3.4 and 3.5, as integrated in the software GaBi version 8.7, were used. Manufacturers’ primary data was checked for completeness and plausibility. The bill of materials for production of the stove and boiler is detailed and extensive - in both cases, at least 95% of the total weight can be determined. Emissions of CO, NOx and particulates were determined during the operation. Small differences in the LCA results were found between the second and third approach, but both were substantially different from the first approach using exclusively ecoinvent-based data. However, for the log stove, a noticeable difference for GWP and HTP in the operating phase can be attributed to CH_4 and N_2O emissions, while only small differences occurred between the second and the third approach in several other categories (acidification, eutrophication, ozone depletion, and photooxidant formation potentials). In the poster, the differences in results will be further analyzed and discussed.

WE125

Life cycle assessment calculative practices in the Swedish biofuel sector: Governing biofuel sustainability by standards and numbers

M.A. Martin, IVL Sweden Environmental Research Institute / LCA and Environmental Management; D. Lazarevic, SYKE Finnish Environment Institute

Since the introduction of the European Union's Renewable Energy Directive (RED), biofuel-producing firms are required to perform life cycle assessment (LCA) based greenhouse gas accounting in order to fulfill part of directive's sustainability criteria. This study adopts the concepts of “governing by standards” and “governing by numbers” to understand the LCA practices of biofuel-producing firms and assess the critical moments of friction between these alternative modes of governance. We focus our analysis on the use of LCA in the Swedish biofuel industry, undertaking case studies on the use of LCA in four Swedish biofuel-producing firms and semistructured interviews with industry associations and governmental bodies. Results indicated that the RED not only influences what biofuel sustainability entails but also structures the calculative practices used to measure it. At the same time,\nour results point to friction between achieving regulatory compliance and improving biofuel sustainability.

WE126

Sustainability Evaluation for tourism and MICE in Japan focus on tourism type Using Hotspots Analysis

Y. Kitamura, Y. Ichisugi, H. Suzuki, N. Itsubo, Tokyo City University

This study is the first phase development of sustainability evaluation for tourism and MICE (Meeting/ Incentive Travel/ Convention/ Exhibition and Event) in Japan. This time we introduce the study framework and examine the analysis results of priority check using Hotspots Analysis (HSA) based on Life Cycle Assessment(LCA). Tourism and MICE industry is said to have significantly higher growth speed than other industries and expected to have a high economic ripple effect. A recent study pointed out that the global tourism industry has a great negative contribution to climate change. In addition, international targets such as Sustainable Development Goals (SDGs) encompass not only focusing on climate change, but also considering some other topics. Therefore, our opinion is multiple criteria evaluation is needed in this industry. It follows LCA method can evaluate and analyze multiple effects and use assessment based on the Input-Output Tables (I/O). By using the HSA method, it becomes possible to confirm the important sources of environmental Impacts before each event. Here is a summary of our results. Calculations of the environmental impact and CO2 emissions were made to show characteristic of Tourism and MICE in Japan.

Results showed domestic tourism is found to have a large impact on land use, climate change and air pollution. Life Cycle Assessment (LCA) from CO2 emissions shows domestic tourism is the highest contributor. In addition, impact of air transportation and accommodation services is found to be high. Percent impact from souvenirs such as cosmetics and confectionery is also high. Total impact of tourism and MICE showed calculated CO2 emission result is 7.54% of the whole of Japan (2015). This research shows in the future it is possible to make trial calculations easily for each update of the survey data on the amount of consumption provided by the JAPAN TOURISM AGENCY (announcement of the latest year edition). We were able to show the same trend as in a recent study. Our study found not only air transportation and accommodation services, but also cosmetics and confectioneries such as souvenirs were found to contribute to the environmental impact and CO2 emissions in tourism and MICE in Japan. It is necessary to consider ways to reduce environmental burden from transportation as well as accommodation services and souvenirs.Therefore, this study will become part of the foundation for the Japanese tourism and MICE industry to achieve world sustainability.

Environmental Monitoring and Risk Assessment of UV Filters in Aquatic Environments (P)

WE127

Responses of periphyton and benthic macroinvertebrate communities to 4-MBC in stream mesocosms

D. Campos, University of Aveiro / Biology Department and CESAM; A.L. Machado, University of Aveiro / CESAM Department of Biology; D. Nunes Cardoso, CESAM, University of Aveiro / department of Biology & CESAM; A.R. Silva, University of Aveiro / Dept.of Biology & CESAM; P. Silva, Universidade de Aveiro / Biology Department and CESAM; A.C. Rodrigues, Department of Biology & CESAM - University of Aveiro / CESAM & Biology; F. Simao, Aveiro University & CESAM; S. Loureiro, Universidade de Aveiro / Biology; K. Grabicova, University of South Bohemia in CB / Faculty of Fisheries and Protection of Waters, South Bohemian Research Center of Aquaculture and Biodiversity of Hydrocenoses; P. Nováková, University of South Bohemia in Ceske Budejovice / Faculty of Fisheries and Protection of Waters; A.M. Soares, University of Aveiro / department of Biology & CESAM; J. Pestana, CESAM & University of Aveiro / Biology

Concerns about the effects of ultraviolet radiation (UV radiation) in human health have lead to the increased use of personal care products containing Ultraviolet-filters (UV-filters). These compounds are frequently detected in aquatic ecosystems worldwide at concentrations reaching up to 2.4 mg/Kg (dry weight) in freshwater sediments. Thus, it is expected that benthic macroinvertebrate communities and phytobenthos, especially those living in areas with high human pressure, are being negatively affected by exposure to these contaminants. The aim of the present study was to assess the ecological effects of 3-(4-methylbenzylidene) camphor (4-MBC), frequently detected in European aquatic environments. For that, indoor artificial streams were used, where a natural benthic invertebrate community was exposed to sediments contaminated with 4-MBC. Effects were evaluated regarding macroinvertebrate abundance, as well as leaf decomposition and primary production. Results show that the macroinvertebrates community and leaf decomposition rates were not affected by 4-MBC exposure, but strong reductions in primary production were observed. This study highlights the importance of higher tier ecotoxicity experiments to assess ecological effects of low concentrations of organic UV-filters within freshwaters.

WE128

Organic UV filters in the Mondego River, Portugal

C. Apel, Helmholtz-Zentrum Geesthacht; C.P. Bento, Helmholtz-Zentrum Geesthacht / Department for Environmental Chemistry; C.S. Ferreira, Escola Superior Agrária de Coimbra; R. Ebinghaus, Helmholtz-Zentrum Geesthacht / Department for Environmental Chemistry

Organic UV filters are of emerging concern due to their potential adverse effects on ecosystems and the human health. They are used as ingredients in personal care products (PCPs) such as body creams, facial make-up and sunscreens to protect the human skin against UV radiation. Furthermore, UV filters are widely used in industrial products such as plastics, paints, and textiles to improve the photo protective properties. UV filters may enter the aquatic environment directly through recreational activities or indirectly through wastewater treatment plant (WWTP) discharges. Their presence has been shown in different environmental matrices (e.g., sediments, biota, freshwater, marine water), revealing their potential for persistence or pseudo-persistence. This study investigates the occurrence of organic UV filters in the Mondego River, which is the largest entirely Portuguese River (258 km length) located in central Portugal. The Mondego River is subject to discharges from several WWTPs. It is also used for recreational purposes due to several fluvial beaches, particularly during spring and summer time. In September 2018, water and sediment samples were collected at 20 stations along the final 60 km of the river, from Penacova until Figueira da Foz, where it enters the Atlantic Ocean. The samples were analyzed for 26 UV protecting compounds. The water samples were enriched and eluted using an automated solid-phase extraction (Freestyle Xana, LCTech, Germany) method. The freeze-dried sediment samples were extracted using an accelerated solvent extractor (ASE-350, DIONEX, Germany) method. The instrumental analysis was performed on an Agilent UHPLC-MS/MS system operating with dopant-assisted atmospheric pressure photoionization (DA-APPI). This study shows the occurrence of UV filters in the Mondego River for the first time. In the water phase, the widely used compound octocrylene (OC) and the hydrophilic substances Benzophenone-4 and 2-Phenylbenzimidazole-5-sulfonic acid (PBSA) were dominant and found in concentrations up to 270 ng/L, 220 ng/L, and 90 ng/L, respectively. In the sediment, mainly hydrophobic substances were identified at concentrations in the low ng/g dw range. UV filters enter the Mondego River through several input pathways. This reflects their disperse uses in PCPs and industrial products.

WE129

Benzotriazole UV Stabilizers in Urban Rivers - Behaviour During Storm Run-Off and Source Identification

A. Parajulee, University of Toronto / Department of Physical and Environmental Sciences; Y. Lei, University of Toronto / Physical and Environmental Sciences; B. Awonaike, University of Toronto, Scarborough / Physical and Environmental Science; C. Mitchell, University of Toronto, Scarborough / Physical & Environmental Sciences; F. Wania, University of Toronto, Scarborough / Physical and Environmental Sciences

Benzotriazole ultraviolet stabilizers (BT-UVs) are a sub-group of benzotriazoles with 2-hydroxyphenol attachments and various alkyl substituents on the phenol ring. Because their structures impart broad spectrum UV resistance, they find use in the prevention of UV-induced discoloration and deterioration of a range of materials. Whereas BT-UVs have previously been detected in rivers and sediments, their dynamic behaviour during storm runoff events in urban streams is poorly understood. We measured BT-UVs in (i) suspended sediments during two rainfall events in the highly urbanized Mimico River watershed in Toronto, Canada, (ii) plastic debris collected from the watershed and (iii) in pre-production plastic pellets. The concentrations of BT-UVs in suspended solids from Mimico Creek were the highest ever reported in the peer-reviewed literature for this type of sample. In particular, the contamination is considerably higher than what has been reported for major rivers in Germany and highly polluted waters in Japan. Based on the widespread use of BT-UVs in sunscreens and as polymer additives imparting resistance to UV-induced ageing and degradation of plastics, we are exploring different potential sources of BT-UVs to Mimico Creek. The highly urbanized nature of the Mimico Creek watershed results in an unusually high amount of plastic waste within and close to the stream.Several items of plastic debris from the watershed showed high concentrations of UV238 (pylon, golf balls) and UV234 (artificial turf). Such items contain BT-UVs as additives and are likely sources of BT-UVs to Mimico. All other plastics collected from the watershed (plastic bags, food and beverage containers, etc.) and all of the pre-production plastic and fibrescontained negligible amounts of BT-UVs. Most previous investigations into the transport and fate of BT-UVs have focussed on industrial and domestic wastewaters as key sources of BT-UVs. We demonstrate that BT-UV contamination can be comparable, if not greater in streams that are not directly affected by such wastewater streams. When combined with the wide range of BT-UV levels measured in plastic products, it appears that informal disposal of selected products containing BT-UVs plays a prominent role in BT-UV cycling in highly urban rivers.

WE130

Are sunscreens the solution for UV radiation deleterious effect for human and the problem for the environment?

S. Diaz-Cruz, IDAEA-CSIC / Environmental Chemistry

Personal beauty and hygiene products market is an expanding and increasingly diverse market. Product categories include skin, dental, hair and nail care products, cosmetics, fragrances, bathing and shaving creams, among others. Sun protection is the most important segment of the sun care market with expenditure of 7.0 billion € in 2014, and EU countries accounts for 32 % of the world market [1]. Many ingredients of these products are considered as pseudo-persistent contaminants of emerging concern (CEC), as a consequence of their wide use and release into the environment and a deficient elimination in wastewater treatments. However, there is a lack of regulation regarding their occurrence in the environment. Major components of sun care products are organic and inorganic sunscreens (also known as UV filters). The organic substances have radiation absorption capability in the range 320-400 nm (UVA) and 280-320 nm (UVB), whereas inorganic sunscreens reflect and scatter the sunlight. In order to protect in this wide radiation region, more than one sunscreen are included in the products. Previous studies have reported not only the occurrence of sunscreens in the environmental compartments (water, sediments and biota), but also show that sunscreen agents are toxic for aquatic biota and are accumulated and biomagnified [2]. Many organic sunscreens, as well as TiO_2 at nanosized scale are endocrine disruptors to humans and wildlife, being toxic to corals, fish and other reef organisms. Beside this knowledge, the ecotoxicity effects that many sunscreens and their transformation products may display in short and long terms are mostly unknown. Moreover, despite these evidences a lack of inquiry into their toxicities, lack of occurrence data, and even in some cases lack of reliable analytical methods prevent accurately assess whether they pose a real and present danger to these habitats [3]. In this presentation main occurrence (water, sediments, fish, dolphins, seafood, bird eggs,…), toxicity and risk assessment studies within our research group will be shown to provide a wide and up to date picture of current knowledge and potential threat posed to the environment in relation to sunscreen agents.

WE131
Environmental Risk Assessment of UV filters in Freshwater and Marine Environments: State of Science and Challenges
I. Davies, Personal Care Products Council / Science
UV filters are ingredients in personal care products that protect consumers against the\nadverse effects of UV radiation. UV filters are also used as photoprotective agents in other products, such as\nplastic and apparel items. Organic UV filters have diverse chemistries and moieties. Inorganic UV filters are\nmetallic and can be nanoscale or non-nanoscale. UV filters such as benzophenones share chemistries with\nnaturally occurring compounds. For example, oxybenzone is a natural compound produced by higher plants. It\nis crucial to appreciate these various chemistries and sources when assessing environmental fate and effects of\nUV filters. \n\n Environmental exposure to UV filters occurs via point and diffuse pathways. Point exposure\noccurs when UV filters wash-off bathers. This includes exposure to coastal sediment when, for example,\naerosolized UV filters are applied to people on a beach. Diffuse exposure occurs when UV filters are washedoff\ndown the drain and enter the waste water system. UV filters have been detected at low ng/L to µg/L levels;\nmainly in the marine environment. However, more monitoring studies are needed before a clear picture of\nexposure can be painted; the first step in an environmental risk assessment. \n\n When UV filters enter the\naquatic or marine environment they are subject to various fate and transport mechanisms. Very little is known\nabout these mechanisms, yet such data are essential to understand the concentration and timing of potential\nexposure of organisms to UV filters and/or their metabolites/degradation products. Further fate and transport\nresearch is therefore required to establish partitioning of UV filters between water and organic phases, biotic\nand abiotic degradation pathways and bioaccumulation of these materials. In addition to the limited amount of\ndata regarding the concentration of UV filters in the environment, very few ecotoxicological data are available\nto assess whether UV filters are hazardous at environmentally relevant concentrations. Although some\nlaboratory ecotoxicological studies have been conducted for a handful of UV filters, many questions remain\nover the extrapolation of these studies to the environment. Overall, huge data gaps exist for UV filters with\nregard to exposure and toxicological hazards, including endocrine activity. More research is therefore required\nto fill these data gaps and establish the risk these materials pose to organisms residing in the marine and aquatic\nenvironment.

Recent Approaches in Establishing Linkages between Exposure Science and the Environmental Effects of Trace Organic Contaminants (P)

WE132
Environmental fate and behaviour of a Tribenuron methyl metabolite in different types of soil, and its influence on soil fauna
A. Godziek-Botor, Institute of Industrial Organic Chemistry Branch Pszczyna / Department of Ecotoxicological Studies; W.K. Winiarska, Institute of Industrial Organic Chemistry / Department of Ecotoxicological Studies; A. Żmijowska, M. Wójcik, W. Dec, Institute of Industrial Organic Chemistry Branch Pszczyna / Department of Ecotoxicological Studies; A. Wróbel, Institute of Industrial Organic Chemistry Branch Pszczyna
Yearly 2.6 mln metric tons of pesticides contaminate the environment. Most of them, i.e. 85%, are used in agriculture and get into the soil. There is no doubt that pesticides play an essential role in maintaining high levels of food production, but on the other hand, they affect soil fauna and many biological processes involving it. Hence, it is extremely important to determine the dynamics of pesticide degradation in the soil and the impact of pesticides and their metabolites on soil fauna. For this study a tribenuron methyl metabolite whis was a representative of pesticides belonging to the sulfonylurea group, was selected. This group of pesticides commonly occurs in various herbicides commercially available in Poland. Sulfonylurea herbicides are largely employed for the control of many grasses and broad-leaved weed species in crop protection of vines, rice, citrus, corn, potatoes, and tomatoes. The aims of this study were to (i) determine the rate of degradation of the tribenuron methyl metabolite in three types of soils commonly found in Europe; (ii) assess the adsorption and desorption behaviour of the tribenuron methyl metabolite on five different soil types; (iii) determine the K_d, K_{oc}, K_{Fads}, and K_{des}; (iv) determine the influence of the selected pesticide metabolite on the reproduction of the predatory mite Hypoaspis (*Geolaelaps*) aculeifer, the earthworm *Eisenia andrei*, and the collembolan *Folsomia candida*. The obtained results, showned that the dynamics of degradation of the investigated metabolite of tribenuron methyl depended on the soil pH level, which was also confirmed in reproduction tests when artificial soils were used. The presented study provided diverse data on the toxicity to the predatory mite, Hypoaspis (*Geolaelaps*) aculeifer, the earthworms *Eisenia andrei*, and the collembolan *Folsomia candida.* Also it proved that these tests should be an element of the routine ecotoxicity testing.

WE133
Can shell alterations in limpets be used as alternative biomarkers of coastal contamination?
I.B. de Castro, Universidade Federal de São Paulo / Instituto do Mar; N.G. dos Santos, Universidade Federal de São Paulo
The assessment of levels and impacts related to inputs of hazardous chemicals in coastal areas is an important way for implement protective measures for aquatic environments. In this regard, mollusks are widely used to assess environmental contamination and ecotoxicity. Furthermore, recent studies proposed morphometric alterations in mollusk shells as good proxies for assessing adverse biological effects of chemical contamination in multi-impacted coastal zones. The present study evaluated the association among traditional biochemical biomarkers with biometric, morphometric, and elemental composition of *Lottia subrugosa* shells from three multi-impacted coastal areas in Brazil. The study was carried out in Todos os Santos Bay (BTS), Santos/São Vicente Estuarine System (SESS) and Paranaguá Estuarine Complex (CEP), using three sampling sites to seek contamination gradients in each area. Results showed that all biomarkers evaluated responded to environmental contamination, regardless the presence (SESS and CEP) or absence (BTS) of a gradient of contamination. In fact, the response found by the new proposed biomarkers (biometric and morphometric parameters) are consistent to the traditional biomarkers of exposure and effects (lipid peroxidation and DNA damage). Indeed, changes in elemental composition of *L. subrugosa* shells suggest that exposure to contaminated environments is probably responsible for the alterations detected. Due to the simplicity and lower cost of biometric and morphometric analyzes, these parameters seem to be a promising tool for future assessments, especially in areas where technological resources are scarce. The findings from the present study were observed in three aquatic systems distributed over a wide range of latitudes, which strongly indicates that gastropod shells reflect effects resulting from environmental contamination.

WE134
Toxicokinetic parameters causing the discrepancy between the measured and predicted bioconcentration factors of pharmaceuticals and personal care products in fish.
R. Tanoue, K. Nakayama, Ehime University; M. Kondo, National Fisheries University; K. Nomiyama, Ehime University; T. Kunisue, S. Tanabe, Ehime University / Center for Marine Environmental Studies
Bioconcentration of organic compounds is generally considered as the partition between water and the organism's lipid phases, and thus lipophilicity of chemicals can be the critical factor. Nevertheless, our previous field-monitoring studies on pharmaceuticals and personal care products (PPCPs) in fish showed that the bioaccumulation factors of some PPCPs largely differed from bioconcentration factors predicted on the basis of their lipophilicity ($BCF_{predicted}$). In the present study, we determined the uptake and depuration kinetics of 95 PPCPs in common carp (*Cyprinus carpio*), Nile tilapia (*Oreochromis niloticus*), and Japanese medaka (*Oryzias latipes*), to examine the factors causing the discrepancy between the $BCF_{predicted}$ and the bioconcentration factors calculated from the measured PPCP concentrations in the water and fish ($BCF_{measured}$). Assuming a worst-case and multiple-exposure scenario, fish were exposed to treated municipal wastewater for 8 days followed by clean water for 14 days. Uptake (k_1) and depuration (k_2) rate constants were successfully determined for 22 compounds. When comparing $BCF_{measured}$ in the three fish species with the $BCF_{predicted}$, similar values were observed for more than 40% of these 22 compounds. On the other hand, $BCF_{measured}$ were 2−4 orders of magnitude lower than the $BCF_{predicted}$ for telmisartan, rebamipide, fexofenadine, and triclocarban in all the fish species. This was likely due to rapid metabolism and excretion of these PPCPs, as the calculated half-lives were < 5h. In contrast, approximately 20 times higher $BCF_{measured}$ than the $BCF_{predicted}$ were observed for haloperidol in medaka, which can be explained by a fast uptake rate (k_1, 510/day) and slow depuration rate (k_2, 0.19/day). Similarly, fast uptake rate (k_1, 44/day) and slow depuration rate (k_2, 0.21/day) of chlorpheniramine in tilapia plasma resulted in approximately 10 times higher $BCF_{measured}$ values than the $BCF_{predicted}$. The k_1 values of the two compounds were relatively high compared with other compounds regardless of fish species, implying a specific partition to non-lipid components. To develop BCF prediction models in fish, possible factors affecting the k_1 and k_2 of chemicals, e.g., partitioning to non-lipid components and hepatic clearance, should be quantified and applied. Our results highlight the importance of understanding toxicokinetics of PPCPs in fish for the full implementation of predictive toxicology approaches.

WE135
Biological activities of antidepressants in wastewater to fish monoamine

transporters
M. Ihara, M.O. Ihara, D. Kato, H. ZHANG, H. Tanaka, Kyoto University
Over recent years, growing numbers of human pharmaceuticals have been detected in effluents of wastewater treatment plants (WWTPs) and river water. Antidepressants are one of most commonly detected human pharmaceuticals, and concern about their potential risks to aquatic species has been raised. It is possible to measure the concentrations of selected antidepressants by chemical analysis, but such concentrations do not indicate the biological activity of the antidepressants in waters. To determine whether antidepressants in aquatic environments alter the behaviour of aquatic organisms, we must know the extent to which such organisms may be exposed to antidepressants as determined by the antidepressants' mode of action. So far, we have succeeded to detect biological activities of antidepressant in wastewater against human transporter (e.g., serotonin transporter (SERT)) by using the newl developped in vitro assay, antidepressant assay. However, until now biological activity of antidepressants in wastewater against fish has not been investigated. In this study, we aimed 1) to investigate whether human antidepressant can inhibit medaka (*Oryzias latipes*) and zebrafish (*Danio rerio*) SERT by in vitro antidepressant assay, and 2) to measure the biological activity of antidepressants in WWTP effluents against fish SERT. We constructed plasmids which express medaka and zebrafish SERT, respectively. At first, we confirmed that antidepressants can inhibit not only human but also fish SERT. Interestingly, both medaka and zebrafish SERTs were strongly inhibited by antidepressant compared to human SERT. Next, we applied the in vitro antidepressant assay to WWTP effluent extracts. All wastewater extracts showed reduction of APP uptake for not only human but also fish SERT. Interestingly, medaka and zebrafish SERT were more strongly inhibited compared to human SERT. When activities detected in wastewater extracts were quantified as fluoxetine-EQ, which ranged from 500 to 1,000 ng-fluoxetine-EQ/L for human SERT, 1,000 to 2,000 for medaka SERT, and 800 to 1,100 for zebrafish SERT. These results indicate that at least molecular level, fish might be more seriously affected by antidepressants in water environment than human. When we discuss risks of antidepressants in environmental water to aquatic species, species differencies should be considered. In vitro antidepressant assay using fish SERT shown in this study is potentially useful tool to predict risk for fish. \n

WE136
Impact of water management on arsenic and cadmium accumulation by rice (Oryza sativa L.)
M. Hidalgo, M. Iglesias, University of Girona / Department of Chemistry; F. Camps, Mas Badia Foundation Field Station-IRTA
The accumulation of As in rice is a public health concern since As is toxic to humans; in particular, inorganic As can cause many chronic diseases including cancer. Rice crops are prone to accumulating As, in part, due to the anaerobic soil conditions triggered by the traditional continuously flooded irrigation practice. It is also known that As accumulation in rice grains differs with the rice variety. In addition to arsenic, crops can also take up cadmium, which also presents high toxicity to humans. However, unlike As, the lowest concentrations of Cd are found in rice grown by flooding, but information, particularly on irrigation, is scarce on a field scale. The aim of the present study was therefore to investigate the impact of different irrigation practices on the accumulation of Cd and As in several rice cultivars. Eight rice *(Oryza sativa L.)* varieties were employed in field experiments with four water management regimes comprising flooded, intermittent flooding, localized or drip irrigation and saturation irrigation. Total As and Cd concentrations were determined in rice grain and soil. Additionally, in some samples, roots and straw were analyzed at maturity stages of crops growth. Our results confirm that total As concentrations in brown rice grains are higher than in white rice grains, with average values of 284 $\mu g.kg^{-1}$ and 167 $\mu g.kg^{-1}$ respectively. Our results also confirm that the adoption of less reducing conditions in the soil during the rice growth causes the reduction of the total As amount in rice grains. This effect appears to be small when changing to continuous flooding to saturation irrigation (average total As values of 312 $\mu g.kg^{-1}$ vs 224 $\mu g.kg^{-1}$) but becomes more significant when traditional irrigation was replaced by intermittent flooding or drip irrigation (mean total As concentrations were 163.6 $\mu g.kg^{-1}$ and 68.38 $\mu g.kg^{-1}$ respectively). Regarding Cd content in rice grains, average concentrations ranged from 6 $\mu g.kg^{-1}$ (continuous flooding) to 30 $\mu g.kg^{-1}$ (drip irrigation).

Adverse Effects of Chemicals on Host-associated and Free-living Microbiomes (P)

Diethylhexyl Phthalate Causes Alterations in Host and Microbial Nutrient Metabolisms: A Potential Obesogenic Mechanism
A. Buerger, University of Florida / Environmental and Global Health; D.T. Dillon, University of Florida / Department of Anthropology; O. Adamovsky, Masaryk University / Research centre for toxic compounds in the environment RECETOX; C.J. Martyniuk, University of Florida / Physiological Sciences; J. Bisesi, University of Florida / Environmental and Global Health
The unprecedented rise in obesity prevalence over the last 50 years cannot be explained by poor diet and lack of exercise alone. Recent evidence suggests that ubiquitous environmental chemical contaminants, such as plasticizers, may contribute to the epidemic. Chemicals suspected to influence obesity are known as obesogens. Phthalate plasticizers have been implicated as obesogens, however, mechanisms by which phthalates contribute to obesity are unclear. Because the gastrointestinal (GI) system is the most frequent site of phthalate exposure, the effects of phthalates on the GI microbiome in conjunction with alterations in host molecular changes may contribute to the development of obesity. While evidence for phthalate exposure in the absence of other stressors is inconclusive, mounting evidence suggests co-exposure to phthalates and overfeeding may exacerbate obesity compared to overfeeding alone. Thus, we hypothesize dietary diethylhexyl phthalate (DEHP) exposure, in addition to overfeeding, results in microbial dysbiosis, which modulates obesity in combination with alterations in host metabolic processes. *Danio rerio* were assigned to a normal feeding regime, overfeeding, or overfeeding with DEHP exposure for 60 days to study the exacerbation of obesity by DEHP exposure. Following euthanasia, gut and fecal matter were excised for RNA and 16S microbial sequencing, respectively. Processes related to lipid metabolism and immune function were significantly altered in the overfed + DEHP group compared to both control and overfed. Additionally, the co-exposure of overfeeding and DEHP resulted in alterations in microbial β diversity, increases in Bacteriodes, and decreases in Fusobacteria and Tenericutes compared to control and overfeeding. Additionally, co-occurrence network analysis of 16S data revealed decreases in cluster size and fracturing of the network into unconnected components compared to DEHP-free treatment. Functional analysis of microbial sequences with PICRUSt revealed alterations in various processes related to lipid and carbohydrate metabolism, paralleling the changes observed in the host metabolism. These data reveal DEHP exposure intensifies metabolic changes in the host and microbiome compared to overfeeding alone, which may ultimately result in exacerbated obesity.

WE138
Do nano-biomaterials designed for drug delivery affects soil microflora?
K. Hund-Rinke, Fraunhofer IME / Ecotoxicology; K. Schlich, Fraunhofer IME - Institute for Molecular Biology and Applied Ecology
A biomaterial (BM) is defined as any material that has been designed to interact with biological systems for a medical purpose. Conventional BM are well regulated, however existing guidelines need to be extended to address specific nano related concerns. In the EU-project BIORIMA we investigated the ecotoxicity with a focus on soil microflora. NBMs (nanobiomaterials) excreted by treated patients can via sewage get into wastewater treatment plants and via sewage sludge applied as fertilizer to soil and soil microflora. Several materials designed for targeted drug delivery were tested on the potential ammonium oxidation activity (first step of nitrification) which proved to be a very sensitive test system for conventional nanomaterials. Additionally, the effect on basal and substrate induced respiration with two test systems was investigated. Due to the high number of various NMs a reduced testing effort is essential. The MicroResp™ test system for measuring microbial respiration, could be an alternative test system to conventional test devices. So far, it has not been used to study effects on soil microbial processes in a regulatory context, but EFSA (2017) recommends that its capacity in that respect is determined. We compared the results of a conventional approach (Sapromat; online measurement of microbial activity requiring soil amounts of at least 100 g soil dry matter per replicate) with the miniaturized approach (only two measurement times: start, end; about 300 mg soil per replicate). Conclusions: 1. Due to biological variability the investigation of several concentrations and several time points are necessary for an assessment of NBM on soil microflora. 2. For dispersed materials, the additional investigation of the pure dispersant is required. 3. An ecotoxicological effect of NBM cannot be excluded – however presumably only at high concentrations and thus does not have any environmental relevance; 4. To understand the changes in the soil microbial community, both microbial activities (respiration, nitrification) have to be considered. Depending on the activity, stimulation and inhibition can be detected for the same NBM in the different test systems. 5. There are obvious differences in the respiration results between the two test systems and these need to be studied in future research. This project has received funding from the European Union's Horizon 2020 research and innovation programme under grant agreement No 760928.

WE139
Effects of a biopesticide produced by Artemisia absinthium on metabolic diversity of soil bacterias
M. Pino, San Jorge University / Facultad ciencias de la salud; J. Val, D. Ballestero, Universidad San Jorge; E. Navarro, CSIC - Spanish National Research Council / IPE; E. Sánchez, Colegio internacional Anfora; A. González-Coloma, CSIC Spanish National Research Council / Instituto de Ciencias Agrarias; A.M. Mainar, Universidad de Zaragoza
Biopesticides are increasingly used to replace synthetic pesticides in pest control and those of plant origin have shown numerous advantages over conventional pesticides. However, very few studies analyze in detail the effects that these biopesticides can cause to the environment, especially on non-target organisms. This study focused on the aqueous extract (hydrolate) of *Artemisia absinthium. So*

far, hydrolates have been considered a mere by-product of the process of obtaining essential oils, but now their biological properties are generating attention because they can become a sustainable source of new biopesticides. Hydrolate of *Artemisia absinthium* showed recently nematicide properties. *A. absinthium hydrolate* effects were tested on a natural soil microbial community whose taxonomy was analyzed through 16S rRNA Gene Sequencing. The physiology of the community was only slightly modified, namely through an increased ability to degrade substrates, except amines and amides that have a mild decrease. These effects are more markedly only at 100% concentration. These results allow for a better understanding of the impacts of biopesticides in the soil environment as a pest management alternative. *The authors thank the financial support of MINECO-FEDER (CTQ2015-64049-C3-2-R), Gobierno de Aragón-FSE (GATHERS E39_17R). We thank J. Burillo and J. Navarro-Rocha for his generous cession of the extracts used in this study.*

Effects of ingestion of Cu- and Ag nanoparticles on endogenous microbiota and gut physiology in rainbow trout

N. Brande-Lavridsen, Heriot Watt University / Institute for Life and Earth sciences; T. Vishnivetskaya, University of Tennessee / Department of Microbiology; R.J. Strange, University of Tennessee / Department of forestry, wildlife and fisheries; D.E. Williams, University of Tennessee / Center for Environmental Biotechnology; R. Von Balen, University of Tennessee; T. Henry, Heriot-Watt University / The School of Energy, Geoscience, Infrastructure and Society

Nanotechnology is rapidly developing exploiting the unique properties the nanoparticles (NPs) display. Some NPs, such as Silver- and Copper-NPs display antimicrobial properties and this ability to kill or impede the growth of pathogenic bacteria is important in products like medicine and personal care products. Production and incorporation of these NPs into consumer products will ultimately lead to release into the environment and may lead to unintended exposure to organisms. A likely route of exposure is by ingestion where they may affect beneficial/protective bacteria in the digestive system, and lead to immunosuppression and potential negative health effects. We investigated the effects of manufactured Ag- and Cu-NPs (and their ionic bulk) (50, 500 and 2000 mg/kg food), in a dietary experiment, on the microbiome of rainbow trout (*Oncorhynchus mykiss*) and aimed at linking changes in the composition to the health of the fish with respect to direct damage to the intestinal epithelium and changes in gene expression in the gut tissue, with special emphasis on immunological response. Data from the exposures is still being analyzed. The information obtained from this study provide knowledge of host-microbiome interactions in fish; information that is useful for determining the effects of NPs on environmental health and subsequent risk assessment.

WE141

Effects of Microcystis aeruginosa cultures on the composition and functions of the gut microbiota in the medaka fish (Oryzias latipes)

A. Gallet, Muséum National dHistoire Naturelle; H. Huet, ENVA; C. Duval, B. MARIE, S. Duperron, Muséum National dHistoire Naturelle / UMR7245 MCAM

Over the past few years, host-microbial associations are intensively studied to better understand and grasp mutual involvements in their relationship. Many investigations highlighted diverse effects of environmental stressors on microbial communities of organisms, notably in ecotoxicology studies. Due to global changes and eutrophication, cyanobacterial blooms producing bioactive metabolites start to be increasingly frequent, abundant and persistent worldwide occuring mainly in freshwaters. So far, researchers focused their work, among others, on cyanotoxin effects on aquatic fish physiology. To our knowledge, no research has analysed bloom-forming cyanobacteria effects on fish microbiota yet. In this study, we investigate potential effects under a wide range of concentrations from a culture of clonal strain of *Microcystis aeruginosa*, the most observed cyanobacteria in freshwaters and producing a large set of bioactive components, on the composition of the fish gut microbiota. To this end, the freshwater model fish, the medaka *Oryzias latipes*, is exposed through microcosm and mesocosm approaches. A comparative analysis of 16S rRNA gene sequences and associated functions are performed to examine gut microbial communities and functionnalities in each individual at given concentration, besides histopathological examinations to assess hepatotoxic effects.

WE142

Impact of a contaminated environment on the microbiome of Mauremys leprosa, an endemic freshwater turtle of the Mediterranean basin

L. Grecias, R. Forné, CEFREM UMR CNRSUPVD; M. Noyer, O. Verneau, C. Palacios, CEFREM UMR 5110 CNRS-UPVD

Located at the interface between the host and its environment, the microbiota influences many processes in its host. Thus the assemblage host-microbiota, called holobiont, seems to be essential in the response of organisms to environmental changes. However, in a context of global change, variations in physicochemical factors are often privileged over ecotoxicological research. Particularly scarce are studies concerning host microbial communities in disturbed ecosystems. As part of our study, we focused on the impact of wastewater treatment plant (WWTP) effluents on the cloacal microbiota of the Mediterranean pond turtle, *Mauremys leprosa*. The core microbiome of this species, independently of turtle's location, was mainly composed of bacteria of the Deinococcaceae, a family known to be tolerant to multiple stressors. Moreover, a significant difference in the composition of the microbiota from individuals located at both sides of the WWTP was observed. The WWTP discharges had a negative impact on the bacteria diversity, notably by lowering the equitability. The composition of communities was also affected, both in their abundance and in the identity of the taxa observed. In particular, female turtles were more impacted by the WWTP than males, with a downstream microbiota highly populated by fecal bacteria of the Enterobacteriaceae. The results obtained concerning the microbiota of the Mediterranean pond turtle, the relative sensitivity of this species to pollution - which has been demonstrated from a ROS (Reactive Oxygen Species) study - as well as its ubiquitous presence in the Mediterranean basin, make of this species a new holobiont model to assess water quality in this region.

WE143

Investigation of antimicrobial activities of sodium and zinc pyrithione against microorganisms in water systems and assessment of their cytotoxicity by confocal and transmission electron microscopy

G. Akca, Gazi University / Department of Medical Microbiology; C. Vejselova Sezer, H.M. Kutlu, Eskişehir Technical University / Department of Biology; F. Erkoç, Gazi University / Department of Biology Education

Sodium omadine (sodium pyrithione, NaPT) and zinc omadine (zinc pyrithione, ZnPT) are biocides in the ecosystem with the risk of damaging mainly invertebrates such as algae, fungi, mollusks, macro fouler groups like plants and other living forms. NaPT have been using as inhibitors to control the growth and settlement of microbes, higher plant and animal species, especially on the underwater surfaces. ZnPT have been using for being an antifouling biocide as well as in the pharmaceutical applications such as antidandruff effect, seborrheic dermatitis**.** The aim of this study was to evaluate the antimicrobial efficacy of NaPT and ZnPT against various microorganismsin the environmental water systems by using disk diffusion methodto prevent its ecotoxicity. The cytotoxicity of the agents by MTT assay on NIH/3T3 (ATCC® CRL-1658™),the cell proliferation were evaluated and the viability percentages were calculated. For morphological changes, after the application of IC_{50}values of NaPT and ZnPT, all samples were stained and imaged under Confocal microscope and the changes in the cell's morphology were assessed. Changes in the ultrastructure of NIH/3T3 cells exposed to IC_{50}values of NaPT and ZnPT for 24 hours were evaluated by transmission electron microscopy (TEM). Statistical comparison of the samples was carried out by one-way analysis of variance for multiple comparisons using GraphPad Prism 7.0 for Windows. All biocides showed antimicrobial activity against all of the strains. The bactericidal effect of NaPT and ZnPT was reduced in direct proportion to the decrease in concentrations and all concentrations. NaPT was found more effective on *E. coli*than other microorganisms.All concentrations of ZnPT showed more antimicrobial effect on *Candida albicans* than other bacterial strains. 1,25% concentration of ZnPT showed the highest antimicrobial effect to all strains.In NIH/3T3 cells exposed to NaPT and ZnPT the cytoskeleton was damaged namely perforated possibly because of the fragmentation of cytoskeletal elements induced by the applied IC_{50}values of the agents. Results of TEM analyses indicated that the ultrastructure of the NaPT and ZnPT treated cells was altered. Microscopy results revealed the cytotoxic activity of NaPT and ZnPT on NIH/3T3 cells implying to induced cell death mechanisms, but the mode of action and the type of the cell death need to be further cleared.

WE144

Mixture toxicity of three NSAIDs and pharmaceutical wastewaters using Daphnia magna and a luminescent bacterium

I. Lee, A. Jo, I. Lee, J. Choi, T. Kim, M. Kim, K. Zoh, Seoul National University; K. Choi, Seoul National University / School of Public Health

Pharmaceutical residues in water may cause serious ecological consequences. While pharmaceuticals in aquatic environment exist in mixture, their interactions and ecotoxicity are not well-characterized. Pharmaceutical industries and hospitals are among the major sources of release of pharmaceuticals to ambient environment. In the present study, three frequently used non-steroidal anti-inflammatory drugs (NSAIDs), i.e., diclofenac (DIF), ibuprofen (IBP), and naproxen (NPX), were chosen and their toxicities in mixture were evaluated. In addition, influent and effluent of wastewater treatment plants of two university hospitals in Korea were chosen. To determine ecotoxicity, a standard acute 48 hr *Daphnia magna* test and Microtox assay using *Allivibrio fischerii* were used. In addition, the heartbeat of *D. magna* measured following 1 hr exposure was also used as an observation endpoint. For each NSAID, a range of concentration (3, 10, 30, 100, and 300 mg/L) was tested. For mixture study, mixture ratios of DIF, IBP, and NPX were determined based on the ratio of each NSAID detected in the hospital wastewater. For the *D. magna* 1 hr heartbeat assay, 7-10 days old *D. magna*were exposed to a series of dilutions of test solutions in the 96-well plates. After 48 hr exposure to three subsets, immobility of *D. magna* was increased in a dose-dependent manner. In the *D. magna* heart rate test, NPX showed a decreased trend, while DIF and IBP showed an increased trend. After the exposure to NSAIDs mixture, heartbeat rate of *D. magna* was dose-dependently increased, but

that of wastewater was decreased. Decreased trends were observed in all Microtox tests. Due to similar modes of action of NSAIDs, predicted toxicities of the pharmaceutical mixture estimated based on concentration addition (CA) assumption showed similar levels of those measured directly from the mixture. Interestingly, one pharmaceutical wastewater sample among two collected samples showed greater toxicity in the effluent than the influent. Greater toxicity of the effluent can be partly explained by the effects of disinfection by-products and residual chemicals from the wastewater treatment processes. Ecotoxicity of pharmaceutical mixture dominated by NSAIDs appears to be reasonably estimated by concentration addition approach.

WE145
Novel ecotoxicology method based on metaproteomic analysis on soil
V. Lizano-Fallas, Linköping University; S. Cristobal, Linköping University / Department of Cl. and Exp Medicine, Cell Biology
Ecosystem assessment is turning the attention to the impact on the ecosystem function. Methodologies are not focused on a holistic understanding that could connect environmental function, impact and ecosystem services. Method in ecotoxicology evaluates the effects of stressors through a panel of model/sentinel species without the required global view. Proteomic-based methods that can assemble multivariate information have provided a global view of the cellular response to exposure but only from single species. Metaproteomics is a community analysis tool that could link the functional identity of proteins, from species directly responsible for ecosystem services, with the population eco-physiological response to stressors. We present our development of a metaproteomic-based method to track the dynamics of soil microbiome that could be translated into understanding the impact of pollutants on soil function. In the pilot study, natural standard soil LUFA 2.2 were exposed to copper (bulk and nanoparticles) in two concentrations (100 and 500 mg/Kg) for 28 days. Soil microbiome was analyzed by metaproteomics and soil biochemistry. Proteins were extracted from the soil and fractionated by LC. Peptides were digested and then analyzed on an Orbitrap Velos Pro. The MS/MS spectra were analyzed by MetaProteomeAnalyzer open source software. Our results indicated that the key factor in our method development was: i) the utilization of a standardized environmental sample and microbiota that could guarantee experimental robustness and reproducibility for metaproteomic data; ii) miniaturizing the exposure experiment to a platform that could be performed in any basic lab, and iii) implement protein extraction and sample fractionation. Regarding enzyme activity, for phosphatase, a significant decrease was detected for the highest concentration (500 mg/Kg nano Cu) while for glucosidase and urease the activity increased, being significantly for the concentration of 500 mg/Kg bulk Cu. Our metaproteomic data indicated that the complexity of soil microbial community could be correlated to both changes in the biodiversity and the molecular responses of the communities to exposure to pollutants and therefore interpret and predict the ecosystem response to identical stressors.

WE146
Physiological responses of Caenorhabditis elegans to arsenic tolerant Lysinibacillus sphaericus B1CDA.
J.C. Mangu, Orebro University / Department of Science and Technology; N. Rai, Orebro University / The Life Science Centre,s School of Science and Technology; A. Mandal, University of Skövde / Systems Biology Research Center, School of Bioscience,; P. Olsson, Orebro University / The Life Science Center-Biology; J. Jass, Orebro University / SCHOOL OF SCIENCE AND TECHNOLOGY
High concentrations of metals found in the environments pose serious ecological risk to living organisms. The first biota that undergoes direct and indirect negative impacts of heavy metals are the microorganisms. Metals not only affect microorganisms by reducing their number, diversity, biochemical activity but can also lead to establishment of metal tolerant microbial populations. Studies have reported effect of metal contamination on the physiology of metal tolerant microbes. However, their impact on the food chain and subsequent host has not been explored properly. *Caenorhabditis elegans*, a bacteriovorous nematode is naturally colonised with microorgnaisms in the environments, and this makes it an interesting model to study host physiology. *Lysinibacillus sphaericus* B1CDA, an arsenic accumulating strain isolated from an arsenic-contaminated site, has arsenic transforming ability (arsenate to arsenite) has been used in this study. The aim of the study was to investigate the nematode host physiology when fed the arsenic tolerant bacteria, *L. sphaericus* B1CDA,in the presence and absence of arsenic. *C. elegans* were fed bacteria exposed to both arsenate (AS_V)and arsenite (AS_{III}) and gene expression, lifespan and fat analysis were used to explore the physiological responses. Nematodes fed arsenic pre-treated *Escherichia. coli OP50* (control) and *L. sphaericus* B1CDA during the L1 to early adult (L4) stage showed altered gene expression in genes associated with metal stress, oxidative stress, innate immunity and fat metabolism. The altered fat metabolism of the nematodes was confirmed using fat staining. The worms fed with *L. sphaericus* showed extended lifespan compared to the *E. coli* control, however, the lifespan was significantly reduced in the presence of AS_V or AS_{III}. The lifespan reduction was more prominent in the presence of As_{III} than for As_V indicating the difference in toxicity of the two species of arsenic. A better understanding of the effects of metal tolerant bacteria on hosts can reveal possible mechanisms of host-microbiota interactions and their implications in stress response and diseases.

WE147
RELATIONSHIP BETWEEN POLLUTION AND HUMAN HEALTH
K. Adegbenro, Neymar Multi-Trade Venture / Chemistry
RELATIONSHIP BETWEEN POLLUTION AND HUMAN HEALTH
Ecotoxicology enable us to understand the chemical effect (contaminants) on individual, population, natural communities and ecosystem. This study is essential in interaction of organisms with its environment. While, human toxicology include identification & assessment of environmental exposure of human health and pollutants, mechanism by which it get into human system, induce disease, adverse effect, prevent and estimation of acceptable level of exposure for protection of public safety. The safety of public health is paramount to study of the relationship between human being and environmental pollution. At this level, strict regulation of industrial discharge is therefore recommended. Omics can be applied in human toxicology for proper assessment of effect of pollutants on human health. It involves total data analysis in information gathering in a body, thus enabling independent experimental to be carried out (invivo) in such body, in order to contain the effect of the pollutants or find a solution to any disease caused by the pollutant.

WE148
Toxicity of Glyphosate and AMPA to Aquatic Bacteria
R. Dimitrova, Aalborg University / Department of Chemistry and Bioscience; P. Roslev, Aalborg University / Biology and Environmental Science
Glyphosate [N-(phosphonomethyl)glycine] is the most frequently used active ingredient in broad-spectrum herbicide formulations. There is concern that glyphosate-based herbicides may adversely affect environmental microorganisms. In this study, six bacterial strains isolated from a lake ecosystem were examined for their susceptibility to glyphosate and the primary degradation product aminomethylphosphonic acid (AMPA). The toxic responses of the environmental bacteria were compared to responses in laboratory strains of *Escherichia coli*, *Pseudomonas fluorescens* and *Aliivibrio fischeri*. Minimum inhibitory concentration (MIC), regrowth potential and changes in enzyme activity were examined under different nutritional conditions in the presence and absence of AMPA or glyphosate. Traditional MIC values for glyphosate were high when environmental bacteria and laboratory strains were tested in nutrient rich medium containing amino acids but often much lower when examined in nutrient poor medium under amino acid limited conditions. The regrowth potential of the environmental bacteria was also strongly affected by nutritional conditions. EC10 and EC50 values for sensitive aquatic bacteria were more than 100 fold lower in the absence of amino acids compared to EC values measured in the presence of an exogenous amino acid source (0.04 mg/L and 0.06 mg/L, respectively). Similarly, the bacterial toxicity of AMPA was also greater under nutrient limited compared to nutrient rich conditions. Inhibition (EC50) estimated from changes in bacterial regrowth was comparable to inhibition (EC50) estimated from changes in bacterial hydrolysis of fluorescein diacetate (FDA) suggesting that both methods can be used to indicate AMPA and glyphosate toxicity. In contrast, the standard luminescent test organism *Aliivibrio fischeri* was much less responsive to AMPA and glyphosate exposure suggesting that this bacterium is not a good surrogate for measuring microbial toxicity of these chemicals. The results of the study corroborate studies suggesting that glyphosate may affect the biochemical pathway for aromatic amino acid synthesis in some environmental bacteria (Shikimate pathway). The results also suggest that nutrient limited aquatic bacteria may be adversely affected by glyphosate at environmentally relevant concentrations. The aquatic bacteria isolated in this study may be included in test batteries for toxicity screening of pesticides including glyphosate-based herbicides.

WE149
Using flow cytometry for bacterioplankton community analysis as a fast assessment tool complementary to Water Framework Directive in prioritization of impacted sites
M. Santos, University of Aveiro / Department of Biology; H. Oliveira, Universidade de Aveiro / Biology Department and CESAM; S. Peixoto, University of Aveiro / Biology Department and CESAM; J. Pereira, University of Aveiro / Department of Biology & CESAM; A.T. Luis, University of Aveiro; M.J. Pereira, University of Aveiro / Department of Biology and CESAM; F.J. Gonçalves, University of Aveiro / department of Biology & CESAM; I. Henriques, University of Coimbra; T. Vidal, University of Aveiro / Biology department
Freshwater ecosystems support an enormous variety of biological communities and provide simultaneously goods of critical importance to human societies. Anthropogenic disturbances such as mining, agriculture, industrial and household leachates, provoke losses in biodiversity through contamination, which affects the overall quality of water. In order to protect and ensure a good quality, Water Framework Directive (WFD) was implemented in Europe in 2000, however the WFD application is time-consuming and costly. This study proposes an assessment of the bacteriological community of the water column, using fast flow cytometry (FCM) methods and 16S rRNA gene-based denaturing gradient gel

electrophoresis (DGGE). The results of both bacterial community analysis techniques were used to compare with macroinvertebrate and diatom community structure analyses. Caima river (Northern Centre Portugal) was used as case study and 3 sampling sites were selected: site 1- with little impact; site 2- downstream a Waste Water Treatment Plant; site 3- exposed to mine drainage. Sites were studied over the 4 seasons of the year. In general, multivariate analysis performed for each biological community individually showed that all macroinvertebrates, benthic diatoms and bacterioplankton were able to clearly separate the sampling site burdened with excess of nutrients and turbidity (site 2) and the river headwater (site 1), associated with high oxygen levels. The DGGE analysis of the bacterioplankton community structure matched the results obtained by FCM. Therefore, FCM can be a rapid bioassessment tool to complement the WFD methodology, by signaling/prioritizing potentially impacted areas needing attention to reach the good ecological status demanded by WFD. However, further investigations are needed to confirm the feasibility of this method, as a complementary tool for water quality assessment.

WE150

Gut microbiome attenuates toxicity of cadmium in Caenorhabditis elegans

S. Lee, Y. Kim, University of Seoul; N. Chatterjee, J. Choi, University of Seoul / School of Environmental Engineering

Soil microorganisms carry out important role in soil ecosystem, such as, cycling of carbon and nutrients, support of plant growth, and fitness and stress response of soil organisms. In this study, we investigated effect of soil microbiome (SMB) on the response of the soil nematode Caenorhabditis elegans when exposed to one of the major soil contaminants, cadmium (Cd). As C.elegans is a bacterivore, soil microbiome was supplied as food source, which could also provide role of gut microbiome on the fitness of C.elegans, as well as stress response to chemical exposure. C.elegans was fed with microbiome sampled from Korean soil and life history traits and its stress response to Cd exposure were compared between SMB- and OP50-fed worms. It was found that SMB-fed worms showed faster growth rate, higher reproduction and longer lifespan, compared to OP50-fed worms. Increased reproduction by SMB feeding was maintained over 10 generations. After confirming beneficial effect of microbiome to C.elegans, we then investigated effect of SMB feeding on C.elegans stress response by using Cd exposure. Increased tolerance to Cd exposure was found in SMB-fed worms when using reproduction as endpoint. We postulated enhanced tolerance in SMB-fed worms may be due to boosted immunity by microbiome. To test this hypothesis, gene expression analysis was conducted using panel of immune (i.e. clec-67, irg-2, lys-1, lys-2, pmk-1) and chemical response genes (i.e. cdr-2, mtl-2, cyp35a2, ugt-1, sod-3). Clear difference was observed between immune and chemical stress response genes expression in SMB- and OP50-fed worms. Cd exposure led to increased expression of Cd biomarker gene (i.e. *mtl-2*) in OP50-fed worms, whereas such an activation was not observed in SMB-fed worms. On the other hand, expression of immunity related genes (i.e. *irg-2, clec-67, lys-2*) was more pronounced in SMB-fed worms than OP50-fed ones when exposed to Cd. Gene expression result insinuates that boosted immunity by microbiome might play a role in attenuated toxicity of subsequent Cd exposure. Finally, we investigated *C.elegans* gut microbiome by comparing microbial community in absence and presence of Cd. Proportion of Actinobacteria phylum, known as Cd resistant, significantly increased after Cd exposure. Our results suggest SMB affects response of *C.elegans* to Cd exposure, highlighting the importance of gut microbiome on host stress response mechanism.

Advances in Soil Ecotoxicology and Risk Assessment - Impact, Ecotoxicity Tests, and Concepts for a Retrospective Environmental Risk Assessment (P)

Cocoon hatching success as ecotoxicological endpoint: A potential tool to assess metal contaminated soils

M. Maboeta, North-West University / Unit for Environmental Sciences and Management; H. Eijsackers, WUR/NWU; J. Wahl, North-West University

South Africa produces large amounts of solid mine waste, covering vast areas of land in the form of tailings dam facilities (TDF). Tailings material contains high levels of metals which poses potential risk for the environment and human health due to leaching and erosion into the surrounding area. Agricultural practices such as tilling and chemicals added also bring these soils into perspective regarding erosion and leaching. Both these soils are disturbed on a physical level, influencing the soil structure, chemical composition and soil fauna present. The aim of this study was to investigate the possibility of utilizing cocoon hatching success as ecotoxicological endpoint to assess metal contaminated soils. Ten *Eisenia andrei* cocoons were exposed to 250g of mine tailing soil, agricultural soil, natural soil and to the control in plastic containers (12 cm x 6 cm) with perforated lids. Once in the soil, the cocoons were given a 23-day hatching window and a further 17-day growth period (to allow worms to be of suitable sizes for handling and weighing) before monitoring of growth started. Results indicated that the mean number hatchlings per cocoon were significantly lower ($p< 0.05$) in metal contaminated mine soils compared to the control, agricultural and reference soils. The same trend was also observed when investigating the growth of the juveniles over time. It can be concluded that utilizing cocoon hatching success as ecotoxicological endpoint might be sensitive and could possibly be used in the assessment of metal polluted soils. **Keywords:** Tailings dam facilities; earthworms; ecotoxicity; cocoons

WE152

Sewage sludge and sewage sludge char soil application: effects on earthworms' growth and reproduction

J. Zaltauskaite, Vytautas Magnus University / Department of Enviromental Sciences; I. Kniuipyte, Vytautas Magnus University; M. Praspaliauskas, N. Striugas, Lithuanian Energy Institute

Sewage sludge production in the world is increasing and its management is a growing problem worldwide. Land application of sewage sludge in agriculture or short rotation energy forestry plantations is a preferred sewage sludge disposal (reuse) route in European Union. As sewage sludge is rich in essential plant nutrients (N, P), it can be applied as fertilizer to soils in order to improve and maintain productivity of soils. However, the use of sewage sludge may pose environmental risk as it has an extensive range of heavy metals and persistent organic pollutants that may accumulate in the soil, be transferred from soil to soil dwelling organisms and be incorporated into the food chain. In this study we have examined the effects of sewage sludge and sewage sludge pyrolysis char soil application to earthworms *Eisenia fetida*. Adult *E. fetida* were exposed to 25-100 t ha^{-1} of sewage sludge and sewage sludge char in soil for 8 weeks. The impact on earthworm survival, growth rate and reproduction was evaluated.

WE153

Soil risk assessment of the fragrance ingredient, Helvetolide®

S. Gimeno, Firmenich / Legal and Compliance; F. Zoete Maglia, C. Lachausse, Firmenich SA; M. Simon, Fraunhofer IME / Applied Ecology; K. Schlich, Fraunhofer IME - Institute for Molecular Biology and Applied Ecology; P. REMUZAT, CEHTRA SAS; P. Thomas, CEHTRA SAS / Ecotoxicology and Risk Assessment

Alicyclic musks and macrocyclic musks are fragrances that were developed in the 1970's as alternatives to the nitromusks and polycyclic musks which were already controversial due to their persistence and bioaccumulation potential. The olfactory characteristics of musks - warm, sensual, animalic and natural - are of great value to perfumers and consumers and as such musks are added in cosmetics as well as in laundry products. Alicyclic musks and macrocyclic alternatives are mostly readily biodegradable and have been shown not to be bioaccumulative despite their relatively high log Kow values. However, some of the earlier developed alicyclic musks are only partially biodegradable according to screening biodegradation tests. We report here the environmental profile of Helvetolide® and focus on the soil risk assessment, whereby the chronic effects on soil microorganisms and worm have been tested. The inhibitory effects of Helvetolide® on nitrogen transformation activity of soil microorganisms was assessed following the OECD TG 216 resulting in a 28d-EC10 value of 161 mg/Kg dw. The effects of Helvetolide® on soil worm reproduction were assessed using *Eisenia andrei* following the OECD TG 222 up to 250 mg Helvetolide®/kg dry mass soil. Soil samples were taken at multiple times for chemical analyses of Helvetolide® and of the transformation product helvetol. Rapid loss of the Helvetolide® was observed within the first week of the test, while most of the helvetol was eliminated after several weeks. The 56d-EC10 value based on number of offsprings hatched from the cocoons was determined to be 86 mg/kg dw based on nominal concentration of Helvetolide®. These results are used to derive the PNEC soil and compared with the PNEC soil derived by using the equilibrium partitioning method. Finally the equation of PEC soil /PNEC soil ratio below 1 confirms that Helvetolide® can be used safely and does not pose any risk to soil organisms. In addition, we demonstrate that the degradation product, helvetol is less bioaccumulable and less toxic than the parent molecule Helvetolide®.

WE154

Bioaccumulation kinetics of conazole fungicides in earthworms

L. Bielská, RECETOX, Faculty of Science, Masaryk University / Faculty of Science, RECETOX; L. Skulcova, Masaryk University, RECETOX / Research Centre for Toxic Compounds in the Environment (RECETOX); N. Neuwirthová, Masaryk University Faculty of Science RECETOX; K. Kročová, RECETOX, Faculty of Science, Masaryk University

Earthworms are one of the most important bioindicators in the terrestrial environment as well as valuable endpoints for assessing the bioaccumulative potential and bioavailability of soil pollutants. Earthworms interaction with soil occurred via exposure to contaminants present in the integument and in the gastrointestinal tract, thus providing two possible routes of exposure. The resulting body burden is determined by uptake, metabolism and excretion processes while these processes themselves are soil-, compound-, and time-dependent. As such, bioaccumulation can be considered a complex process where the role of all influential factors remains still relatively unclear. Therefore, in the present study bioaccumulation was investigated in a series of experiments in order to account for the role of compound characteristics, of soil properties, and of the exposure time on the bioaccumulation kinetics of conazole fungicides by earthworms. Conazole fungicides represent widely used pesticides and their residues may persist in soil into following growing season(s) and pose toxicity to non-target organisms. Thus, they represent relevant soil contaminants with potential negative environmental impacts. In the study, two approaches were used for determining the extent of bioaccumulation (i.e., the bioaccumulation factor (BAF)) and compared. First, concentrations of chemicals in earthworms and in soil wereplotted against time. From the data, the uptake rate constants and elimination rate constants were gained and used for BAF determination ("the dynamic approach"). Second, BAFs were calculated for fixed exposure periods ("the static approach"). The study provides an insight on compound-earthworm-soil interactions, on the bioaccumulation process itself, as well as on the bioaccumulation potential of potentially risky pesticides by non-target species.

WE155

Aporrectodea caliginosa: A long-term laboratory study with different untreated and Copper treated field soils

E. Wagenhoff, Eurofins Agroscience Services Ecotox GmbH; O. Klein, Eurofins Agroscience Services Ecotox GmbH / Ecotox Field; T. Vollmer, Eurofins Agroscience Services Ecotox GmbH / Field Ecotoxicology; M. Weidenauer, Battelle / Agribusiness; T. Moser, Eurofins Agroscience Services Ecotox GmbH; S. Knaebe, EAS Ecotox GmbH / Ecotox Field

Currently, *Eisenia fetida/andrei* is used as model organism for earthworms in the environmental risk assessment (ERA) of Plant Protection Products (PPP). However, *E. fetida/andrei* is an epigeic species and nearly absent in most agricultural soils. Moreover, it is unclear if its sensitivity is comparable to e.g. endogeic species like *Aporrectodea caliginosa* (EFSA 2016) which live preferably in the mineral soil layer. Data for a meaningful comparison between *Eisenia* and other earthworm species are limited and in case of chronic (reproductive) endpoints even not available. Therefore, results on long term laboratory studies with earthworm species other than *E. fetida/andrei* might help filling the gap and further, give option to use those in standard testing for a more realistic ERA. *Field caught Aporrectodea caliginosa* were tested in two uncontaminated natural grassland soils and two soils from the same grassland site where Copper had been applied three times per year at a nominal rate of 8 kg Cu/ha/year for the past 14 years. The soils were collected (top soil; soil depth of approx. 5 cm; including vegetation) at two different field sites in South-Western Germany. The soils were deep frozen, thawed and homogenized before usage. Four replicates were used for each soil, 5 worms were inserted per replicate. The total duration of the experiment was 112 days. Mortality and biomass development were assessed at 28-day intervals until day 112; the reproductive output (i.e. number of cocoons and number of juveniles) was assessed once at day 112.

WE156

Assessment of soil ecotoxicity derived from the application of sewage sludge with biological indicators of soil health (microorganisms, plants and invertebrates) for remediation option appraisal

E. URIONABARRENETXEA, PiEUniversity of the Basque Country; N. García-Velasco, University of the Basque Country / Zoology and Animal Cell Biology, Research Centre for Experimental Marine Biology and Biotechnology PIEUPVEHU; M. ANZA, C. GARBISU, NEIKER; U. ARTETXE, R.G. LACALLE, J.M. BECERRIL, University of the Basque country UPVEHU; M. Soto, University of the Basque Country / Zoology and Animal Cell Biology, Research Centre for Experimental Marine Biology and Biotechnology PIEUPVEHU

Industrial activity, together with a high human population density and scarcity of useful land, have contributed to the proliferation of dumps, landfills and waste disposal points at different urban, peri-urban and natural areas in the Basque Country. According to the Basque Country Landfill Inventory (2005), the total number of landfills in this region is 1,277, thus being one of the most important ground pollution sources (affecting water sources and air quality as well). Among these inventoried landfills, "Landfill 17" is located at 43°19'28.9"N 2°40'30.9"W. This landfill was employed as sewage sludge disposal point for, at least, two decades. Among the species more likely to be affected by such disposal, plants, microorganisms and soil invertebrates like earthworms must be emphasized due to their close contact to the soil matrix and, hence, soil pollutants. The aim of the present work was to assess the ecotoxicity exerted by pollutants present in the sewage sludge repeatedly spilled into Landfill 17 as a preliminary step to remediation option appraisal, considering phytoremediation, bioremediation and vermiremediation technologies. For ecotoxicological evaluation, and in order to assess impacts at different levels of biological complexity, different standardized tests (OECD-222 and OECD-207) and the Calcein-AM assay (cell viability) were carried out using earthworms. Earthworms were maintained for 7, 14 and 28 days in soil amended with the sewage sludge containing trace elements (Pb, Ni, Cd and Cr), PAHs (benzo(a)pyrene) and pesticides (dieldrin). At day 7 and 14, measurements of weight loss, mortality and coelomocyte viability (Calcein-AM assays) were obtained. Effects on earthworm reproduction were assessed after 56 days of exposure. In addition, germination and root elongation plant bioassays were carried out in order to quantify soil phytotoxicity and, pollutant phytobioavailability. To this purpose, bioassays with *Lactuca sativa* and *Allium cepa* were performed. Microbial soils properties and other edaphic parameters were also assessed. Different sewage-induced effects were observed, compared to control soil (OECD standard soil), at different levels of biological complexity, demonstrating the accuracy of the combination of earthworm, plant and microorganism tools for soil ecotoxicity assessment. Acknowledgements: Basque Gov (IT810-13; ITO18-16), CTM2017-87766-R, AGL 2015-64481-C2-1-R and AGL2016-76592-R from MINECO, PhytoSUDOE-SOE1/P5/E0189.

WE157

The bioavailability of metals in multi-contaminated mining and quarry soils (NW Spain)

A. Rodriguez Seijo, GreenUPorto, University of Porto / Department of Biology; J. Lourenco, University of Aveiro; D. Arenas-Lago, Universidade de Vigo / Department of Plant Biology and Soil Sciences; M. Lago-Vila, Universidade de Vigo / Department of Plant Biology and Soil Science; S. Mendo, University of Aveiro / Department of Biology CESAM; F.A. Vega, Universidade de Vigo / Department of Plant Biology and Soil Science; R. Pereira, Faculdade de Ciências da Universidade do Porto / Biology

Abandoned mining and quarry areas are a source of potentially toxic elements (PTEs), through to lixiviates or transfer processes of bioavailable fractions from mining wastes and tailings. Previous works have been carried out to assess metals availability through single and sequential soil extractions, and soil to plant transfer of potentially toxic elements (bioaccumulation on native plants, seed germination and root elongation bioassays). However, ecotoxicological effects on soil biota were not evaluated for these soils. In this sense, earthworms (*Eisenia fetida*) were exposed for 28 days to two mining soils from a lead/zinc mine (up to 43, 6700 and 32000 mg kg^{-1} of Cd, Pb and Zn), and two quarry soils from an old serpentine quarry (up to 147, 2600 and 18000 mg kg^{-1} of Co, Cr and Ni). The effect of soil exposure to earthworms was assessed at the biochemical level (acetylcholinesterase, catalase, glutathione-s-transferase, lactate dehydrogenase and lipid peroxidation through TBARs content) and DNA damage (comets assay). The exposure of earthworms was confirmed by metals bioaccumulation in tissues. Results showed a highest bioaccumulation for Ni, Pb and Zn, although bioconcentration factor values never exceeded 1. Regarding biochemical activities, Ache was always significantly inhibited in earthworms exposed to all the contaminated soils, however no clear signs of oxidative stress and DNA damages were recorded. The results from the earthworm's exposure point for the low bioavailability of metals in the tested soils (below than 15% of total content).

WE158

Impact of diclosulam, paraquat, glyphosate, metsulfuron and its mixtures on growth and reproduction of Eisenia fetida.

I. García, Centro Universitario Paysand, Universidad de la Repblica / Paysandú; G. Fernández, Universidad de la República

Non target organisms are reached by herbicides during its application on agricultural systems. The aim of this study was to assess the impact of 4 herbicides and 2 mixtures frequently used during fallow, on the growth and reproduction of *Eisenia fetida*. The mixtures of diclosulam+paraquat and glyphosate+metsulfuron, as well as the single herbicides, were tested using OECD (2004) modified protocol (5% of peat content and 24 hours of light). Two concentrations were assessed, the commercial recommended dose and the worst scenario was represented by a 10 times higher dose than the former. Five replicates per treatment were used, and data was analysed by ANOVA followed by a Tukey test. The analysed variables were relative growth rate (RGR), number of hatched and unhatched cocoons, number of juveniles, and hatching rate. Diclosulam low dose was the only treatment with positive RGR, and different from glyphosate low dose which had the most negative RGR. This variable did not show correlation with the reproductive ones. On the contrary, glyphosate showed a stimulus in reproduction, presenting more juveniles, hatched and total cocoons than the untreated control. On the other hand, diclosulam presented lower number of hatched cocoons and hatching rate, than the untreated control. Metsulfuron did also decrease hatching rate. Diclosulam and paraquat mixed behaved very similar in terms of reproduction to single diclosulam and differed from paraquat. The mixture presented a lower hatching rate, and a tendency ($p = 0.0759$) to have fewer hatched cocoons than single paraquat. The mixture of metsulfuron and glyphosate showed intermediate results of hatching rate and number of juveniles regarding the single herbicides. In contrast, considering hatched cocoons, it resembles to single glyphosate and differs from metsulfuron. Herbicides had different effects on *E.fetida* depending on dose, mixture and response variable considered. On these conditions, diclosulam at both doses, single or mixed, posed the higher risk for *E.fetida*, decreasing its reproductive rate. On the other side, glyphosate at the recommended dose promoted *Eisenia*'s reproduction, not accelerating it, but increasing their number of offspring. The results highlight the need to consider different biomarkers in ecotoxicity studies.

WE159

Ecotoxicity of roadside soils in Moscow: finding correlations between traffic-related contaminants and their ecotoxicological effects

O. Nikolaeva, M.V.Lomonosov Moscow State University / Research and Training soil-ecological centre of Lomonosov MSU; V. Tikhonov, MV Lomonosov

Moscow State University / Faculty of Soil Science; M. Vecherskii, A.N. Severtsov Institute of Ecology and Evolution; E.V. Fedoseeva, Pirogov Russian National Research Medical University / Pediatric faculty; A. Astaikina, MV Lomonosov Moscow State University / Soil Science

Road transport is responsible for 57-75% of total emissions in urban areas and tends to be the key source of environmental pollution in cities [WHO, 2006]. Roadside soils perform as polycontaminated systems of intense pollutant accumulation originating from motor vehicles: total petroleum hydrocarbons (TPH), polycyclic aromatic hydrocarbons (PAH), heavy metals (HM), deicing salts (DS). The purpose was to find correlations between traffic-related contaminants in the roadside soils and their ecotoxicity across a typical highway (125,000 vehicles per day) in the city of Moscow, Russia. The topsoils (0-3 cm depth) were sampled perpendicular to the road at 1, 6, 10, 18 and 50 m distances from the roadbed in three replicates. TPH, PAH, HM in total and phyto-available forms, and DS were determined. A battery of soil-contacting organisms was tested: phytotoxicity of rye (*H. vulgare* L.) and garden cress (*L. sativum* L.); *E. foetida* earthworm growth rate and mortality; basal and substrate-induced respiration activity, nitrogen fixation and the denitrification activity of the soil microbial complex. To determine the possible risk to aquatic ecosystems, the algal toxicity test (*S. quadricauda*) was provided. Correlations between «chemical» data and intensity of «biological» effects were analyzed. Concentrations of most contaminants declined to the background values with distance from the road increase. However, the toxicity of roadside soils was obtained for all examined organisms within the whole 50 m zone. Live organisms exhibited different sensitivities to roadside soils pollution. The intensity of inhibition effects decreased in order: higher plants > earthworms and microorganisms > algae. The risk for aquatic ecosystems was assessed as low. Higher plants toxicity correlated with TPH, PAH, some HM, and DS; earthworm toxicity correlated with TPH, some PAH, HM, and DS; microorganism toxicity correlated with TPH and DS; algae had no observed correlations with contaminants. TPH and DS were general ecotoxicants affecting all organisms. Higher plants may be considered the PAH indicators and earthworms as HM indicators. Thus, biological methods are a prospective tool for assessing roadside soils. Chemical analysis must be accompanied by biological studies for comprehensive ecological assessment. A set of higher plants and earthworms may be recommended as the reduced test-battery of relevant organisms for cost-effective assessment of the toxicity of roadside soils.

WE160

Toxicity of lanthanides to boreal soil invertebrates over time

J. Princz, H. Lemieux, P. Boyd, C. Fraser, Environment and Climate Change Canada / Biological Assessment and Standarization Section; J. Velicogna, R. Scroggins, Environment and Climate Change Canada / Biological Assessment and Standardization Section

The advent of new commercial technology applications has led to recent exploratory efforts within Canada for future mining of lanthanide rare earth elements (REE). Although naturally present in soils, additional inputs occur as a result of mining and refining operations, leachate from landfill due to discarded technology, and the application of phosphorous fertilizers (produced in part by REE rich monazite minerals). As such, certain REEs have been identified as priorities for chemical risk assessment under the Government of Canada's Chemicals Management Plan. Data gaps exist for soil hazard data in Canadian boreal regions, where new mining activities are likely to occur. As a result, a series of studies were conducted to assess the toxicity of Praseodymium (Pr), Samarium (Sm), Neodymium (Nd) and Yttrium (Y) in two horizons of a brunisolic boreal forest soil: an LFH and Ah-Aej-Bm horizon. The soils were spiked with metal salts, aged for 2 weeks, and then leached with deionized water to remove the excess salts. Three species of soil invertebrates (earthworm *Dendrodrilus rubidus*, springtail *Proisotoma minuta*, and oribatid mite *Oppia nitens*) were exposed to a series of concentrations of the leached soils. Of the REEs assessed, the two most toxic elements were aged for 6 months and toxicity reassessed. Toxicity varied with species, with Pr being among the most toxic REEs assessed to date. The toxicity data will be presented, along with discussion of the implications of metal availability across horizons and time.

WE161

Toxicokinetics and toxicodynamics of cadmium in soil collembolan Paronychiurus kimi exposed in simplified soil solutions

J. Son, Korea University / Ojeong Eco-Resilience Institute; J. Wee, Korea University / Division of Environmental Science and Ecological Engineering; e. Ko, Korea University; K. Cho, Korea University / Division of Environmental Science and Ecological Engineering

Conventional toxicity testing has proceeded in a manner that assesses the toxicity of a chemical at a given point in time, which ignores the effect of time on uptake and toxicity of a chemical. In this study, time-dependent accumulation and toxicity of cadmium in soil collembolan *Paronychiurus kimi* were investigated with the aim to link toxicokinetics to toxicodynamics. The *P. kimi* were exposed for 10 d to different cadmium concentrations (uptake phase) in simplified soil solutions embedded in quartz sand, followed by a 14-d elimination phase in clean simplified soil solutions embedded in quartz sand. Internal Cd concentration and mortality were determined at 7 different time intervals. Internal Cd concentration in *P. kimi* increased with increasing exposure time and median lethal concentration (LC50) decreased with increasing exposure time. The overall results were interpreted from the perspective of toxicokinetics and toxicodynamics using a one-compartment model to calculate the uptake rate constant (k1) and elimination rate constant ($k_{2\text{-TK}}$). The results of present studies emphasize the need to reflect changes in toxicity values over time, which should be taken into acount in future toxicity testing and ecological risk assessment.

WE162

Assessing the effects of plant protection products on enchytraeids under field conditions: test of carbendazim as a toxic reference

J. Amossé, G. Henkes, Rifcon GmbH

According to the Scientific Opinion addressing the state of the science on risk assessment of plant protection products for in-soil organisms (EFSA PPR Panel, 2017), Specific Protection Goal options have been identified for different groups of soil organisms. For Enchytraeidae, "*the maximum initial magnitude of effect that might be tolerated in-field without impairing the general protection goal is suggested to be small effects less than 35% for months on the ecological entity 'populations of different enchytraeid species' or medium effects less than 65% for weeks.*" However, to validate magnitudes of effects on enchytraeids under field conditions, no active substance for the negative control is clearly identified. Our study aimed at testing under field conditions the effects of carbendazim - a fungicide already used as a toxic reference in earthworm field studies - on enchytraeids. The field study was conducted in a meadow located near Brensbach (Germany) in 2018. Eight study plots (4 control plots and 4 plots treated once with carbendazim at 10 kg a.s./ha in March 2018) with a size of 10 m x 10 m each were randomly located. Seven months after carbendazim application (in November 2018), six cores (10 cm depth, 5 cm in diameter) were taken using a split corer from a 6 m x 6 m core area in the central part of each study plot. Sampling, heat-gradient extraction and counting of Enchytraeidae were conducted in accordance with the ISO norm 23611-3 (2018). Our first results showed that enchytraeid abundance was significantly ($p < 0.001$, *t*-test, n=4) reduced by 72% in the carbendazim treatment compared to the control with a mean abundance of 21 (± 6, standard deviation) and 75 (± 15) individuals, respectively. These results are in accordance with a field study conducted in a grassland (Flörsheim, Germany) where the enchytraeid abundance was lower eight and sixteen weeks after single carbendazim applications (i.e. 9.72, 29 and 87.48 kg a.s/ha) compared to the control plots (Moser et al., 2004). Carbendazim could thus be considered as a relevant active substance for toxic reference in enchytraeid studies. Moreover, enchytraeid field studies could be adapted from the ISO standard method 11268-3 (2014) for earthworm field studies. Investigation of enchytraeid community composition (i.e. genus/species levels or r/K strategy types) would also bring key information on community change, biodiversity loss and potential impact on the soil functioning in agroecosystems.

WE163

A mesocosm experiment on the effects of nitric acid and sulfurc acid on below- and above-ground species: white radish and a Collembolan species

J. Wee, Korea University / Division of Environmental Science and Ecological Engineering; Y. Lee, Y. Kim, Korea University; E. Ko, Korea University / Division of Environmental Science and Ecological Engineering; J. Son, Korea University / Ojeong Eco-Resilience Institute; M. Lee, J. Hong, Korea University; K. Cho, Korea University / Division of Environmental Science and Ecological Engineering

Storage and transport of large quantities of chemicals have increased, resulting in an increase of chemical accidents. Since released chemicals caused by chemical accidents can cause not only widespread but also persistent damage on an ecosystem, understanding the effects of chemicals that can cause chemical accident has been of concern. We conducted a mesocosm experiment that allowed us to examine the effects of nitric acid and sulfuric acid on the soil organisms. The soil used in this experiment was sampled except for the organic layer from Deokso (N 37° 34' 56", E 127° 14' 8") and in October 2018. After defaunation, 2 kg of soil was transferred to each pot. We planted the mesocosm with white radish (*Raphanus sativus*), which is frequently cultivated in Korea. After 21 days, nitric acid and sulfuric acid at NOEC calculated by laboratory experiments was spiked and then, 30 adult individuals of Collembolan species (*Paronychiurus kimi*) native to Korea were inoculated. After 28 days, the mortality and reproduction rate of *P. kimi* was observed and root and shoot biomass of *R. sativus* were recorded. Unlike the results of laboratory experiments, root and shoot biomass of *R. sativus* was increased by the exposure of nitric acid and decreased by the exposure of sulfuric acid. The number of juveniles produced by adults *P. kimi* and survived adults *P. kimi* were decreased as the concentration-dependent manner in both nitric acid and sulfuric acid. These results suggest that low concentrations of chemicals released by chemical accidents can cause detrimental effects on the soil ecosystem.

WE164

Thirty Nine Threshold Guide Values (TGV-ex situ) to environmental risk assessment of contaminated soils with Cantareus aspersus

m. louzon, Department of Chrono-Environnement, UMR UFC/CNRS 6249

University of Bourgogne Franche-Comté, 16 Route de Gray, 25000 Besançon; F. Gimbert, University of Bourgogne Franche-Comté / UMR ChronoEnvironnement; B. Pauget, TESORA; N. Crini, University of FrancheComte / Department ChronoEnvironment UMR UFCCNRS; S. Maly, Central Institute for Supervising and Testing in Agriculture, 2 Hroznova, 656-06, Brno; D. Rieffel, Q. Devalloir, Department of Chrono-Environnement, UMR UFC/CNRS 6249 University of Bourgogne Franche-Comté, 16 Route de Gray, 25000 Besançon; C. Amiot, University of Franche-Comte / Department Chrono-Environment - UMR 6249 UFC/CNRS; A. de Vaufleury, University of Franche-Comte / Department of Chrono-Environment

The environmental risk assessment (ERA) of polluted fields and soils should ideally be carried out with complementary approaches (chemical and biological) conducted *in situ* and *ex situ*. If biological methods based on effect and bioaccumulation exist for bioindicators of the soil fauna such as landsnails, the methodology is currently only applicable on site to metallic elements (ME). To better understand the role of soil in snail exposure and also to give new relevant tool for polluted field managers, the aim of this work is to determine *ex situ* (under simplified exposure conditions) threshold guide values (TGV-$_{ex\ situ}$) in the viscera of the terrestrial snails (*Cantareus aspersus*) for 16 metallic elements (ME), 16 polycyclic aromatic hydrocarbons (PAH) and 7 polychlorinated biphenyls that are environmental indicators (PCBi). In this purpose, snails were exposed under controlled conditions for one month to various European soils (n=67). The soils chosen have different types and level of contaminations, and physico-chemical characteristics (granulometry, pH, organic matter content, carbonates, exchangeable cations, cation exchange capacity) that can influence the bioavailability of contaminants. After exposure, contaminants were measured in viscera by ICP/MS for ME and GC/MS for PAH and PCBi. Thirty nine TGV-$_{ex\ situ}$ were calculated for ME (As, Cd, Co, Cr, Cu, Hg, Mn, Mo, Ni, Pb, Sb, Se, Sn, Sr, Tl, Zn), PAH (ACE, ACY, ANT, BaANT, BaPYR, BbFLT, BghiPL, BkFLT, CHY, dBahANT, FLT, FLU, IcdPYR, NAP, PHE, PYR) and PCBi (28, 52, 101, 118, 138, 153, 180). TGV-$_{ex\ situ}$make it possible to characterize *ex situ* excesses of transfer to the snails of bioavailable contaminants contained in contaminated soils by calculation of accumulation quotient (AQ) and sum of excess transfer (SET) index. The TGV-$_{ex\ situ}$ also permit to Evaluate the Risk of the Transferred ME, or PAH, or PCB by weighting AQ and SET by the intrinsic toxicity of the contaminants based on the toxicity points. The TGV-$_{ex\ situ}$ of snails are a basis for interpreting contamination levels in the aim to help polluted soils managers in their choices: when TGV-$_{ex\ situ}$ are exceeded (AQ>1), the pollutant is bioavailable and therefore the polluted soil should not be used *e.g.,* for embankment after excavation. The presented results provide complementary solution to prioritize management of polluted soils (rehabilitation, monitoring) according to environmental risks that are estimated with risk index.

WE165

Ecotoxicological risk assessment of highly purified paraffin oils in banana plantations of Martinique and Guadeloupe.

P. Lemaire, E. Bureau, S. Jubault, TOTAL Fluides; S. Gony, P. Adrian, CEHTRA SAS; G. Destrycker, CEHTRA EUROPE; B. Journel, CEHTRA SAS

Paraffin oils of high purity (CAS 64742-46-7, CAS 72623-86-0 and CAS 97862-82-3) as produced by TOTAL Fluides are authorized pesticides in EU but are also used as an adjuvant for fungicides in banana plantations at an application rate of 15 L/ha equivalent to 12 kg/ha with maximum 15 applications. In the framework of Yellow and Black Sigatoka disease control caused by *Pseudocercospora musae (formerly Mycosphaerella musicola) and Pseudocercospora fijiensis (formerly Mycosphaerella fijiensis*), the fungicide mixture is applied locally in order to protect the youngest leaves of the banana tree. The efficacy of paraffin oils is based on physical effects by making a film that prevent organisms from breathing. Such process gives its insecticidal and acaricidal properties. That is why when used as an adjuvant for fungicide, particular attention was given to the risk to terrestrial arthropods following the treatment of Black and Yellow Sigatoka in banana. The risk assessment conducted for terrestrial arthropods including pollinators and soil arthropods, concluded to an acceptable risk for all groups except for the non-target arthropod representative species *Typhlodromus pyri* under EU standard risk assessment scheme. The toxicity reported for the phytoseid mite *Typhlodromus pyri* together with the high application rate and the high number of applications lead to a potential risk conclusion. Therefore, a risk assessment refinement was conducted, starting with taking into account the particular agricultural practices of banana plantations where banana trees are trimmed on a fortnight basis, regularly eliminating the oldest leaves. Consequently, the actual number of applications received by each leaf is drastically reduced and limited to a maximum of 2 applications under the growth conditions in Martinique and Guadeloupe. On the other hand, the ecology of the phytoseid mites shows that they live mainly under the leaves, and are therefore less exposed to the sprayed mixture which spraying is “crop-directed” and reaches mainly the upper face of the leaves in the canopy. Moreover, although it is the most sensitive taxonomic group to paraffin oils, phytoseid mites are not ecologically important in banana plantations compared with other tropical crops where they are at least 10 times more numerous. Based on the refined exposure, no unacceptable risk was found for non-target arthropods from the use of Paraffin oils in bananas at the recommended rate.

WE166

The sensitivity of Caenorhabditis elegans (Nematoda) to pesticides in soil compared to other standard test organisms

S. Höss, Ecossa / Animal Ecology; M. Faupel, Rifcon GmbH

Nematodes are, due to the evolution of different feeding strategies (bacterial-feeders, fungal feeders, ominvors, predators), key drivers for ecosystem services such as nutrient cycling, which is also recognized by EFSA (EFSA Pannel on PPP and their residues, 2017, EFSA Journal 15 (2), 4690). *Caenorhabditis elegans* is a known representative of soil nematodes and can be used as a test organism for assessing the toxicity of plant protection products (PPP). The well-established soil toxicity test according to ISO 10872 allows setting up chronic toxicity endpoints for PPP in soils on the basis of a quick (96h) and inexpensive test system. However, until now, only few data are available to compare the sensitivity of *C. elegans*compared to the standard soil test organisms as required by regulation (EC) 1107/2009. Therefore, we tested 13 PPPs (4 fungicides, 4 insecticides, 4 herbicides, 1 nematicide) in terms of their toxicity on *C. elegans*’ reproduction and growth in spiked soil (Lufa St. 2.2). We provide a comparison of nematode toxicity to available endpoints of the standard soil test organisms earthworms, springtails and soil mites based on most recent publicly available EU documents.

WE168

Evaluation and validation of field studies with soil organisms exposed to Plant Protection Products

P. Kotschik, Umweltbundesamt / Federal Agency of Environment / Risk assessment for plant protection products; H. Madrenes, UBA Federal agency for environment; S. Pieper, German Federal Environment Agency (UBA) / Plant Protection Products

The higher tier risk assessment for non-target soil meso- and macrofauna (e.g. earthworms, collembolan and mites) exposed to Plant Protection Products (PPP) is currently mostly based on studies in the field. Recommendations dealing with the study setup, the conduction of field studies with earthworms as well as the requirements of the test site are currently captured in the guidance ISO 12268-3 (2014 [1]). Guidance on how to evaluate the performance of field studies with earthworms is given in De Jong et al (2006) [2]. For other soil organisms (e.g. collembola or mites), no guideline or guidance is available so far. From a regulatory point of view, several requirements should be considered in terms of determination of captured animals, evaluation of test results as well as choice of statistical evaluation procedures and interpretation of test results. Especially the current statistical power of the field tests with soil animals is a matter of high concern. Due to the high natural variability and the current set up of field studies (e.g. 4 replicate samples in each of 4 replicate plots), the statistical detection of results at the desired level can be hampered. In order to avoid masking ecologically relevant effects, the test design as well as the way of interpreting the results should be adapted. First results of an ongoing research project tackling several of these points have already been presented [3] and will finally lead to proposal for an OECD Guidance for earthworm field studies. In this contribution, we aim at proposing a way forward in the evaluation of currently submitted field studies with earthworms and soil mesofauna, including a quality check, the possible setting of ecological relevant effects and an interim proposal for assessing the study results in view of the planned revision of the Guidance Document on Terrestrial Ecotoxicology by EFSA. Sensitivity comparison of double- and triple- bioluminescent enzyme systems to soil toxicants

O.S. Sutormin, Siberian Federal University / Biophysics; E. Kolosova, Siberian Federal University / Biophisical; V. Kratasyuk, Siberian Federal University / Biophysical

Intensive production and use of new chemicals in agriculture lead to an extreme soil contamination. Modern methods for assessment of quality and contamination of the soil, for example, methods of chemical analysis, are not always able to quickly predict the negative impact of the new used chemicals on humans, ecosystems and the biosphere as a whole. In this paper, we demonstrate a new principle of biochemical design for the development of a new generation of enzymatic bioassays. The principle is based on the replacement of living organisms to sets of enzymatic biotests, which are gathered together with the following feature - “key enzymes represent functioning of a body”. The basis for the design of both specific and integral methods of analysis is the coupled enzyme system of luminous bacteria NADH: FMN-oxidoreductase (R) + luciferase (L), which proved itself earlier as a simple and low time-consuming tool in the field of the bioassay. The unique feature of R + L enzyme system is the possibility of coupling with R + L enzyme system different NAD^+-dependent enzymes. In this case, there is a perfect tool for measuring the activity of more than 100 enzymes. In addition, the use of enzyme reactions as a test system instead of living organisms allows manipulating the sensitivity of creating enzymatic bioassays, depending on the problem to be solved. The aim of this work was to compare the sensitivity of double- (R + L) and triple- (LDH + R + L) enzyme systems to pesticides and metal ions for their future application in environmental monitoring of soils. The study of the sensitivity of the enzyme systems to aqueous solutions of toxicants (malation, diazinon, and copper chloride (II), shows that the triple enzyme system (LDH + R + L) has greater sensitivity, from 3 to 15 times to the toxicants than R + L enzyme system. The obtained values of the EC_{20} parameter, which shows the detection limit of the enzyme systems to the toxicants, show that the sensitivity of the enzyme systems to the toxicants depends as on the nature of the toxicant as on the soil texture. For example, the sensitivity of R + L enzyme system to copper chloride (II) is 1-fold decrease when the chernozem soil sample has contaminated this toxicant. In contrast, the sensitivity of LDH + R + L enzyme system to copper chloride (II) is 3-fold decrease when the medium loam soil sample has contaminated the toxicant. The received results show huge abilities of the enzyme systems for the assessment of contamination of the soil samples.

Tracing the metabolism of 2,4-D in Cupriavidus necator JMP 134 using deuterium and carbon isotope probing

M. Abboud, Helmholtz Center for Environmental Research - UFZ GmbH / Isotope Biogeochemistry; S. Kümmel, L. Adrian, Helmholtz Centre for Environmental Research UFZ / Isotope Biogeochemistry; K. Nowak, TU Berlin / Institute for Environmental Research (Biology V)

Pesticides are organic contaminants of particular interest since they are applied deliberately and in large amounts to soils. The main pathway of their ultimate detoxification is considered to be microbial degradation. The carbon or nitrogen from an organic contaminant can be used by microorganisms to synthesize their biomass compounds. After the microorganisms die, these biomolecules are incorporated into the organic matter of soil or sediment forming ultimately the so-called biogenic non-extractable residues (bioNER). Stable isotope tracers such as ^{13}C or ^{15}N enable the detailed study and quantitation of the C and/or N flux from a targeted pesticide via microbial biomass to bioNER. However, ^{13}C or ^{15}N-labelled pesticides are not easily available; they need to be custom synthesized and at high costs. In contrast, deuterated compounds are cheaper and available more easily, since they are commonly used as internal standards to compensate matrix effects in quantitative analyses by LC-MS/MS. Here we test the applicability of D labeling to study the fate of pesticides with a particular focus on D incorporation into the microbial biomass. A model bacterium *Cupriavidus necator* JMP 134 was grown on D and ^{13}C labeled 2,4-Dichlorophenoxyacetic acid (2,4-D) -a widely used herbicide- and the turnover mass balance was determined for both labeling approaches. The extent of D incorporation into the microbial biomass and into phospholipid fatty acids of *C. necator* was quantified and compared with that of ^{13}C. If deuterium labeling proved successful, it would be a cheaper and more realistic approach to study the fate of pesticides.

WE172

Nanoremediation: evaluation of effectiveness for heavy metal removal and ecotoxicological impact

C. Fajardo, Universidad de Alcala; M. Nande, S. Sanchez-Fortun, UCM; C. Martin, Universidad Politecnica de Madrid / Biotechnology-Plant Biology; G. Mengs, Natural Biotec; G. Costa, Universidad Complutense de Madrid; M. Martin, Universidad Complutense Madrid

Among the risks that threaten the soil/water system maintenance, the heavy metal (HM) contamination in soil is of great concern due to its numerous sources, toxicity, non-biodegradability and accumulative behavior. The need of an efficient *in situ* stabilization strategy to ensure a reduction on metal and metalloids bioaccesibility is still a goal to be achieved. Among the proposed remediation technologies, the zero-valent iron nanoparticles (nZVI) represents a promising option for its use in highly damaged environments to minimize bioavailable/mobile fractions of HMs in soil and water (nanoremediation). However, the environmental associated risks to the application of nZVI remain uncertain and research on the safety and ecotoxicity of nZVI is of extreme importance. In this study, we addressed the efficiency of the nanoremediation strategy in case of co-mingled HM pollution in a highly damaged soil environment. The objectives included monitoring the stability of the strategy for the *in situ* removal of Pb, Zn and Cd from a contaminated soil considered in the long-term, as well as its impact on different soil organisms. We applied a combined set of physical-chemical, toxicological and molecular analyses to monitor the remediation process. The integrative approach applied, using combined technologies and high-throughput –omics tools, enabled us to evaluate if the reduced bioavailability of HMs after nZVI treatment is equated with reduced environmental risk, and if it is demonstrated to be long term. The obtained results indicated that addition of nZVI successfully stabilized Zn, and particularly Pb, even at extremely high concentrations, and the efficient immobilization of HMs was reflected in a diminution of toxicity towards *Vibrio fisheri*. However, the extent and duration of the potential beneficial effects of this treatment were lower than few weeks. Moreover, our results indicated that no significant recovery of the microbial community structure, diversity and functionality was found in the nZVI-treated soil. Therefore, the lack of recovery of biodiversity and the reversible nature of nanoremediation must be carefully considered to validate this technology where assurance of medium to long-term immobilization of HMs is required. Keywords: nZVI, heavy metal, ecotoxicity, microbial community

WE173

EFFECTS AMETRYN MUTAGENIC FOR TRADESCANTIA PALLIDA

A. Justiniano Régo, Universidade de Sao Paulo / Ecotoxicology; E.D. Bidoia, Universidade Estadual Paulista Júlio de Mesquita Filho Unesp Rio Claro; K. Mendes, University of São Paulo / Ecotoxicology lab; V.L. Tornisielo, CENA Center for Nuclear Energy in Agriculture / Ecotoxicology Laboratory; M.C. Arruda, Universidade de Sao Paulo

Due to the increase in the appearance of contaminants in the environment and the search for an understanding of their effects on biota, environmental assessments at molecular levels are necessary, such as the quantification of the appearance of micronucleus during the cell division process, to monitor the mutagenic effects of the contaminant over the exposure time of the test species. The plant species *Tradescantia pallida*, is widely used in environmental biomonitoring studies, being sensitive for the detection of mutagenic compounds present in the environment, through the quantification of the appearance of micronuclei. Micronucleus are the result of chromosomal fragments that disintegrated during the process of cell division, resulting from the mutagenic action of the contaminant, which are not included in the nucleus of a new cell to be formed, being found in the cytoplasm. One of the environmental contaminants already detected in surface water and groundwater in some parts of the world and still used in some countries like Brazil, is the herbicide ametryn. This contaminant is applied to sugarcane crops, having toxic effects on the microbial community and other non-target organisms. Thus, this work aimed to evaluate the mutagenic effects of ametryn (125 µg/mL) for *T. pallida*, in soil with no herbicide application history. It was also evaluated the influence of microbial biostimulation in the presence of the contaminant, through the application of Tween 80 surfactant, as well as of the bioaumentation with the addition of microbial consortium adapted to the presence of ametryn. The effects evaluated was the quantification of the appearance of micronuclei in the treatments. As a positive control, trifluralin and negative control deionized water were used. Ametryn was found to cause mutagenic effects on *T. pallida* in soil, resulting in a higher frequency of micronucleus (5 MCN/300 tetrad). However, with the application of surfactant and microbial consortium the mutagenic effect (1 MCN/300 tetrad), resembling the control soil, which had no application of ametryn. Therefore, such responses are of concern because they cause damage to germ cells and somatic cells, which can result in hereditary diseases. Thus, the necessity of the evaluation of the mutagenic properties for organic compounds, becomes more and more essential to employ measures for the bioremediation of contaminated areas.

WE174

Species-specific impact of silver-graphene oxide on seed germination

m. kim, W. Kim, Korea University; H. Chung, Konkuk University

Silver-graphene oxide (Ag–GO) is widely applied in environmental fields as antibacterial agents, catalysts, and absorbents due to its unique properties. The potential for using Ag–GO to control agricultural diseases is also increasing, and this may lead to its release into the terrestrial ecosystems. However, little is known about the impact of Ag–GO on plants. In this study, we determined the impact of Ag–GO on seed germination and early growth of crop species by analyzing the germination rate, growth of roots and shoots, hydroperoxide (H_2O_2) accumulation, and the uptake of Ag in alfalfa, radish, and cucumber treated with 0.2–1.6 mg ml^{-1} of Ag-GO. Treatment with Ag–GO at 0.2 – 1.6 mg ml^{-1} increased the shoot growth of radish but decreased that of cucumber at 0.4 mg ml^{-1}. In addition, 0.2 mg ml^{-1} Ag–GO enhanced root elongation of radish but inhibited that of alfalfa treated with 0.2, 0.8 and 1.6 mg Ag-GO ml^{-1}. Ag–GO treatment induced H_2O_2 in alfalfa and radish in a concentration-dependent manner. The amount of Ag accumulated in seedlings under Ag–GO treatment was concentration-dependent. Our study shows that Ag–GO may have negative effects on early growth of plants in a species-specific manner, and further studies employing a broad range of plant species are required to confirm its safety in its use as control agent of crops and other environmental fields

WE175

Pollution characteristics and health risk assessment of heavy metals in the vegetable collected from northern part of Serbia

B. Škrbić, University of Novi Sad, Faculty of Technology Novi Sad / Faculty of Technology; J. Živančev, I. Antic, M. Buljovčić, University of Novi Sad, Faculty of Technology Novi Sad

The objective of this study was to investigate heavy element contamination in three major vegetables (potato, carrot and onion) and determine the health risk of Serbian population in the agricultural region of the northern part of Serbia after the flood. Additionally, the content of 9 heavy elements (As, Cd, Pb, Cr, Cu, Co, Ni, Fe and Mn) in the flooded arable soil determined to evaluate the levels of heavy element pollution and human health risks using several indexes as ecological risk factor (Er), geo-accumulation index (I_{geo}), potential ecological risk index (RI) and pollution load index (PLI). These indexes pointed out different level of pollution of analysed soil with selected heavy elements. Furthermore, the potential health risk was assessed through target hazard quotation (THQ) for each element determined in vegetables as the ratio of determined dose of contaminant to a respective dose level. Also, the individual THQs together with total THQs (i.e. TTHQ as sum of THQs assessed for each crop) and hazard index (HI expressed as combined non-carcinogenic effects of multiple elements) were calculated. The THQ values for all analysed elements were below 1, indicating that intake of a single element through consumption of vegetables do not pose a significant potential health hazard. Potential health risk evaluated as HI was < 1, not representing significant risk to Serbian adult population. To the best of the our knowledge, this is first investigation carried out in the flooded arable region (of Vojvodina Province) as attempt to assess health risk which might be attributed to chain soil-plant-human.

WE176
Density-dependent growth responses of Arabidopsis to copper: High densities are beneficial for efficient contaminant uptake
A. Dingus, Ashland University / Department of Chemistry, Geology, and Physics; S. Brauner, Ashland University; A. Sinkkonen, University of Helsinki; J. Weidenhamer, Ashland University
Plant growth responses to toxic copper concentrations are density-dependent. Copper toxicity is reduced at high plant densities for reasons that are not clear. One possible mechanism is the release of citrate from roots in response to excess copper. Citrate binds metals, and thus pooled exudates at high plant densities could reduce copper uptake. This hypothesis was tested using *Arabidopsis thaliana* cultivars that either produce (wild type, Columbian-0) or do not produce (mutants m65 and m85) citrate in response to metals in soil. An ecotype reported to be tolerant to metals (Santa Clara) was included for comparison. Copper treatments were applied five days after transplanting seedlings at rates of 75, 125, and 175 micrograms copper per gram of soil. Plants were grown at four densities (1, 3, 5, and 7 plant per pot). Plants were harvested before bolting, 15 days after treatment. Dry shoot biomass was measured, and plant material was then digested in nitric acid and copper content analyzed by atomic absorption. Copper uptake was more efficient at higher plant densities, indicating that resource competition enhances copper extraction. For each cultivar, the amount of copper removed from the soil increased with plant density. At each density, the Santa Clara ecotype was the most efficient in copper extraction. Copper toxicity was reduced at higher plant densities, but the role of citrate in reducing toxicity is not clear. For both of the mutant, non-citrate producing genotypes, the concentrations of copper per gram biomass at harvest were more than double those of wild type plants. This supports the hypothesis that root exudation of citrate reduces copper uptake on a per biomass basis. However, the greater copper uptake by the mutant varieties did not result in greater toxicity in comparison to control plants. Copper treatments increased variability of plant size, and this effect increased with copper dose. These findings are directly relevant to phytoremediation of soils and to standard ecotoxicological testing, which typically does not take into account the importance of plant densities. More research must be done to understand the mechanism behind density-dependent effects. The impact of copper on size variation among plants may also have important consequences for competition outcomes in contaminated soils.

WE177
Influence of soil physicochemical properties on the depth profiles of perfluoroalkylated acids (PFAAs) in soil along a distance gradient from a fluorochemical plant
T. Groffen, Systemic Physiological and Ecotoxicological Research (SPHERE), University of Antwerp / Department of Biology; M. Eens, E. Prinsen, N. Verbrigghe, L. Bervoets, University of Antwerp / Department of Biology
Perfluoroalkylated acids (PFAAs) have been produced for over five decades. Their hydrophobic and lipophobic character makes them suitable for a wide range of applications. PFAAs may enter the environment where they accumulate and may cause detrimental effects. The widespread use of PFAAs has led to a global presence. As a result, the major global manufacturer, 3M, phased-out the production of perfluorooctane sulfonate (PFOS) and perfluorooctanoic acid (PFOA) in 2002. Despite these regulatory measures, these compounds can still be detected in high concentrations in the environment and biota. The fluorochemical plant near Antwerp has been characterized as a PFAAs hotspot of environmental contamination. In the present study, we investigated how 15 PFAAs (11 perfluoroalkyl carboxylic acids (PFCAs) and 4 perfluoroalkyl sulfonic acids (PFSAs)) were distributed in different soil layers collected at three sites representing a distance gradient from a fluorochemical plant. Additionally, we examined correlations between multiple physicochemical properties of the soil (temperature, pH, clay content and total organic carbon (TOC)) and the PFAA concentrations in the soil layers. Finally, we tested the correlations between PFAA concentrations and microbial activity, microbial biomass and soil respiration in the top layer at five sites, along the same gradient. The only compounds that were detected in more than 50% of the soil samples were PFOA and PFOS. In the top layer, PFOS concentrations were positively correlated with pH and increased up to 2km away from the plant. Hereafter concentrations decreased. Similarly, PFOA concentrations were also positively correlated with pH and decreased at sites further than 2km away from the plant site. Soil temperature was not correlated with concentrations of PFOA or PFOS in the top layer. Soil respiration was positively correlated with PFOS concentrations, whereas microbial activity was not correlated with both PFOS and PFOA concentrations. The outcome of this study will provide more information on the factors that might affect sorption of PFAAs to soils and the potential effects of PFAAs on microbial communities in soil.

WE178
Implementation of bioavailability in the derivation of soil threshold concentrations for arsenic: linking ecotoxicological data with soil extractable metal concentrations and soil properties
K. Oorts, ARCHE; J. Roembke, J. Brack, B. Foerster, S. Jänsch, R. Minati, A. Scheffczyk, ECT Oekotoxikologie GmbH; D. Rückamp, Federal Institute for Geosciences and Natural Resources; E. Giese, Federal Environment Agency
Soil quality thresholds expressed as single total metal concentrations do not reflect the large variation in bioavailability of these metals across soils. A realistic risk assessment of metals in soil however should consider such bioavailability aspects. Therefore, the aim of this project is to connect bioavailable fractions of arsenic with ecotoxicological effect concentrations, taking into account soil properties (texture, pH, organic matter content etc) and various metal extractions (1M NH_4NO_3, 0.01M $CaCl_2$, $Ca(NO_3)_2$with ionic strength corresponding to soil solution, DTPA/$CaCl_2$, 0.43M HNO_3, aqua regia). Arsenic was chosen due to its high relevance as a soil contaminant, its low data availability compared to other metals and because it is an element of concern included in many soil regulations. Six soils covering a wide range of Central European soil properties were chosen and spiked with sodium arsenate dibasic heptahydrate (Na_2HAsO_4•$7H_2O$). Chronic toxicity endpoints were tested for several plants, invertebrates and microbial endpoints, according to ISO standard guidelines, allowing derivation of soil threshold concentrations via a species sensitivity distribution (SSD) approach. The ecotoxicity results (given as NOEC, $EC_{10}$and EC_{50}values) for the endpoints tested based on nominal concentrations, as confirmed by total (i.e. aqua regia extractable) concentrations, vary up to 2 orders of magnitude among the soils tested. The impact of soil properties and the variation in ecotoxicity among soils was however strongly dependent on the species and endpoint tested. The extraction strength of the different methods and soils differ at least by an order of magnitude and the order for most soils is NH_4NO_3< $CaCl_2$< $Ca(NO_3)_2$< DTPA < $HNO_3$and aqua regia. Expressing the ecotoxicological data based on the different extraction methods significantly affects the remaining variation in ecotoxicity results among soils and can decrease this variation among the soils tested to a factor of minimum 2 to 5. The best extraction method, i.e. resulting in least variation in toxicity data among soils, differs for the different species and endpoints tested. It is currently investigated to what extent the variation in soil properties can explain the remaining variation in toxicity data based on the different extraction methods. All this information will be combined and used to include bioavailability into the derivation of soil threshold concentrations for arsenic.

WE179
Removal of arsenic from natural waters by membrane technologies and adsorption
H.M. Valkama, E. Turpeinen, K. Kursula, B. Rathnayake, K. Ainassaari, University of Oulu / Environmental and Chemical Engineering Research Unit; I. Jordan, G.E.O.S. Ingenieurgesellschaft mbH; E. Muurinen, University of Oulu / Environmental and Chemical Engineering Research Unit; R. Keiski, University of Oulu / Environmental and Chemical Engineering
Arsenic contamination in agricultural soils and freshwaters is a serious and global threat to food production and safe water supply. High arsenic concentrations have been found in agricultural soils e.g. at chemical weapons destruction areas of the World War I in France and the old mining regions in Germany in Europe. Consequently, high loads of As and other pollutants are released to water systems from the remains of weapon destruction and former mining activities. To avoid pollution of adjacent areas, the leachate waters have to be collected and treated. To ensure food and fodder safety, the agricultural use of those areas requires particularly economically and environmentally sustainable treatment processes.\nThe aim of this research was to remove arsenic and other contaminants efficiently from polluted surface waters with membrane and adsorption technologies, and to evaluate the sustainability of these processes. First, arsenic removal by low-pressure reverse osmosis and nanofiltration was studied in screening experiments. Synthetic waters similar to the contaminated natural waters in the pilot areas in France and Germany were used and the effect of pressure and temperature was studied to determine the optimal conditions for arsenic removal. In addition, the removal of other contaminants was studied. The results show that membrane technologies are suitable purification methods for the synthetic waters and thus potential purification methods for the contaminated waters of the pilot areas.\nAfter the screening experiments, arsenic removal from real contaminated natural waters originating from the pilot area in France was performed. The experiments were conducted separately and sequentially by

membrane and adsorption technologies. A low cost schwertmannite based adsorbent prepared from side products was utilised in these experiments and compared with a commercial adsorbent. The results from the purification tests show that arsenic removal of the schwertmannite adsorbent was superior to that of the commercial one. Benefit from combining membrane technologies and adsorption into a hybrid process was also evaluated. The sustainability of the purification processes was evaluated based on data obtained from the experiments and literature. The ultimate aim of this research is to develop a sustainable arsenic removal process taking into account environmental, economic and social aspects.

WE180

What's in our Playgrounds? Distribution and Bioaccessibility of Metals in Urban and Peri-Urban Parks in Metro Vancouver, BC, Canada

M. Dodd, Royal Roads University / School of Environment & Sustainability; T.A. Fomunyam, M. Kavanagh, Royal Roads University

Metals can be introduced into urban soils including parks and playgrounds through natural processes, automobile exhaust and tire wear, metal fabrication and recycling industries and the use of inorganic fertilizers and pesticides. Exposure to metal contaminants in the soils can occur during use of parks and playgrounds through soil contact and incidental ingestion. This study investigated the potential human health risks associated with exposure to metals in soils at parks and playgrounds in Metro Vancouver, the third largest metropolitan area in Canada. One hundred and seven surface soil samples were collected from locations with high potential for human soil contact within 37 urban and peri-urban parks and playgrounds. The samples were analyzed for total metals, pH, total organic carbon and metal bioaccessibility. The relationships between metal concentrations and other physicochemical properties to point source emissions, surrounding land use and proximity to major traffic corridors were explored to ascertain the potential sources of the identified metal contaminants and factors which contributed to their introduction into the environment. Arsenic, copper, lead or zinc concentrations exceeding the Canadian Council of Ministers of the Environment soil quality guidelines for residential/parkland use were identified in soils from five of the parks investigated. Metals bioaccessibility values were variable; the mean values for select metals were As: 25%, Cd: 63%, Cr: 3.2%, Co: 12%, Cu: 33%, Ni: 11%, Pb: 51% and Zn: 24%. The results of the human health risk calculations incorporating bioaccessibility, the relationships between soil properties and bioaccessibility, and the plausible sources of the identified contaminants will be presented.

WE181

Assessing risks to soil function at a site impacted by DDT using the TRIAD approach

M. Florberger, R. Moraes, K. Nilsson, Golder Associates AB; K. Forsberg, H. Persson, Geological Survey of Sweden; H. Branzén, J. Vestin, Swedish Geotechnical Institute; M. Viketoft, A. Taylor, Swedish University of Agricultural Sciences SLU

For nearly 50 years a former division of the Swedish Forest Agency operated a plant nursery in Kårehogen located on the west coast of Sweden where different pesticides, including DDT, have been used. Today, investigations and remediation regarding on-site contamination is under the responsibility of the Geological Survey of Sweden. Previous studies have shown DDT concentrations in soil above the Swedish generic guideline value for sensitive land use (0,1 mg/kg), developed by the Swedish Environmental Protection Agency. Dimensioning for the value is the protection of the soil ecosystem. The objective of this study is to conduct a site-specific ecological risk assessment using the TRIAD approach (ISO 19204), where chemical, toxicity and ecological lines-of-evidence are evaluated to assess potential effects on soil ecosystem function at the Kårehogen site. Although the basic ideas of the TRIAD approach (e.g. the combination of information from chemistry, ecotoxicology, and ecology) have been accepted in Sweden, a national framework has not yet been developed, and its application in risk assessments of contaminated soils is rare. Thus, one additional objective is also to test the applicability of the TRIAD approach for soils contaminated with DDT. The same investigations and surveys were conducted at the impacted site and at a nearby reference site, which has similar soil physical and chemical conditions and vegetation cover, but with no evidence of use or impact by DDT or other pesticides. Concentrations of DDT and derivates were measured in 10 surface soil samples (0-30 cm deep) from each site. DDT in earthworm tissue was analyzed in 10 samples from the Kårehogen site. Effects on the invertebrate community were measured as abundance of earthworms, collembolas and nematodes, and species composition and biomass of earthworms at the 10 locations in each site. Effects on reproduction of earthworms (ISO method 11268-2) and collembola (ISO method 11267-2) were assessed using chronic toxicity tests on five surface soil samples from each site. The same soil samples were evaluated for potential impacts on the microbial activity using nitrogen and carbon tests (OECD tests 216 and 217). Results and the conclusion of the risk assessment will be presented. Additionally, the benefits and possible application of the TRIAD methodology in the approximately 40 other former plant nurseries currently administrated by the Geological Survey of Sweden will be discussed.

WE182

Soil vertical profiles and fate of Hg in different agricultural areas within a large historically contaminated site

C. Morosini, University of Insubria / Department of Science and High Technology; E. Terzaghi, University of Insubria (Como) / Department of Science and High Technology, Como; E. Zanardini, University of Insubria / DISAT; G. Raspa, Sapienza University of Rome / Department of Chemical Engineering Materials and Environment; S. Borin, DeFENS University of Milan / Department of Food, Environmental and Nutritional Sciences; F. Mapelli, University of Milan- DeFENS / Department of Food, Environmental and Nutritional Sciences; S. Armiraglio, Municipality of Brescia / Museum of Natural Sciences; V.M. Sale, S. Anelli, P. Nastasio, ERSAF; A. Di Guardo, University of Insubria / Department of Science and High Technology

Among the national priority polluted sites, the SIN Brescia Caffaro is located in a mid size city, Brescia (200,000 inhabitants), in northern Italy. The Caffaro factory was among the largest former polychlorinated biphenyls (PCBs) producer in Europe and due to its chloro-alkali process, using mercury cells, released metallic mercury into the wastewater stream, which ended up in an irrigation canal. Such irrigation water was used in different crops for about 50 years, on about 100 Ha. In this project, Hg was measured in three different former agricultural areas (A, R, T, three different points per area), in vertical cores of up to 1 m depth. The resulting samples were representative of 0-10, 10-20, 20-30, 30-40, 40-60, 60-80, 80-100 cm. The three areas were selected based on their different use of soil: i) the points in area A belong to an area characterized by soil conditions typical of a mixture of grass and arable land, continuously irrigated, during winter, by contaminated waters (water meadow). Such situation could be responsible for oxygen content reduction in soil, by contributing to create prolonged anoxic conditions, favorable to Hg release; ii) the points in area R are representative of a former semi permanent grassland, before and after PCBs production, with a short break due to a conversion to arable land during PCBs production; iii) the points in area T are typical of an area which was characterized by intense plowing and continuous mixing of arable layer. These conditions were responsible for relatively large differences in concentration profiles among the areas. The results of concentration measurements with depth confirmed a general tendency of mercury to be confined to the upper 40-60 cm, while, in some cases, concentrations were higher at greater depths. A speciation analysis was also conducted. The results allow to reconstruct the soil concentration profiles during the historical contamination and to predict the vertical movement as well as the amount of mercury volatilized in time. Finally, such results can be also used to evaluate the potential losses of mercury to air and groundwater during the future phytoextraction-based remediation actions.

WE183

No-Till agriculture for reducing effects of groundwater salinity and contamination in corn cultures using experimental microcosm

S. Bouguerra, GreenUPorto & Faculty of Sciences, University of Porto / Dept Biology Faculty of Sciences of the University of Porto; B. Rodrigues, Faculty of Sciences, University of Porto; C.F. Soares, F. Fidalgo, GreenUPorto & Faculty of Sciences, University of Porto; A. Cachada, CIIMAR; R. Pereira, GreenUPorto & Faculty of Sciences, University of Porto / Dept Biology Faculty of Sciences of the University of Porto

Agriculture is one of the most important and oldest economic activities in the district of Estarreja in Portugal. The irrigation of agriculture land is mainly based on the use of groundwater, exploiting the quaternary aquifer. Nevertheless, several studies showed the presence of nitrates, chlorates, organic and inorganic contaminants, and a high conductivity level in well waters. Observed contamination was mainly due to the various industrial activities in the area and in particular to the “Estarreja Chemical Complex.” The use of these waters to irrigate agriculture fields was expected to affect soil’s quality and increase their level of salinization, which interferes with plant nutrient absorption and alter the soil properties and functions. Thereby, it is expected that using the appropriate farming practices a sustainable production could be established. Several studies pointed out the importance of the no-tillage (NT) system farming for improving soil quality such as increasing soil porosity, reducing soil salinity stress (above 70%), and enhancing soil organic matter. In this context, the development of NT farming system can be beneficial. Therefore, with the present work it is intend to study the ability of NT farming strategies to minimize impacts on soil and corn (*Zea mays* L.) culturesirrigated with contaminated groundwater, comparing to the present farming practice (tillage farming). For this purpose, a plant-soil microcosm experiment was used. *Zea mays*was seeded and grown on agricultural soil after *Trifolium repens*sp (the white clover) decay, which was used as green manure, and left in soil surface (no till) or incorporated into soil (till). The evaluation of both practices was based on measuring physico-chemical changes in soils and some ecological indicators such biochemical and physiological parameters in treated agricultural soil and cultivated plants, respectively. The gathered results indicate that groundwater irrigation significantly increases soil’s salinization and contamination in both agriculture systems and resulted in inhibition of plants growth. However no-till system seems to be not sufficient to minimize damage in soils and cultivated plants. The results also reinforce the urgent need for studies to mitigate the negative impacts of irrigation practice in Estarreja.

WE184
Salinization effects on soil ecosystems: a SSD approach
C.S. Pereira, CFE - Centre for Functional Ecology / Department of Life Sciences University of Coimbra; A. Bednarska, Institute of Environmental Sciences, Jagiellonian University in Krakow / Institute of Nature Conservation; R. Laskowski, Institute of Environmental Sciences, Jagiellonian University in Krakow / Ecotoxicology & Stress Ecology Group; J. Sousa, University of Coimbra - Centre for Functional Ecology / Department of Life Sciences; S. Chelinho, CFE Centre for Functional Ecology / Department of Life Sciences of University of Coimbra
Salt-affected soil areas are increasing worldwide with negative consequences for soil fertility and biodiversity. Soil fauna and flora have been proved to be affected by saline conditions. However, no safety values of salinization for soil ecosystems have been derived. The aims of this study were: 1) to assess the effects of soil salinization on the reproduction and survival of soil invertebrates, and on the germination and biomass of agricultural plants, as well as 2) to derive safety values of salinization for soil ecosystems. To fulfill the first goal, the survival and reproduction of 8 soil invertebrate species (4 annelids and 4 arthropods), and the germination and growth of 6 agricultural plant species (3 monocotyledonous and 3 dicotyledonous) were evaluated through standard laboratory assays. The EC_{50s}were calculated for each species using the mean of the soil conductivity measured at the beginning and the end of each test (in a ratio of 1:5 soil:water fresh weight). Results showed that reproduction of soil invertebrate species was affected at lower salinity levels than their survival, with EC_{50s}ranging from ca. 50 μS/cm for the most affected earthworms to 900 μS/cm for the least affected mites. Regarding plant species, the parameter affected at lower salinity levels was the germination at the beginning of the test (IG), while no effect of salinization was found for root biomass. The sensitivities of both monocotyledonous and dicotyledonous seemed to be similar in terms of IG, with EC_{50s}ranging from ca. 600 to 1300 μS/cm. To fulfill goal (2), Species Sensitivity Distributions (SSD) were performed using the EC_{50s}obtained for soil invertebrate reproduction or the EC_{50s}obtained for IG of plants. Hazard conductivity values (HC) affecting 10 and 50% of the invertebrate species tested were ca. 180 and 820 μS/cm, respectively; while for the plant species tested, the HC10 and 50 were ca. 580 and 810 μS/cm, respectively. All values are below conductivity values measured in natural saline soils. For example, conductivity values measured using the same method in a South African soil is ca. 1650 μS/cm. At that salinity, the reproduction/IG of all tested invertebrate and plant species would decrease by at least 50%. The derivation of safety values for soil salinization towards soil ecosystems is of great need, but the sensitivity of communities in areas already exposed to saline stress should be also incorporated as their sensitivity might be different from non-exposed ones.

WE185
ECOLOGICAL SAFETY AND EFFECTIVENESS OF ANIONIC AND NON-IONIC SYNTHETIC SURFACTANTS FOR OIL-CONTAMINATED SOILS AND SLUDGE TREATMENT
O. Kulikova, Gubkin University / Institute for Industrial Ecology; E. Mazlova, Gubkin University; V. Terekhova, Lomonosov Moscow State University / Lab of Ecotoxicological Soil Analysis; M. Agadzhanyan, Gubkin University
A reagent method for oil-contaminated soils and oil sludge treatment has several advantages and disadvantages. The benefits include the economy of clean water for soil washing, increasing the efficiency of dispersion separation, the possibility of extracting oil as a valuable resource, preparing the soil for subsequent phyto- and bioremediation. However, the reagent method is characterized by the secondary pollution with toxic substances, changes in the morphological characteristics of soils. Thus, the study of the chemical reagents toxicological properties is one of the important steps determining the surfactant applicability for the intended purposes. Synthetic surfactants used as chemical reagents for treatment (washing) of oil-contaminated soils and oil sludge must have met the environmental safety requirements. The research objective was determination of the biotoxicity level and effectiveness of an anionic and non-ionic surfactants. Laboratorial test was conducted for variety of surfactants; their biotoxicity was elucidated for the freshwater infusorians *Paramecium caudatum* Ehrenberg. The tests results would make it possible to create surfactant applicability matrices for various purposes. In this matrix graphically depicts the risks of selecting surfactants for oil-contaminated natural soils treatment. The matrix shows that highly effective, but toxic surfactants can't be considered applicable for the natural soils reclamation. However, these chemical reagents still can be used for oil sludge treatment, since after cleaning, their return to the environment is not provided. From the above, it follows that the choice of a chemical reagent for oil-contaminated soils or oil sludge treatment should be based on various requirements for environmental safety, toxicity of the surfactants under consideration.

WE186
A low cost, real-time measurements of CO2 uptake/emission as an early indicator of exposure to xenobiotics in plants and animals
T. Djerdj, Department of Biology, University of Osijek / Department of Biology; V. Peršić, Department of Biology University of Osijek; N. Stjepanović, University of Osijek / Department of Biology; D.K. Hackenberger, B.K. Hackenberger, Department f Biology, University of Osijek / Department of Biology
Respiratory rates of metabolically active organisms are objectively quantifiable, reflecting the magnitude of living processes essential for the survival of cells and organisms, in terms of its chemical products - particularly CO_2. Changes in environmental conditions as well as exposure to various xenobiotics result in alternations of metabolic activity that are reflected in CO_2 production/uptake dynamics. In this study we wanted to explore the usability of CO_2 uptake/emission measurement using low-cost sensors in continuous monitoring as an early indicator of exposure to xenobiotics in experimental organisms (plants and earthworms) and to compare it to different biochemical biomarkers. For the measurement of CO_2 an Arduino platform-based respiratory activity measuring system (ResTox) comprising sensors for measuring parameters relevant for the analysis of biological activity was developed. For plant experiments a *Lemna minor* was exposed to several metals: $HgCl_2$, $CuCl_2 \times 2H_2O$, $CdCl_2$ and $CoCl_2 \times 6H_2O$ and herbicides: diquat, clopyralid, nicosulfuron and tembotrione, separately. And for animal experiments three earthworm species (*Eisenia fetida*, *Dendrobaena veneta* and *Lumbricus terrestris*) were exposed to chlorpyrifos and copper oxide in nano form in both filter paper and artificial soil set-up. The results of CO_2 measurements in *L. minor* demonstrated that tested metals (Co, Cu, Hg, and Cd), as well as herbicides (nicosulfuron, diquat, and tembotrione), stimulated the CO_2 exchange rates at low doses, while at high doses CO_2 exchange rates were inhibited. CO_2 production data obtained in experiments involving earthworms exposed to chlorpyrifos and nCuO showed a dose-response type relationship between the concentration of toxicant and the amount of CO_2 produced, while the changes in measured biochemical biomarkers corresponded to those changes. With these experiments a continuous measurement of CO_2 exchange rates could be implemented as a promising tool for the initial screening of potential toxicity to obtain valuable information needed for further examination of toxicity mechanisms and risk assessment in both plant and animal organisms.

WE187
Statistical framework for regulatory risk assessment of field studies for soil organisms
Y. Bayona, F. Brulle, A. Boivin, ANSES / U3EIV
A regulatory risk assessment is performed for all Plant Protection Products (PPP). For the ecotoxicological risk assessment, a large range of organisms testing according to current guidance and assessment according to regulation 1107/2009 are required usually following a Tiered Approach. Regarding the soil organism, risk assessment covers worst-case situations (*i.e* conservative estimates and toxicity laboratory studies) to more realistic assessment (*i.e.* Field studies). A recent EFSA scientific opinion on "the state of the science on risk assessment of plant protection products for in-soil organisms" proposed a new framework for risk assessment of soil organisms and an revised protection goals defined for soil organism groups (*i.e.*, enchytraeids, arthropods etc…). Still, no statistical tool was made available to analyze field studies proposed for higher tier. The aim of the present work is to propose a statistical framework of existing tools already used for higher tier studies risk assessment at scale of population and communities. The statistical framework include community analysis that allow including the overall soil community decribed on the field. This last is based on multivariate analysis or generalized linear models. The population density and/or biomass are compared date-by-date using univariate test. The percent Minimum Detectable Difference (%MDD, Brock et al., 2015) should be also include to ensure the reliability of core data for the statistical analysis of comparison between treated and control populations. The ISO guidance for earthworm field studies (2014) provide the experimental setting recommendation for selecting the field, plots size and margin between them, as well as sampling and extraction of earthworm. ISO guidance on "Soil quality: effects of pollutants on earthworms" also provide some validity criteria especially regarding the sampled density of earthworm (number of individual /m²). Therefore, it is also noticed here that the %MDD may also be used to adapt the sampling strategy during the preliminary investigate of the chosen site to obtain a relevant number of earthworm (*e.g.* may be mitigate by increasing the number of plot or their size). This work could help to fill the current lack of harmonized statistical framework for field studies of soil organisms in the context of regulation of PPP.

Novel Developments in Testing Chemicals for Endocrine Disrupting Properties (P)

WE189
Plant protection products, endocrine disruptors and amphibians - where to start?
V. Mingo, J. Baumann, J. Wiewel, Eurofins Agroscience Services Ecotox GmbH /

Aquatic Ecotoxicology; B. Szczesniak, M. Candolfi, Eurofins Agroscience Services Ecotox GmbH; V. Schiller, Fraunhofer IME / Aquatic Ecotoxicology

Amphibians are gaining an increasing prominent role in the field of ecotoxicology. Especially, the lacking data and uncertainty regarding potential sublethal effects, as well as different modes of action of pesticides and endocrine disruptors in amphibians when compared to fish has been of increasing concern in the last few years. Recently, a scientific opinion regarding the need to evaluate the risks of pesticide applications to amphibians and reptiles was published by EFSA. Here, it became very clear that ecotoxicological data regarding these taxa is greatly lacking, and methodologies need to be adapted in order to complete a reliable risk assessment scheme. Similarly, regulations EC 1107/2009 and EC 528/2012 were recently amended in order to incorporate the assessment of endocrine disruptors with regard to aquatic organisms. It is generally accepted that in the majority of cases, acute toxicity of amphibians is covered by aquatic testing on fish. However, there are still many concerns whether this may also apply to sublethal effects such as development, gonadal development and metamorphosis. In light of the differing life-history and peculiar developmental biology of amphibians, this is of special importance. In an attempt to discern between the potential different sensitivities and effects of endocrine disruptors (e.g. pesticides) on these two different taxa, we conducted two tests using the same concentrations of an endocrine disrupting pesticide using *Oryzias latipes* and *Xenopus laevis* as test organisms.

WE190

Implication of Control Variability in Point Estimated-Based Assessment of Thyroid Disruption in the Amphibian Metamorphosis Assay

S. Pawlowski, M. Dammann, S. Champ, BASF SE; I. Herrmann, BASF SE, Agrarzentrum Limburgerhof; M. Petersen-Thiery, BASF Personal Care and Nutrition GmbH; M. Mathis, D.J. Fort, Fort Environmental Laboratories, Inc.

In accordance with OECD Test No. 231 and USEPA Test Guidelines OPPTS 890.1100, the amphibian metamorphosis assay (AMA) represents a level 3 test within the OECD conceptual Framework for Endocrine Disrupting (EC) chemicals. The test exposes Nieuwkoop and Faber (NF) (5) stage 51 *Xenopus laevis* larvae to different concentrations of the test substance for 21-days and the following endpoints are measured: mortality, hind limb length (HLL), body length (snout to vent [SVL]), body weight, developmental stage, asynchronous development, and thyroid histopathology. Of these endpoints, SVL and body weight are considered measures of growth, whereas developmental stage, asynchronous development, HLL, and thyroid histopathology are considered in the assessment of thyroid axis disruption. Presently, guidance for the test provides a design for the establishment of concentration-based endpoints, but not ECx (i.e. EC10) values. Despite the ongoing regulatory discussion regarding the use of derived effect concentrations (ECx) rather than no effect (NOEC) values from chronic environmental studies, several requests have already been made by European member states to use ECx threshold in lieu of NOEC values. Specifically, the derivation of an EC10 value was requested by regulatory authorities for AMA studies. However, the biological variation of the test system was not considered resulting in uncertainty regarding the usefulness of this endpoint. The European Water Framework (WFD) Directive guidance document includes both EC10 and NOEC derived options, with no specific preference. However, additional investigation indicated that control variability in the AMA was greater than 10%, and thus the derivation of an EC10 value was of no biological relevance and therefore should not be used for regulatory purposes. To further evaluate the implication of control variability on the derivation of point estimates in AMA studies, control variability was assessed in 10 independently conducted AMA studies. Results of these analyses and the implications on the interpretation of AMA results will be presented.

WE191

Screening thyroid hormone disruption mechanisms of several chemicals using hepatic cell lines of human, rat, and zebrafish origin along with rat pituitary cell line

B. Kwon, School of Public Health, Seoul National University / Graduate School of Public Health; M. Kim, G. Jung, H. Kim, Y. Park, Seoul National University Hospital / Department of Internal Medicine; B. Oh, Lee Gil Ya Cancer and Diabetes Institute, Gachon University College of Medicine / Department of Physiology; S. Chu, J. Kim, Seoul National University / School of Public Health; S. Kim, Seoul National University of Science and Technology / Department of Environmental Engineering; K. Choi, Seoul National University / School of Public Health

Many chemicals that are frequently detected in humans can disrupt thyroid hormone balances. Since thyroid hormones play key roles in energy metabolism, growth, development, and reproduction, such disruption could lead to various health consequences. However, there are significant gaps in knowledge on mechanisms of the disruption, especially on metabolism in the liver. The present study was designed to understand the effects of several model chemicals on thyroid hormone metabolism using liver cell lines of different origin, i.e., human, rat, and zebrafish. For this purpose, human liver cell (Hep G2), rat liver cell (McA-RH7777), and zebrafish liever cell (ZFL) were chosen. In addition, a rat pituitary cell (GH3) was also used to understand the effect of these chemicals on central regulation of thyroid hormone balance. As test chemicals, five known thyroid disrupting chemicals (TDCs) based on either epidemiological or experimental studies, i.e., *p,p'*-DDE, PFOS, DEHP, BPA, and BP-3, were chosen. In addition, two more chemicals that are used in great quantity as sunscreen and plasticizer, i.e., EHMC, and DINCH, were also added. Following exposure to various concentrations of selected chemicals for 24 hours (Hep G2 and McA-RH7777) or 48 hours (ZFL and GH3), transcriptional changes of key genes were quantified using RT-qPCR. Exposure to PFOS and BPA significantly down-regulated *TBG* gene and up-regulated *PPARA* and *UGT1A1* gene in Hep G2 cells ($p < 0.05$). Regulatory changes of *DIO1* gene were observed but the direction varied by chemical substances. In McA-RH7777 cells, exposure to EHMC significantly down-reglated *Ugt1a1*, *Dio1*, *Ttr*, *Sult1b1* and *Ppara* genes ($p < 0.05$). However, the rest of chemicals did not show significant regulatory changes. In ZFL cells, exposure to BPA caused significant up-regulation of *ugt1ab* gene ($p < 0.05$). In addition, marked increase pattern of *ugt1ab* gene was shown following exposure to *p,p'*-DDE, DEHP, or BP-3 (>1.5 fold change). In GH3 cells, exposure to *p,p'*-DDE caused significant down-regulation of *Tshb* gene, while exposure to EHMC up-regulated *Tshb* and *Trhr* genes. The results of this study show possible species difference in hepatic metabolism of thyroid hormones or thyroid disrupting chemicals. Futher experimental studies are warranted to validate our observsations and to describe consequences in thyroid hormone regulation in vivo.

WE192

Thyroid disruption screening method using zebrafish vertebrate model

O. Jaka, C. Martí, M.J. Mazón, BioBide; A. Muriana, BioBide / RD; I. Iturria, BioBide / R&D Department

Endocrine Disrupting compounds are being increasingly detected in the environment and may have a profound impact on the development and physiology of vertebrate organisms. Thyroid Disrupting (TD) compounds specifically alter the function of thyroid gland through the interference with the synthesis, transport and/or binding of the thyroid hormones. Several environmental contaminants such as polybrominated diphenyl ethers or halogenated organophosphates, used as plasticizers and flame retardants, are suspected to produce a TD effect. Given so, chemical manufacturing entities could benefit from cost-effective methodologies for the screening of TD substances in order to deselect candidates during the early phase of the development. The zebrafish vertebrate model is broadly used in both human and aquatic toxicity assessment due to their low cost, small size, rapid development, and homology with mammals. Besides, the existence of numerous transgenic strains enables to perform fluorescence-based screening assays with medium throughput. In this work, a screening method for TD substances assessment was developed using the Tg(tg:mcherry) transgenic zebrafish line. The fluorescence of the reporter gene allows monitoring *in vivo* the upregulation of the thyroglobulin gene expression as a compensatory reaction to thyroid gland disruption. In this assay, the exposure concentrations of test substances were selected according to the results of a preliminary acute toxicity assay to avoid any interference by non-specific toxicity. Afterwards, transgenic embryos were exposed to the test substances from 48 to 120 hpf (hours post-fertilization) and subsequently imaged by fluorescence microscopy. A dose-dependent increase of the fluorescence was observed, and the intensity values were fitted to a concentration-response regression model to calculate TD predictors, such as the Benchmark Concentration (BMC), Thyroid Disrupting Index (TDI), and Relative TD Potency (RTP). Finally, an rt-qPCR gene expression assay was developed over known markers of thyroid pathway (tshβ, tg, and tpo) to characterize the mechanism of action involved in the endocrine disrupting effect. The screening method presented in this work has been developed and validated using a set of 19 environmentally relevant TD substances. This screening methodology showed to be a sensitive and cost-effective assay to evaluate the potential thyroid disruptor activity of chemicals.

WE193

Toward an AOP-based tiered testing strategy for thyroid hormone disruption in fish

D. Knapen, University of Antwerp / Zebrafishlab Dept Veterinary Sciences; E. Stinckens, University of Antwerp; L. Vergauwen, University of Antwerp / Zebrafishlab Dept Veterinary Sciences & SPHERE Dept Biology; J.E. Cavallin, Badger Technical Services, U.S. EPA / National Health and Environmental Effects Research Laboratory; G.T. Ankley, U.S. Environmental Protection Agency / National Health and Environmental Effects Research Laboratory; D.L. Villeneuve, U.S. Environmental Protection Agency / Mid-Continent Ecology Division

Assessment of thyroid hormone disrupting chemicals (THDCs) is considered a major gap in current approaches for the testing of endocrine disrupting chemicals. The thyroid hormone system is involved in several important physiological and developmental processes, and many chemicals found in our environment may interfere with the thyroid system. The need to advance screening and testing strategies for THDCs includes the development of *in silico* and *in vitro* methods that anchor chemicals acting through a thyroid mechanism to adverse responses.The Adverse Outcome Pathway (AOP) framework may therefore be particularly helpful for the identification of relevant assays and endpoints. Here, we demonstrate the use of *in chemico* assays targeting specific key events of an established AOP network to predict higher biological endpoints in fish early-life stages. Specifically, an AOP network linking thyroid hormone disruption to impaired swim bladder inflation was used to select assays measuring thyroperoxidase and deiodinase inhibition, key enzymes in the thyroid hormone metabolism. A set of 51 compounds was screened using these assays, and data were used to predict acute and chronic effects on swim bladder inflation. Predictions were validated using FET and FELS *in vivo* experiments in zebrafish and fathead minnow, and *in chemico* to *in vivo* extrapolation threshold values were established. A tiered testing strategy for the identification of THDCs was proposed based on these data. Our thyroid hormone disruption AOP network is part of the OECD AOP development programme workplan (project 1.35), and the associated assays align with the thyroid-related assays that are listed in the OECD Conceptual Framework for Testing and Assessment of Endocrine Disrupting Chemicals (revised 2018) as assays forwhich no formal guidance has been written at present. In addition, as part of their endocrine disruptor screening program, the US EPA included this work while assembling a conceptual thyroid hormone disruption AOP network spanning different taxonomic groups (fish, amphibians, mammals) to assist high throughput assay development. The ongoing JRC EURL ECVAM validation effort of *in vitro* assays for THDCscreening is making use of this project's data to ensure synergies and overlap. Finally, our AOP network will be used as background for the H2020 project ERGO, "Breaking down the wall between human health and environmental testing of endocrine disrupters".

Thyroid disruptors interfere with eye development and function in zebrafish

L.A. Baumann, University of Heidelberg / Aquatic Ecology and Toxicology; H. Segner, University of Bern / Centre for Fish and Wildlife Health; T. Braunbeck, COS University of Heidelberg / Aquatic Ecology and Toxicology; D. Knapen, University of Antwerp / Zebrafishlab Dept Veterinary Sciences; L. Vergauwen, University of Antwerp / Zebrafishlab Dept Veterinary Sciences & SPHERE Dept Biology

Vertebrate eye development is partly regulated by thyroid hormones (THs). We investigated the effects of thyroid-disrupting chemicals (TDCs) on eye development of zebrafish at morphological and transcriptional level. To this end, zebrafish embryos were exposed to either propylthiouracil (PTU), a TH synthesis inhibitor, or tetrabromobisphenol A (TBBPA), which interacts with TH receptors, until 5 days post fertilization (dpf). The TDC exposure induced reduction of eye size and pigmentation together with altered cellular retina structure. We expected the TDC exposure to cause transcriptional changes of visual-system-related genes, which find their phenotypic anchoring in the observed eye malformations. Moreover, we investigated if the different TDC modes of action would affect similar molecular pathways in the eyes. Full genome microarray analyses of RNA isolated from eye tissue revealed that the number of affected transcripts was substantially higher in PTU- than in TBBPA-treated larvae. However, multiple essential components of phototransduction (e.g. phosphodiesterase, opsins) were responsive to both TDC exposures. Yet, the response pattern for the GO-class "sensory perception" differed between treatments, with over 90% down-regulation in PTU-exposed fish, compared to over 80% up-regulation in TBBPA-exposed fish. Additionally, the reversibility of effects after recovery in clean water for 3 days was investigated. Transcriptional patterns were still altered, and partly overlapped between 5 and 8 dpf, showing that no full recovery occurred. However, pathways involved in repair mechanisms were significantly upregulated, which indicates activation of regeneration processes. These results confirm the growing evidence that fish eye development is sensitive to TDC treatment and might represent a promising endpoint for the assessment of thyroid-related effects in fish.

WE195

Interference of hepatotoxicity with endocrine activity in fish

L.A. Baumann, University of Heidelberg / Aquatic Ecology and Toxicology; H. Holbech, University of Southern Denmark / Biology; L. Weltje, BASF SE / Agricultural Solutions - Global Ecotoxicology; H. Schmidt-Posthaus, H. Segner, University of Bern / Centre for Fish and Wildlife Health; T. Braunbeck, COS University of Heidelberg / Aquatic Ecology and Toxicology

Vitellogenin (VTG), a well-established biomarker for the diagnosis of endocrine activity in fish, is used in multiple OECD test guidelines to identify (anti)estrogenic activities of test compounds. However, the synthesis of VTG may not only be modified by typical endocrine-related pathways, but also through non-endocrine-mediated processes. In particular, hepatotoxicity, i.e. toxicant-induced impairment of liver structure and function, might influence VTG as a biomarker, since it is synthesized in hepatocytes. An intimate understanding of the interplay between primary endocrine-related and non-endocrine-related pathways influencing VTG production is crucial for the avoidance of false diagnoses in hazard assessment, since endocrine disruption is used as a cut off criterion for biocide and plant protection product active substances in Europe. To investigate whether hepatotoxicity may interfere with VTG synthesis in the liver of exposed fish, effects by three well-known hepatotoxicants, acetaminophen (APAP), isoniazid (INZ) and acetylsalicylic acid (ASA), were tested in adult zebrafish (*Danio rerio*) in a 21-day flow-through exposure test according to OECD test guideline 230. Various hepatotoxicity- and endocrine system-related endpoints were recorded: mRNA expression of selected endocrine-related and hepatotoxicity-related marker genes in the liver; protein levels of VTG in head/tail homogenates; liver histopathology. All three test compounds induced mild, but significant single cell necrosis of hepatocytes and transcriptional changes of the hepatotoxicity-related marker genes, which confirmed the hepatotoxic effects of the chosen compounds, even though effects were not pronounced. Only minor changes in VTG levels were observed, which were neither compound- nor gender-specific, nor did the substances evoke a uniform VTG response. Likewise, transcriptional responses of endocrine/estrogen-related genes in the liver were sex- and compound-dependent and indicating that the hepatotoxicants investigated did not have major (indirect) impacts on endocrine activity. The results show that a clear correlation between hepatotoxic effects and VTG synthesis in the liver could not be demonstrated in the chosen exposure scenario. This suggests that − under the exposure conditions of OECD TG 229 and 230 − it is unlikely that chemicals cause hepatotoxic effects interfering through this mode of action with the hepatic capacity for VTG synthesis.

WE196

The Extended one generation reproduction test with zebrafish, first results from a validation study with tamoxifen-citrate

M. Teigeler, E. Eilebrecht, Fraunhofer IME / Ecotoxicology; S. Kroesen, Fraunhofer IME - Institute for Molecular Biology and Applied Ecology / Ecotoxicology; H. Holbech, University of Southern Denmark / Biology; G. Maack, German Environment Agency / Ecotoxicological Assessment; S. Walter-Rohde, Environment Agency Germany, Dessau-Roßlau, Germany

After acceptance and enforcement of the criteria for identification of endocrine acting substances (EAS), there is increasing need for valuable testing strategies and methods. In this context, fish populations are considered as main targets of endocrine acting compounds in the aquatic environment. In 2015, OECD adopted a protocol for an Extended one generation reproduction test (EOGRT) with Medaka (*Oryzias latipes*). This test protocol includes the exposure of a parental generation (adult fish), a full Filial 1 (F_1) generation (from egg to adult) and a Filial 2 (F_2) generation (until hatch of embryos). As this protocol was designed and validated for a single test species, there was an initiative from Germany to develop a similar test approach considering zebrafish (*Danio rerio*) as a further species. The development of the Zebrafish EOGRT protocol was placed on the OECD workplan in 2016. The protocol considers the timeline as developed for the Medaka EOGRT but adds some method adjustments like true replication of test tanks, absence of tissue samplings during the test and the focus on more species-appropriate settings. Due to the lack of a gene locus defining the genetic sex, a genetic sex determination is excluded from the Zebrafish procedure. First results from a validation study with tamoxifen citrate, a known estrogen receptor antagonist, are available. The data obtained were in line with literature data for zebrafish and other fish species. Comparable sensitivity was observed for e.g. reproduction parameters in terms of fecundity and fertility. A shift in sex ratio towards an increased number of males was observed and defined as the most sensitive endpoint with population relevance. Biomarker measurements revealed a decrease of vitellogenin concentrations in female blood plasma samples. Decreased survival rates for juvenile fish of F_1 and F_2 generation showed corresponding effects levels. It can be postulated, that these effects were the result of an impacted egg qualily. These results confirm the applicability of the test protocol. The data obtained is valuable to identify sensitive endpoints and gain mechanistical information used for ED assessement.

WE197

The impact of synthetic progestins on fish populations: Results from a Zebrafish EOGRT with Dienogest

M. Teigeler, E. Eilebrecht, Fraunhofer IME / Ecotoxicology; G. Maack, German Environment Agency / Ecotoxicological Assessment; S. Schwarz, Umweltbundesamt (UBA) / Animal Physological Ecology; J. Bachmann, German Environment Agency (UBA) / Section IV2.2 Environmental Risk Assessment of Pharmaceuticals

The intake of endocrine acting substances (EAS) can represent a relevant threat scenario for the aquatic environment. Due to a very direct route of exposure, fish populations are recently in the main focus of environmental science and research. The release of human pharmaceuticals and veterinary drugs is steadily increasing. Moreover, the progress in pharma science aiming to design new active pharmaceutical ingredients (API) results in the development of sufficiently stable, specific and potent molecules. There are many examples for substances acting already at very low concentration levels and finally causing adverse effects in the aquatic environment, expecially on fish populations. The regulation of pharmaceuticals increasingly considers the impact on the environment. A current project of German Environment Agency (UBA) aims to develop a tailored risk assessment strategy for the group of new synthetic progestins and glucocorticoids. Effects on aquatic vertebrates, invertebrates and sediment dwellers should build a data base for developing this adapted assessment strategy. Here we present results from a Zebrafish extended one generation reproduction test (ZEOGRT). The synthetic progestin dienogest was chosen as test substance. The study followed a new test protocol for a two generation test with zebrafish (*Danio rerio*), including the continuous exposure of a parental generation (adult fish), a full filial 1 (F_1) generation and finally a filial 2 (F_2) generation (hatch only). The results showed no impact of dienogest exposure to reproduction capability of the parental generation. However, a clear reduction of F_1 post hatch survival was found. Further endpoints to be assessed will be life stage specific growth and survival rates, reproduction in terms of egg number and fertility for F_1, and sex ratio. The available results confirmed the applicability of the chosen study protocol and already show an increased sensitivity of fish compared to other inhabitants of the aquatic environment, also exposed to progestins.

WE198

A lifetime exposure to bisphenol S up to 10 mg/L does not adversely affect growth, reproduction or sex ratio of zebrafish

E. Salinas, BASF SE / Eperimental Toxicology and Ecology; O.T. Schmid, BASF SE / Product Stewardship Engineering Plastics

Bisphenol S (BPS) is used as an intermediate (monomer) in the production of high performance plastics and other polymers and discussed as an alternative for bisphenol A in thermal paper. Several published studies have investigated the effects of long term exposure to BPS on zebrafish and reported endocrine activity at μg/L concentrations. However, there is no consistency among the published studies on the chronic exposure level which results in systemic or reproductive toxicity to zebrafish. In response to an ECHA decision on a substance evaluation for BPS, we conducted a range finding study in zebrafish with the objective to identify a 32-d growth LOEC to use as the high concentration for a definitive extended one generation reproduction test (EOGRT). The study consisted of a negative control and the following concentrations of BPS in groups of 2 replicate aquaria (20 eggs/rep): 0.0032, 0.01, 0.032, 0.1, 0.32, 1.0, 3.2, 10 mg/L. A broad concentration range was investigated in response to the disparity among the published results and exposure concentrations were verified. No adverse effect on growth in live fish was identified up to 10 mg/L after a 32-day exposure (NOEC ≥10 mg/L), therefore the range finder was extended for up to 148 days, covering one full zebrafish generation, in an attempt to define a LOEC on an apical endpoint. Observations of statistically reduced growth in our study were not consistent over time nor was there any concentration response relationship or discernable trend in the data and thus could not be linked to BPS exposure. Over the entire test there were no statistically significant exposure related effects or trends on survival, reproduction (as fertility and fecundity) or sex ratio. The overall NOEC was ≥10 mg/L for apical endpoints under the conditions of this study. The results of this 148 day study of zebrafish over one full generation do not confirm the reported adverse effects of BPS on reproduction and growth in previously published studies with considerably shorter exposures. Since only 2 replicates were included in the study design, definitive conclusions on subtle effects can not be drawn; however given that the exposure extended up to the chronic fish limit concentration, 10 mg/L, it is unlikely that severe chronic toxic effects were overlooked in this study. A definitive assessment of the potential chronic toxicity and adverse endocrine effects of BPS will be evaluated in a zebrafish-EOGRT.

WE199

Exposure to Norgestrel (NGT) and norethindrone (NET) in Gambusia affinis: Effects and Mechanisms

L. Xie, South China Normal University / The Environmental Research Institute; H. Chen, Environmental Research Institute, South China Normal University / Environmental Research Institute; L. Hou, School of Life Sciences Guangzhou University; G. Ying, South China Normal University / Environmental Research Institute

Natural and synthetic progestins in receiving streams can disrupt the normal endocrine systems of fish. Norethindrone (NET) and norgestrel (NGT) are synthetic progestins widely used in oral contraceptives and frequently detected in wastewater effluents. The adult female western mosquitofish (*Gambusia affinis*) were exposed to NET or NGT at environmentally relevant concentrations for 42 d. NGT caused a rapid masculinization of females, an increased frequency of atretic follicular cells in ovaries and impaired mating behaviors exhibited by males toward the NGT-exposed females. Exposure to NET led to rapid masculinization, altered histology of the livers and ovaries. In addition, exposure to NET did not affect the expression of the androgenic and estrogenic receptor genes and *Cyp19a* except for a significant up-regulation of *Era*. However, the expression of *Vtg A*, *Vtg B*, and *Vtg C* were markedly inhibited in the females. Relative to the control females, exposure to NET stimulated the expression of *Hsd17b3* in the livers. The results demonstrate that NGT and NET can cause rapid masculinization of female *G. affinis*, changes in histology of the livers and ovaries, and alterations in genes related to endocrine systems. The results imply that *G. affinis* populations might be threatened in NET- and/or NGT-contaminated environments.

WE200

Comparison of endocrine effects in different life-stages of zebrafish exposed to anti-estrogenic/androgenic substances in varying life-cycle exposure scenarios

S. Kroesen, Fraunhofer IME - Institute for Molecular Biology and Applied Ecology / Ecotoxicology; M. Teigeler, Fraunhofer IME / Ecotoxicology; E. Eilebrecht, Fraunhofer IME - Institute for Molecular Biology and Applied Ecology / Ecotoxicology; E. Bruns, Bayer AG, Division Bayer CropScience / Ecotoxicology; C. Schaefers, Fraunhofer IME - Institute for Molecular Biology and Applied Ecology / Ecotoxicology

During the authorization process of plant protection products a series of toxicity testing has to be performed to ensure an acceptable risk of use for humans or the environment. In these assessments fish populations represent an important spot in ecosystems and are tested for short- and long-term constraints accordingly. Of high interest in the procedure of testing are effects upon the endocrine system as they may alter e.g. the reproductive fitness of adult fish or their progeny. Recently, scientific criteria for the identification of endocrine disruptors (EDs) have been set up by the EC. But despite a long history of research there is still a debate about mechanisms of action of EDs affecting the legislative regulation. These uncertainties arise mainly from the occurrence of non-monotone concentration-response relationships and the applicability of the concept of effect thresholds. To answer these questions we exposed zebrafish (*D. rerio*) during different phases of their life-cycle to an anti-estrogenic substance, tamoxifen citrate, in both a pulsed and a permanent exposure test setup. The pulsed exposure experiments were performed using a spiked water-sediment system, in which three different developmental stages were exposed in parallel. A concentration-dependent mortality occurred in a first experiment (125 μg/L – 1000 μg/L). Nonetheless, in concentrations not affected by mortality and thus no subject to systemic toxicity a shift of the sex ratio towards males was observed. As no NOEC could be established for this sensitive endpoint, the experiment was replicated applying a lower concentration range (12.5 μg/L – 125 μg/L). Similar effects were observed when fish were constantly exposed to the test substance following the protocol of the Zebrafish Extended One Generation Reproduction Test (ZEOGRT), currently undergoing the OECD guideline validation process. Adult fish were exposed to concentrations ranging from 0.2 μg/L to 20 μg/L during their reproductive phase, followed by life-long exposure of their offspring (F_1) until hatching of the F_2-generation. The shift to male animals was conclusively observed in fish of the F_1-generation. Further results from this project will deliver additional information with respect to type and time of onset of effects. The data will be complemented with available data for other EDs (anti-estrogenic/androgenic) using similar testing approaches but covering differences in bioavailability prior to test item degradation.

WE201

Androgen antagonists: are tests conducted on adult fish able to capture activity due to this modality?

M. Arena, EFSA - European Food Safety Authority / Pesticides; D. Auteri, s. barmaz, EFSA - European Food Safety Authority / Pesticides Unit

Compounds acting as androgen antagonists (AACs) may interfere with the endocrine system in different ways such as by competitively binding to the androgen receptor (AR), blocking its activation, and/or subsequently interfering with the expression of genes regulated by the AR. In contrast to estrogens, androgen antagonists have not been well characterised in non-target organisms. In fish, AACs can lead to impaired gonads and sex secondary characteristics development, feminization of males, impaired reproductive behaviours, and reproductive failure in females. Furthermore, adult males can show altered reproductive behaviour such as nest production and courtship behaviours. All those effects can ultimately reduce fertility and fecundity being, therefore, very relevant for the maintenance of the population. In 2018, EFSA and ECHA published a guidance for the implementation of the Regulation 2018/605 laying down the criteria for the hazard identification of endocrine disrupters. Several scenarios are identified based on the available data package and, for each scenario, the testing strategy or recommendations on how to proceed in the assessment are given. In case further data with non-target organisms are needed to elucidate the endocrine activity due to estrogenic, androgenic and steroidogenic modality, level 3 (*in vivo* mechanistic) tests with fish are recommended (OECD TG 229 and OECD TG 230). Those tests are performed on adult fish which are exposed for 21 days to the compound under assessment. Parameters like VTG, gonad histopathology and fecundity/fertility are measured. As reported in literature effects of known compounds acting as anti-androgens are not consistent. Anti-androgens can impair sexual differentiation when early life stages of fish are exposed. However, in case adults are exposed there could be cases where effects due to anti-androgenic activity are not detected for example because fish were exposed after the sexual differentiation occurred. To this aim, additionally available OECD test guidelines (e.g. OECD 234) and guidance (OECD 148) will be considered and their strength and weaknesses will be highlighted as possible alternative solutions to better cover compounds acting as androgen antagonists.

WE202

A novel transgenic zebrafish line (cyp19a1a-GFP): refinement of an OECD test guideline for evaluating the effects of prochloraz on aromatase gene expression and reproduction.

J. De Oliveira, INERIS; E. Chadili, Ineris UMR-I 02 SEBIO; B. Piccini, INERIS; C. Turiès, INERIS / INERIS UMRI SEBIO ECOT; E. Maillot-Maréchal, INERIS / UMRI SEBIO ECOT; O. Palluel, INERIS / INERIS UMRI SEBIO ECOT; H. Budzinski, University of Bordeaux / EPOC LPTC UMR5805 CNRS; F. Brion,

INERIS / Ecotoxicology Unit; X. Cousin, IFREMER / Laboratoire de Ressources Halieutiques de La Rochelle; n. hinfray, INERIS / Ecotoxicology Unit
Concern about the effects of endocrine disrupting chemicals (EDCs) on reproductive health has stimulated the development of mechanism-based models and assays. In this regard, transgenic fish are powerful biological models that can provide mechanistic information regarding the endocrine activity of test chemicals. The objective of this study is to assess the feasibility of using a new biological model in an OECD fish screening assay to provide additional mechanistic information, as compared to wild-type models. In the present study, we used a transgenic zebrafish line *cyp19a1a*-GFP expressing GFP under the control of the "ovarian" aromatase promoter. Based on the OECD Fish Short Term Reproduction Assay (TG229), the effect of a prochloraz (PCZ; 3, 30 and 300μg/L), was assessed on "classical" endpoints. Additionally, fluorescence of ovarian GFP was monitored *in vivo* at 4 times from T0, to determine the baseline level of fluorescence, to T21 days of exposure to determine the kinetic of perturbation. After 21 days of exposure, a significant decrease in the number of eggs laid per female per day was observed at 300 μg/L. PCZ led to a concentration-dependent inhibition of circulating vitellogenin concentrations in females most probably reflecting the decreasing E2 synthesis due to inhibition of ovarian aromatase activity. GFP intensities were similar over treatment groups at 7 and 14 days of exposure but significantly increased after 21 days of exposure at 30 and 300 μg/L. A similar profile was observed on the endogenous *cyp19a1a* gene expression analyzed by qPCR. The overexpression of the aromatase gene likely reflects a compensatory response to the inhibitory action of PCZ on aromatase enzymatic activities consistent with the literature on PCZ. Thus, the *cyp19a1a*-GFP transgenic zebrafish line allows *in vivo* non-invasive monitoring over time of the GFP fluorescence of the ovary, providing information on aromatase expression and its perturbation. The protocol developed for GFP measures has no observable effects on reproduction and survival of fish. Moreover, it allows evaluation of EDCs effects over time and concentrations. Taken together, our findings highlight that the transgenic *cyp19a1a*-GFP model is a sensitive and relevant tool, which can bring complementary data without increasing the number of individuals or costs of the experiments.

WE203
Multiplex gene expression platform for screening endocrine disruptors using zebrafish
S. Jarque, J. Ibarra, M. Rubio, J. García, J. Terriente, ZECLINICS SL
Acute and long-term exposure of living organisms to environmental chemicals have been related to a wide range of physiological alterations and adverse health outcomes. Although mechanisms of action remain mostly to be elucidated, there is growing evidence that some of these effects may be due to changes at level of endocrine system. Zebrafish has been proven an excellent experimental model to screen endocrine disruptors, but current zebrafish-based assays to assess endocrine disrupting potencies (EDPs) have not been standardized yet, meaning that there is not consensus on endpoints to be measured. Moreover, experimental conditions may vary depending on the assays and the endocrine pathway evaluated. With the aim of providing a simple, robust and fast assay to assess EDPs for the three major endocrine axis, i.e. estrogens, androgens and thyroid, we propose the use of a panel of 8 gene expression biomarkers in zebrafish larvae. This includes brain aromatase (*cyp19a1b*) and vitellogenin 1 (*vtg1*) for estrogens, cytosolic sulfotransferase 2 family 2 (*sult2st3*) and cytochrome P450 2k22 (*cyp2k22*) for androgens, and thyroid peroxidase (*tpo*), transthyretin (*ttr*) thyroid receptor α (*trα*) and iodothyronine deiodinase 2 (*dio2*) for thyroid metabolism. All of them were selected according to their responses after exposure to the natural ligands 17β-estradiol, testosterone and 3,3′,5-triiodo-L-thyronine (T3), respectively, and subsequently validated using compounds reported as endocrine disruptors in previous studies. Cross-talk effects were also evaluated for all compounds.

WE204
EFFECTS OF 4-NONYLPHENOL AND 17β- ESTRADIOL ON SYNTHESIS OF VITELLOGENIN AND BALANCE OF STREROID THYROID HORMONES IN Sexually immature yeallowfin seabream, Accanthopagrus Latus
N. Asadi, Khorramshahr University of Marine Science and Technology; S. Nateghi Shahrokni, Islamic Azad malard University
In the study, the esterogenic effects of 4-nonyphenol (4-NP) and 17β-estradiol (E2) and on synthesis of vitellogenin (VTG), level of steroid and thyroid hormones and hepatosomatic index (HIS) in immature yellowfin seabream, Accanthopagrus latus, were assessed. To do this, a total number of 104 fish were abdominally injected by 10, 50,100, 150 and 200 μg/g/week and 2 μg/g/week of E2. The experiments were conducted over a period of two weeks. Induction of vitellogenin generation in plasma of treated fish was assayed indirectly by measuring of total plasma calcium and alkali-labile phosphate. The increased level of the indicators in treated fish's plasma showed the production of 4-NP in liver dose-dependently changed. Meanwhile, a significant dose-dependent increase was observed in HIS which indicated the activation of hepatic VTG production in 4-NP- and E2-injected fish. 4-NP treatment did not have any significant effect on plasma levels of testosterone. In addition, it was observed that 4-NP affect the level of thyroid hormones in fish. Plasma thyroxine levels rose in a dose-dependent manner after 7 and 14 days of the exposure. In contrast, a significant decrease in triiodothyronine levels was observed during the experiment period. Moreover, no significant change was detected for thyroid stimulating hormone levels in 4-NP-treated fish. These results demonstrated that 4-NP is so influential to induce the VTG. Based on the findings, it can be concluded that 4-NP can strongly disturb the balance of steroid and thyroid hormones with potential consequences for sexually immature male yellowfin seabream

WE205
Do the principals analogues of bisphenol A have endocrine activity? In vitro case study.
M. MARTINEZ RODRIGUEZ, Universitat Rovira i Virgili; J. Blanco, Rovira i Virgili University / NEUROLAB; J. Rovira, Universitat Rovira i Virgili / School of Medicine, IISPV; V. Kumar, Universitat Rovira i Virgili / Chemical engineering department; M. Schuhmacher, Universitat Rovira i Virgili / Chemical Engineering
Endocrine disruptors (EDs) can affect the different levels of epigenetic control and in some cases can act transgenerationally, if the exposure to EDs occurs during "critical windows of exposure", especially, the prenatal and the early life period. In this study, it was selected Bisphenol A (BPA) and two analogues of it, Bisphenol S (BPS) and Bisphenol F (BPF). These chemicals are wide spread distributed, and it is known that the prenatal or early exposure to BPA is related with two potential diseases, obesity and diabetes in childhood as well as reproductive, behavioural and neurodevelopment problems. Previous studies described an obesogenic activity of BPA. This compound can affect the expression of master regulatory genes related with adipogenesis such as the peroxisome proliferator-activated receptor gamma (PPARγ) and CCAAT/enhancer binding protein (C/EBPα). Nowadays, the European Commission (EC) has imposed some regulations, such as the withdrawal of baby products containing BPA. However, the principal analogues of BPA (BPS and BPF) are still in them. The overall objective of this project is to compare the obesogenic activity of BPA and its analogues by *in vitro* assays with preadipocytic 3T3-L1 cell line. To proceed with that, MTT assay was performed in order to select the concentrations of each chemical, which did not show a cell viability decrease. Consequently, it was evaluated the adipogenic differentiation capacity of these chemicals by OIL RED O cell staining. Furthermore, the transcription of the master regulatory genes involved in 3T3-L1 differentiation were assessed by real-time PCR (to determine genetic expression) and western blot (to determine protein expression). The results showed a greater toxic effect of BPA at lower concentrations than its analogues. However, BPS followed by BPF showed a greater obesogenic capacity than BPA, which was reflected in an increase in C/EBPα and PPARγ compared with control. This same pattern could be observed in the stain with OIL RED O. As a conclusion of the study, these analogues could present even greater endocrine activity than BPA.

WE206
The fish sex ratio endpoint in the assessment of endocrine disruption
A. KIENZLER, JRC-EC / F3-Chemical Safety and Alternative Methods Unit-EURL ECVAM; Z. DANG, RIVM / LIEC CNRS UMR
In recent years, the scientific community and authorities have been discussing the endocrine disruptors topic and how to regulate it. Significant progress has been achieved in the EU, with the establishment of scientific criteria to identify substances with endocrine disrupting properties both in the Plant Protection Products Regulation (EC) 1107/2009 and the Biocidal Products Regulation (EU) 528/2012, and the publication of the EFSA and ECHA's Guidance Document on the identification of endocrine disruptors (EDs). According to this guidance document it is required to consider for EDs assessment, beside regulatory test results, all already existing data, including available literature data. Sex ratio is an endpoint included in several fish test guidelines, addressing both adversity and endocrine activity, two essential elements for EDs identification for regulatory purpose. However, the interpretation of this endpoint is not always straightforward, due both to an incomplete understanding of the underlying rational of its potential variation and to the diversity of experimental design found in literature studies. The aim of this work was to appraise available sex ratio results in the scientific literature for regulatory use. More than 100 articles published in the last 20 years, reporting data on the sex ratio in zebrafish, Japanese medaka and fathead minnow, have been compiled and assessed. The different methods for quantification of sex ratio have been compared, and several characteristics of the sex ratio have been further investigated, such as the plasticity of the endpoint according to the lifestage and the biology of the species; the reversibility of the endpoint that might be observed in some circumstances; and the natural variability of sex ratio reported in control fish along with the factor influencing it such as the fish strain or culture condition, including temperature. The results will be discussed to better understand the extent to which the different factors can significantly influence the sex ratio endpoint, in relation to the species sensitivity and the test design. Finally, the sensitivity of the sex ratio endpoint will be compared to the sensitivity of other endpoints related to endocrine disruption identification, and the possible use of this sex ratio data for identification, classification, testing and risk assessment in the regulatory context will be discussed.

WE207

The new ECHA/EFSA Guidance for the identification of endocrine disruptors - initial experiences with the assessment for aquatic vertebrates

P. Janz, BASF SE, Agrarzentrum Limburgerhof / Agricultural Solutions - Global Ecotoxicology; L. Weltje, M. Habekost, F. Groezinger, D. Kaiser, BASF SE / Agricultural Solutions - Global Ecotoxicology

The Regulation (EC) No 1107/2009 concerning the placing of plant protection products on the market states that an active substance shall not be approved if it is considered to have endocrine disrupting (ED) properties that may cause adverse effects on non-target organisms (i.e. a cut-off criterion). In April 2018, the European Commission has implemented scientific criteria for the hazard-based determination of endocrine-disrupting properties pursuant to Regulation 1107/2009. According to the ED criteria, a substance shall be considered as having ED properties in non-target organisms (other than humans) if it meets the following three criteria: a) it shows an adverse effect that is relevant for non-target organisms at population level, b) it has an endocrine mode of action, i.e. it alters the function(s) of the endocrine system, and c) the population-relevant adverse effect is a consequence of the endocrine mode of action. In June 2018, ECHA and EFSA published a joined Guidance Document intended to provide guidance to applicants and assessors of the competent regulatory authorities on the implementation of these criteria. The Guidance Document describes how to gather, evaluate and assess all relevant information, conduct a mode of action analysis, and apply a weight of evidence approach, to establish whether the ED criteria are fulfilled. This poster shares the first practical experiences with the new Guidance Document concerning the ED assessment focussing on aquatic vertebrates. It provides an applicant point of view on the assessment procedure, data sufficiency, and potential testing strategies.

WE208

Endocrine assessments for pesticides and biocides - a regulators perspective

M. Reed, HSE; C. Taylor, HSE Health and Safety Executive; R. Moore, CRD, HSE; M. Clook, HSE Health and Safety Executive / Chemicals Regulation Directorate

Following the adoption of the criteria for endocrine disruptors (ED) for pesticides (Commission Regulation (EU) 2018/605) and biocides (Commission Delegated Regulation (EU) 2017/2100) it has been necessary for Rapporteur Member States (RMS) to use information provided by applicants to perform an assessment of the ED properties of the active substance to submit to EFSA / ECHA for peer review. Whilst there are some common elements the different regimes have also presented slightly different situations, so our experience with pesticide active substances, biocide active substances and biocide products are described. The UK has adopted a stepwise approach when preparing the ED assessment in order to reach a robust conclusion as efficiently as possible without requesting additional vertebrate data unless it is essential. This approach and the reason for this approach will be explained in the presentation. The data package for pesticides is typically larger, particularly with respect to chronic data than for biocides, which has resulted in different ED assessments being submitted by applicants. For both regimes we will outline our experince to date with examples of what information we had available to reach the different conclusions. In both cases a human health data package is available which is evaluated initially to consider whether the substance fulfils the criteria that the substance is a ED for human health, which if positive can be used to then assess the population relevance of the effects seen to address the non-target organisms assessment. Our experiences to date have indicated that unless it can be demonstrated that a substance meets the scientific criteria described under the implementing regulation there is often insufficient information to reach a conclusion. As a result our conclusion has frequently been that the scientific criteria described under the implementing regulation are not met, but there is insufficient information available to conclude on the criteria which confidence. This triggers a need for further data / information generation after which time the assessment needs to be repeated.

WE209

EFSA new guidance on endocrine disruptors: comments, critical aspects and a case study

F. Metruccio, F. Galimberti, C. Civitella, ICPS International Centre for Pesticides and Health Risk Prevention / Public Health; V. Guercio, A. Moretto, Università degli Studi di Milano

The EFSA Endocrine Disruptors guidance has been developed to help assessors of the regulatory authorities on the definition of the scientific criteria for the determination of endocrine-disrupting properties in the context of Regulations (EU) No 16 528/2012 and (EC) No 1107/2009. The overall objective resulting from the present project was the compilation of a specific database for a pesticide active substance (named x) and its metabolites, which is comprising all available parameters that are considered relevant when investigating the ED properties. The database represented a practical tool to help assessors in assessing and analyze the evidence for endocrine disrupting properties. A useful-friendly client-side Form of the database was created. The Microsoft Access database was selected as suitable for this specific data collection due to the number of predicted records to be stored in and the ability of the toxicologist to work with this specific platform. To facilitate the data entry phase of the operators and to limit the data entry typos, most of the field were constrained with menu combo boxes and several queries were prepared to check the quality of the inserted data. The list of toxicity study type for mammalian toxicology and wild life toxicology comprises more than 10 different type of studies. Out of 55 studies that were scrutinized, 27 were performed on the active substance and 28 were performed on metabolites (4 metabolites) thus representing more than 50% of the total. In this particular case, the number of toxicity studies performed on metabolites was larger than normal; this is due to particular toxicity potential of three (non mammalian) metabolites that show higher chronic (specifically reproductive toxicity) toxicity than the parent. Studies on mammals (intact organism/cells) were 49 (23 on active substance and 26 on metabolites), while studies on wildlife (fish, amphibians) were 6 (4 on active substance and 2 on metabolites) Wilde life studies to investigate ED properties of active substances were not routinely performed in the past year. Please note that for substance X dossier year of study range from 1979 to 2012. Collection of data from substance x dossier represented a new exercise related to new approach for evaluating ED properties of active substances.

WE210

What to expect from the evaluation of endocrine disrupting properties: hazard versus risk-based approach - an update

B. Scharlaken, A. Vanden Bosch, Arche consulting; S. Navis, Arche consulting / Laboratory of Aquatic Ecology, Evolution and Conservation

Should we assess the potential endocrine disruptive properties of plant protection and biocidal active substances based on hazard or risk? In other words, is the public health and the environment better off with an assessment of the hazardous properties of an active substance to conclude on its potential endocrine disruptive properties, or on management of the exposure? These questions are answered differently in the European Union (EU) and the United States (US). The current case study focuses on the distinct approaches taken in the EU (hazard-based) and US (risk-based). In the EU, very few substances have actually been 'banned' so far based on the conclusion of endocrine disruptive properties and most of the case-by-case ED assessments up until now have been inconclusive. With the publication of the 'Guidance for the identification of endocrine disruptors in the context of Regulation (EU) No 528/2012 and (EC) No 1107/2009' (ECHA and EFSA, 2018) this may change, as finally a framework for evaluation of ED-relevant testing data has become available. In the US, in contrast, an Endocrine Disruptive Screening Program (EDSP) is in place since several years. Tier 1 screenings of selected active substances have led to the identification of chemicals with and without potential to interact with the oestrogen, androgen or thyroid pathway. Of the 52 chemicals considered for Tier 1 screening, already 34 were concluded not to pose risks for endocrine disruption. Of the remaining 18 chemicals, all 18 show potential interaction with the thyroid pathway, 17 of them with the androgen pathway, and 14 also potentially interact with the oestrogen pathway. For these substances, further studies to be generated were identified. In the present case study, we investigate the lessons that can be drawn from the US screening program and possible implications for the ED assessments to be conducted in the EU under the different regulatory frameworks (REACH, BPR, PPPR).

WE211

Use of High Throughput Screening assays to develop local (Q)SAR models on a specific chemical category: A case study on aromatase activity of conazoles

C. Toma, IRFMN / Ambiente e Salute; A. Roncaglioni, Istituto di Ricerche Farmacologiche Mario Negri / Department of Environmental Health Sciences Laboratory of Environmental Chemistry and Toxicology; E. Carnesecchi, Istituto Mario Negri / Environmental chemistry and toxicology; E. Benfenati, IRCCS Istituto di Ricerche Farmacologiche Mario Negri / Department of Environmental Health Sciences

In the last years concerns were raised toward the potential hazard posed by endocrine disrupting chemicals (EDCs). Developing low tier testing methods, like *in vitro* and *in silico* ones, is important to meet the 3R principles giving an effective assesment of potential endocrine disruption. The aim of this work is to develop a Quantitative Structure Activity Relationship (QSAR) model giving a quantitative estimation of the aromatase inhibition potential of conazoles. Conazoles are commonly used antifungal agents and act as C-14 demethylase inhibitors, that shows a high homology with human aromatase. Data were collected from literature to verify the correlation between a selected high throughput assay and the most used *in vitro* tests used in regulatory framework for Plant protection Products (PPP). The results confirmed a good correlation among different tests. Case weighted Random Forest (CWRF) algorithm was applied for QSAR development. This approach uses a large heterogeneous training set but it gives more emphasis to a subset of selected observations during model's derivation (i.e., conazoles). The aim is to develop a model for a specific class of chemicals. Results demonstrated that the method is suitable to assess aromatase inhibition potential of conazoles outperforming classical and local QSAR models.**Acknowledgements:** This study was funded by EU-ToxRisk (Project reference: 681002).

WE212

Virtual Cell Simulations to Probe the Effects of Complex Mixtures from Low to Higher Concentrations

L. Burgoon, U.S. Army Engineer Research and Development Center / Environmental Laboratory

People and ecological receptors are exposed to chemicals as mixtures, not as single chemicals. However, there still exists a great deal of uncertainty with respect to how chemicals interact at low and higher environmental concentrations. The goal of this project is to use the estrogen receptor and gene expression response as a cell signaling model to explore how chemical mixtures respond both in vitro (i.e., the absence of endogenous estrogens) and in the likely in vivo situation (where endogenous estrogens are also present). The model uses known equations from biochemistry and affinity/dissociation constants for chemicals, and estrogen receptor binding to DNA, and gene expression kinetic models to integrate knowledge. We used an agent-based system, where chemicals, the estrogen receptors, and DNA, are all different agents, to simulate how the system as a whole interacts. This allowed us to ask questions about how different amounts and levels of chemicals in our mixture, which all have different dissociation constants, lead to differences in gene expression, and to address if concentration/dose addition or response addition explain the results we are seeing. In general, we found that due to the low concentration of estrogen receptor, and due to the fact that binding is largely competitive and driven by affinity, that when there are large differences in the affinity of members of a complex mixture, that the chemicals with the most affinity tend to win out, with very little interaction between members of the mixture, meaning the potency tended to reflect those chemicals with the most affinity. We assumed for simplicity that efficacy was the same for all chemicals, which we know is not true, and were primarily interested in changes in potency due to the mixture. Future work will expand the model to also include efficacy estimates. The US Army Chief of Engineers has approved this paper for release. The views presented in this article do not necessarily reflect current or future opinion or policy of the U.S. Army Corps of Engineers.

WE213

Androgenic and Estrogenic Potency-Thresholds in Fish: The HRPT Concept in Ecological Hazard Identification, AOPs, and Cumulative Risk Assessment

S. Levine, Bayer AG - Crop Science Division; A. Bone, Bayer Corporation, Research Triangle Park, N.C., USA; C. Borgert, Applied Pharmacology & Toxicology, Inc.

The European Union has recently adopted Criteria and Guidance for the identification of endocrine disrupting chemicals (EDCs), defined as chemicals that produce adverse effects via endocrine mechanisms. Identifying and characterizing toxic hazards based on the manner by which those adverse effects are produced rather than on the nature and likelihood of those adverse effects at relevant exposure levels departs from traditional practice and requires a proper interpretation of the evidence regarding the chemical's ability to produce physiological effect(s) via a specific MoA. The ability of any chemical to produce a physiological effect depends on its pharmacokinetics and the potency by which it acts via the various MoAs that can lead to the particular effect. A chemical's potency for a specific MoA – its mechanistic potency – is determined by two properties: 1) its affinity for the functional components that comprise the MoA, i.e., its specific receptors, enzymes, etc., and 2) it's ability to alter the functional state of those components (activity, activation). Recently an empirical approach was developed for determining the minimum level of mechanistic potency necessary for a chemical to be able to act via a particular MoA in humans, called the Human-Relevant Potency Threshold (HRPT) [1]. Here, we show how the HRPT concept can be extended to analogous mechanistic thresholds in fish using comparative data for human and fish oestrogen and androgen receptor systems. In addition, a practical method is proposed for using taxa-based potency thresholds for the identification of potential ecological hazards through an endocrine mechanism (i.e., is there sufficient mechanistic potency downstream to link to key events in Adverse Outcome Pathways (AOPs). This approach can also be used to assign chemicals to common assessment groups for mixtures risk assessment.

WE214

Human-Relevant Potency Threshold for ER alpha-Agonism

C. Borgert, Applied Pharmacology & Toxicology, Inc.; J.C. Matthews, University of Mississippi School of Pharmacy, University, MS; S.P. Baker, Department of Pharmacology and Therapeutics, University of Florida College of Medicine, Gainesville, FL / Department of Pharmacology and Therapeutics

Potency is a general expression of response per unit of chemical, but it is not single concept that can be applied uniformly to all aspects of chemical effects. Potency for a mode of action (MoA) is conceptually different from potency for an adverse effect; these are measured and interpreted differently. The ability of chemicals to produce physiological effects depends on their pharmacokinetic properties as well as their potency for acting via the various the MoAs underlying the effects. Besides pharmacokinetics, a chemical's ability to produce a physiological effect via a particular MoA depends on its affinity for the functional components (receptors, enzymes, transporters, etc.) that comprise the MoA and its ability to alter their functional state (intrinsic activity or intrinsic efficacy). We refer to the product of affinity and intrinsic efficacy as 'mechanistic potency' to distinguish it from toxicological potency, which refers to the potency by which a chemical produces an adverse effect, and which depends on pharmacokinetics as well as the chemical's ability to act via all of the various modes of action that lead to the particular adverse effect. Mechanistic potency is thus the property that relates to a specific MoA, and which is the requisite property necessary to determine whether a chemical can produce an adverse effect via a particular MoA. We tested the hypothesis that a minimum level of mechanistic potency is required for chemicals to produce physiological effects by a particular MoA in humans by comparing their potencies for the ERα-agonist MoA to data from clinical trials for chemicals with known eostrogenic effects (endogenous hormones and human pharmaceuticals), equivocal estrognic effects (the most potent members of the class of chemicals known as botanical estrogens), and no estrogenic effects (androgens and the least potent botanical estrogens). Potency data from cell-based transcriptional activation assays for human ERα (ERTA) were used to estimate mechanistic potency and the rodent uterotrophic assay (RUA) was selected as an in vivo check on the in vitro potency estimates. Based on these calculations, we proposed a human-relevant potency threshold (HRPT) for ERα agonism of 1E-04 relative to the potency of 17β-estradiol or the pharmaceutical estrogen, 17α-ethinylestradiol.

WE215

Assessment of Endocrine Properties of Bisphenol A in the Environment: A Hypothesis-Testing Weight of Evidence Approach

J. Woelz, Currenta / Product Safety; E.M. Mihaich, ER2

Extensive discussion is occurring in the European Union and internationally on how to identify endocrine disruptors (ED). There is general agreement that the evaluation of ED should be based on the WHO/IPCS (2002) definition. According to WHO/IPCS: *"An endocrine disruptor is an exogenous substance or mixture that alters function(s) of the endocrine system and consequently causes adverse effects in an intact organism, or its progeny, or (sub)populations."* This definition embodies the key elements of adversity, endocrine mode of action, and a causal link between endocrine activity and adverse effect. The mere existence of an endocrine mode of action (*i.e*., endocrine activity) is not a harmful property, a type of toxic effect, or a hazard. Rather, endocrine activity, if causally linked to an adverse outcome, can potentially lead to a hazard to health or to the environment, particularly after long-term exposure. Defining that there is a causal link between an indication of activity and an adverse effect, particularly one that would be the lead or primary toxic effect most relevant for risk assessment is important. The extensive database for bisphenol A (BPA) was evaluated in a robust weight of evidence (WoE) framework, focusing on specific hypotheses related to disruption of estrogen, androgen, and thyroid hormone pathways. The WoE evaluation included the integration of data from high throughput screens, regulatory guideline studies and published literature, corresponding to levels 1-5 of the OECD conceptual framework. Although a weak estrogenic activity is apparent for BPA among various fish species, the profile of adverse effects that have been measured in BPA-exposed aquatic vertebrates and are used in ecological risk assessments (*i.e.,* effects on survival, growth, development, and reproduction) are not all definitively linked to a weak estrogenic mode of action. The use of bioactivity screens and a consideration of the mechanistic potency of BPA, in relation to endogenous hormones, suggests that the lead mode of action is related to non-specific, systemic toxicity rather than an endocrine specific mode of action.

WE216

Feminization effects on male offspring rats through maternal exposure to flutamide, linuron and dienestrol.

E. Schreiber, N. González, Universitat Rovira i Virgili; V. Kumar, Universitat Rovira i Virgili / Chemical engineering department; M. Torrente, J.L. Domingo, M. Gómez, Universitat Rovira i Virgili / Laboratory of Toxicology and Environmental Health

Flutamide, linuron and dienestrol have been classified as an endocrine disruptors altering endocrine system functions and causing possible harmful effects on the F1 offspring. Flutamide is a nonsteroidal androgen receptor (AR) antagonist and it has been used against prostatic carcinoma. Linuron is an herbicide which acts like an AR antagonist in male rats. Finally, dienestrol is a metabolite of diethylestilbestrol and has been used to treat menopausal symptoms. It acts like an estrogen receptors (ER) agonist. Thus, the aim of this study is to determine feminized physiological traits in male pups due to prenatal and lactation periods through maternal exposure, as well as, to determine the viability and possible toxic effects of the offspring. Female Sprague-Dawley pregnant rats (90 days) were treated daily (gavage) from gestational day (GD) 6, until postnatal day (PND) 21. Each experimental group (5 pregnant females/group) was treated with flutamide at 50, 25, 12.5, 6.2 and 3.1 mg/kg bw/day doses and with linuron at 50, 25, 12.5, 6.2, 3.1 and 1.5 mg/kg bw/day doses. For dienestrol, the doses given were 75, 50, 12.5, 6.2, 3.1, 1.5, 0.75 and 0.37 μg/kg bw/day. The compounds were dissolved in sunflower oil. Control groups with and without vehicle were also included. During weaning, at PND 1, 4, 7, 14 and 21, pup examinations were conducted to assess body weight and feminization endpoints: anogenital distance (AGD) and the presence of nipples (nipple retention (NR)). At PND 21, 4 male pups per litter were anesthetized by intraperitoneal injection, and cryptorchidism was assessed. Testis and liver were removed and weighed. Results showed feminization in all groups of flutamide: decreased AGD, nipple retention and cryptorchidism. Higher concentrations of dienestrol (75 and 50 μg/kg bw/day) caused abortions in all pregnant rats and medium doses (12.5 and 6 μg/kg bw/day) showed some miscarriages. Litters of higher concentrations of linuron (50 and 25 mg/kg bw/day) were not viable. Feminization endpoints can be seen in all flutamide groups and no viability of the litters in linuron and dienestrol in higher-doses groups.

WE217

Estimation of phytoestrogen changes in plants by EDCs using TR-FIA

D. Kim, Konkuk University; D. Kim, Konkuk University / Department of Environmental Health Science; Y. An, Konkuk University / Department of Environmental Heath Science

Endocrine disrupting chemicals are known to disturb the endocrine system in living organisms. They are widely used around the world for personal care products and are likely to be released into the soil environment. However, there is no international standard for EDCs-specific soil toxicity assessment method unlike human and animal toxicity tests. On the other hand, phytoestrogens are plant-specific xenoestrogens like xenohormones that mimic estrogen activity. Especially, genistein is associated with estrogen receptors in animals, and consequently affects the reproduction of predators. Their effects depend on the environment of the plant and on external stressors. Therefore, we choose genistein, which is a plant-derived substance, to develop as an endpoint of EDCs-specific phytotoxicity. We exposed mung beans to bisphenol A, β-estradiol, and methylparaben known as representative EDCs for 21 days, and then measured the concentration of genistein in mung beans using time-resolved fluoro-immunoassay (TR-FIA). The results showed that the genistein level in mung bean exposed to low concentrations of EDCs increased and as the concentration of substance increase, the genistein decrease. Furthermore, the concentration of genistein in the plants exposed to the highest concentration significantly decreased. The results indicate that the genistein level in plant is more sensitive than the traditional toxic endpoints of plants, such as growth and photosynthesis parameters. Therefore, it is recommended as a pre-screening endpoint for toxicity of EDCs. *This study was funded by the Korea Ministry of Environment (MOE) as the Environmental Health Action Program (1485014458), and the Graduate School of Specialization for managing information of chemical risk.*

Generation Of NoveL, Integrated and Internationally Harmonised Approaches for Testing Metabolism Disrupting Compounds (GOLIATH)

J. Legler, Utrecht University / Institute for Risk Assessment Sciences; J. Kamstra, Institute for Risk Assessment Sciences Utrecht University / Institute for Risk Assessment Sciences

The new H2020 project GOLIATH (2019-2024, Grant 825489) focusses on one of the most urgent regulatory needs in EDC testing, namely the lack of methods for testing EDCs that disrupt metabolism – chemicals collectively referred to as ‘metabolism disrupting compounds’ (MDCs). MDCs are natural and anthropogenic chemicals that have the ability to promote metabolic changes that can ultimately result in obesity, diabetes and/or fatty liver in humans. GOLIATH will generate the world’s first integrated approach to testing and assessment (IATA) specifically tailored to MDCs. With a focus on the main cellular targets of metabolic disruption – hepatocytes, pancreatic endocrine cells, myocytes and adipocytes - GOLIATH will develop new methods and optimise existing methods that span the entire adverse outcome pathway (AOP) spectrum, using in silico predictive modelling and high throughput screening, (pre-)validated ready-touse in vitro assays and optimised in vivo toxicity testing guidelines. GOLIATH will provide key information on the endocrine mode of action by which MDCs disrupt metabolic pathways and induce adverse effects on human health by incorporating multi-omics technologies, and translating results from in vitro and in vivo assays to adverse metabolic health outcomes in humans at real life exposures. Given the importance of international acceptance of the developed test methods for regulatory use, GOLIATH will link with ongoing initiatives of the OECD for test method (pre-)validation, IATA and AOP development. With a consortium comprised of world-leading experts in endocrinology, molecular biology, toxicology, epidemiology, test method development, validation and chemical regulation, GOLIATH will be pivotal in the development of an internationally harmonised strategy for testing MDCs, with the ultimate aim of slowing the worldwide rise in metabolic disorders that have reached ‘Goliathan’ proportions.

Benefits of BiER: How Biotransformation and Elimination Rate Related Science Can Improve the Regulation and the Sustainable Use of Chemicals (P)

The Bioaccumulation Assessment Tool (BAT): Case studies for assessing "data rich" and "data poor" chemicals for regulatory purposes and informing integrated testing strategies

L. Toose, Liisa Toose Environmental Research; J.M. Armitage, AES Armitage Environmental Sciences, Inc; K. Foster, Karen Foster Environmental Research / Adjunct Professor, Trent University, Applications of Modelling & Quantitative Methods (AMOD); L. Hughes, ARC Arnot Research & Consulting; M. Embry, Health and Environmental Sciences Institute HESI; J.A. Arnot, ARC Arnot Research & Consulting / Adjunct Professor, Department of Physical & Environmental Science/Department of Pharmacology and Toxicology

Persistence, Bioaccumulation and Toxicity (PBT) assessments are carried out by many regulatory programs such as REACh, TSCA, CEPA, and CSCL. These assessments aim to identify the risks posed by chemicals to the environment and human health. The freely-available Bioaccumulation Assessment Tool (BAT) was developed to standardize the collection, evaluation and integration of various lines of evidence (LOE) with available toxicokinetic (TK) information and related B classification criteria. It is a platform designed to aid decision-making using a quantitative weight of evidence approach. The BAT is used to integrate physical-chemical properties and estimates of biotransformation in fish and mammals with measured or estimated bioaccumulation metrics (bioconcentration, bioaccumulation, biomagnification and trophic magnification factors, i.e. BCF, BAF, BMF and TMFs) in aquatic and terrestrial systems. Within the BAT framework is a generic environment with both aquatic and terrestrial foodweb models as well as simulated laboratory models used to estimate these B-metrics. Experimental and in silico LOE are rigorously assessed for reliability, based primarily on OECD guidelines. A summary of the results, including relevance and reliability scoring, are presented in a table as well as in a generated PDF report. This tool is designed to be able to incorporate many types of chemicals and data sources. Both neutral and ionic chemicals can be assessed. We provide an overview of the BAT and demonstrate its application with two case studies. The first example is for a “data rich” chemical for which various LOE exist (e.g. biotransformation rate QSARs, in vitro biotransformation rates, Field BAFs and BMFs, several lab BCFs and various BCF-QSARs). The second case study is a typical “data poor” scenario in which only chemical structure information is available. From chemical structure, relevant physical-chemical property, biotransformation rates are entered into the BAT. Using these data, the tool can generate several LOE and BCF estimates are obtained from QSARs and entered into the BAT. These results can then be used to inform an integrated testing strategy (ITS) to obtain more robust B data if necessary. The BAT is a flexible and transparent framework developed to assess chemicals with varying levels of data availability and properties for their bioaccumulation potential in aquatic and terrestrial organisms.

WE220

Analysis of mammalian toxicokinetic data compilation for use in bioaccumulation assessment

D. Hirmann, European Chemicals Agency (ECHA); T. Hofer, O. Myhre, S. Andersen, Norwegian Institute of Public Health; J. Caley, European Chemicals Agency - ECHA / Evaluation; S. Lapenna, European Chemicals Agency - ECHA; Z. Kloslova, European Chemicals Agency - ECHA / Evaluation Directorate; T. SOBANSKI, J.R. Peltola-Thies, European Chemicals Agency - ECHA

Elimination half-lives of mammals, including humans, have been proposed as a potential complementary metric to expand the assessment of bioaccumulative properties of a substance to cover air-breathing organisms. In order to explore the possibilities of using such data in bioaccumulation assessment and predictions, a compilation of human and terrestrial mammalian elimination half-life data with almost 3000 data points have been analysed. Regulatory reference cases for bioaccumulation in air-breathing organisms are scarce, meaning a relevant reference data set to derive a threshold is missing. The data suggest that half-lives from repeated dose rat studies generally lead to longer half-lives compared to single dose studies. Consideration of toxicokinetic and toxicodynamic information is expected to significantly improve the understanding of the data and which data are most suitable to use when assessing the bioaccumulation potential in air-breathing organisms. Use of the collected data for benchmarking purposes is suggested. Assessment of the bioaccumulation potential in air-breathing organisms will benefit from an integration of various lines of evidence, and elimination half-life data, if available, should be considered as one of them. Calculation of half-lives is encouraged when performing future ADME studies. Many of the PBT/vPvB assessments finalised in the past with the conclusion “not PBT/vPvB” have not considered bioaccumulation potential in air-breathing organisms. For some of those cases a re-evaluation will be necessary in the future.

WE221

Towards the use of elimination rates in bioaccumulation assessment − current challenges and future needs

G. Treu, German Environment Agency Umweltbundesamt / Chemicals; W. Drost, Federal Environment Agency (UBA) / Chemicals; C. Rauert, Umweltbundesamt / International Chemicals Management; S. Krause, K. Goss, Helmholtz centre for environmental research - UFZ / Analytical Environmental Chemistry

The capacity of chemicals to bioaccumulate in biota is recognized as a critical property that contributes to a chemicals risk. The bioconcentration factor (BCF) reflecting the uptake of a chemical from water and the biomagnification factor (BMF) following dietary uptake in fish remain the preferred metrics in bioaccumulation assessment. Based on the current concept, to derive BCF and BMF, animal tests are mandatory for chemicals exceeding a certain level of hydrophobicity but may turn out as non bioaccumulative due to metabolisation.The test systems are expensive, time consuming and are not suitable for screening purposes. Still, terrestrial bioaccumulation is hardly considered. Recent approaches suggest, to derive BCF and BMF by determining the elimination rate constant (k_2) experimentally while the uptake rate (k_1)is estimated. Following this concept the need for animal tests is reduced if the metabolic contribution to k_2 is quantified in *in vitro* experimentswhile the effect of the other pathways (excretion via urine and feces, and ventilation)are estimated based on existing physico-chemical understanding. Biotransformation often increases elimination and thus reduces the extent to which chemicals accumulate in fish and mammals. Thus, a Tier 1.5 can be introduced between Tier 1 (screening based on physico-chemical data) and Tier 2 (exposure studies with animals) where biotransformation rates (k_m) obtained from *in vitro* tests with fish or mammalian cells are extrapolated to whole organisms and then incorporated into existing chemical mass-balance models to predict a BCF or BMF. Only if this model indicates an increased bioaccumulation a higher-tier vertebrate test would be needed. As such a k_2 based extrapolation model allowing to estimate worst case BCF and BMF values by incorporating *in vitro* $k_m$of different tissues, e.g. gills, liver and gastro intestinal tract from different species, could serve as alternative screening criterion under REACH. This would allow to experimentally cover species differences currently ignored in bioaccumulation regulation. However, uncertainties of this approach remain and will partly be addressed in an UBA project launched early 2019. This poster aims at demonstrating current limitations and future needs for the k_2 based bioaccumulation assessment under REACH from a regulatory agency's perspective.

WE222

Bioaccumulation Regulation: do we need a paradigm change?

K. Goss, Helmholtz centre for environmental research - UFZ / Analytical Environmental Chemistry

The bioaccumulation assessment as it is performed under REACH is based on the BCF in fish using a threshold value of 2000. It appears that this regulation has mostly been the result of a political process. From a scientific perspective questions arise concerning the usefulness of the current approach. This presentation will specifically look at the following issues: 1) Is it correct to assume hindrance in uptake and distribution for superhydrophobic / or large molecules \n as it is done in REACH regulation? 2) Is it sufficient to focus at BCF in fish if we also want to safeguard other vertebrates such as mammals and birds? 3) Is the BCF a suitable metric for a bioaccumulation assessment at all?

WE223

Application of Toxicokinetic Models to Simulate Organic Chemicals in Air-breathing Animals for B assessment

J.M. Armitage, AES Armitage Environmental Sciences, Inc / Physical and Environmental Sciences; J.A. Arnot, ARC Arnot Research & Consulting / Adjunct Professor, Department of Physical & Environmental Science/Department of Pharmacology and Toxicology

Bioaccumulation assessment (B) for regulatory purposes has traditionally relied upon data for aquatic organisms (fish) and partitioning properties referenced to water (e.g., octanol-water partition coefficient, K_{OW}). However, emerging regulatory guidance from the European Chemicals Agency (ECHA) includes B screening threshold criteria for air-breathing organisms linked to K_{OW} and the octanol-air partition coefficient (K_{OA}) (e.g., Chapter R11: PBT / vPvB Assessment). Whereas OECD guidance for bioaccumulation testing with fish is available and widely accepted (OECD 305), there is no similar standardized test for air-breathing organisms (e.g., laboratory rats and mice). On the other hand, a wealth of toxicokinetic data has been generated using mammals for other regulatory purposes (e.g., pesticide registration). The objective of this study was to develop and apply one- and multicompartment toxicokinetic models (1-CoTK and PBTK respectively) to simulate the behaviour of organic chemicals in laboratory animals for interpretation in the context of B assessment. The TK models were purposefully developed to be as generic and readily-applicable as possible, based on the understanding that i) assessments are required for both data rich and data poor substances and that ii) the models may be of interest to stakeholders with varying levels of expertise. As a case study, the models were applied to laboratory test data for several organic compounds of interest and their performance assessed. The role of biotransformation in mitigating the bioaccumulation potential of organic compounds in air-breathing animals is particularly evident. Compared to the 1-CoTK model, the PBTK is generally more amenable to simulating and interpreting in vivo laboratory data for B assessment as it explicitly represents different tissues and exchange processes typical of most available testing data rather than operating only at the whole body level. Nevertheless, there are many organic chemicals for which the model performance and output is expected to be very similar between the 1-CoTK and PBTK versions suggesting that the simpler model may be applied with confidence in many scenarios.

Arnot, ARC Arnot Research & Consulting / Adjunct Professor, Department of Physical & Environmental Science/Department of Pharmacology and Toxicology

The CEFIC LRI ECO44 project "Integrating Bioaccumulation Assessment Tools for Mammals (iBAT-Mam)" has the aim to integrate experimental data and data generated by *in silico* approaches, to improve mammalian bioaccumulation (B) assessment. Within this context, models based on *in vitro-in vivo* extrapolations (IVIVE) and Quantitative Structure-Activity Relationships (QSAR) are used to maximize the information available from *in vitro* and *in vivo* measurements and to fill *in vivo* biotransformation rate data gaps. This study presents the preliminary results generated from the statistical analysis of *in vitro* data for intrinsic hepatic clearance available in the iBAT-Mam project database. These data were measured for more than 7000 heterogeneous chemicals in rodents by different *in vitro* assays (i.e. S9, hepatocyte, microsomal). Descriptive statistics were applied, such as Multi-Variate Analysis (MVA) e.g. Principal Component Analysis (PCA) and Cluster Analysis (CA), to evaluate the statistical distribution of experimental responses, correlations and to investigate the presence of structural patterns. In addition, preliminary QSAR models were generated using multiple training sets created on the basis of structural similarity investigated by MVA. Theoretical molecular descriptors used as input for MVA and QSAR modelling were generated from canonical SMILES. Good overlap of the structural domain covered by the three diffent assays i.e. S9, hepatocyte, and microsomal, was highlighted by PCA, with a similar distribution of the studied compounds in the space defined by the molecular descriptors. In addition, Cluster Analysis was applied to divide the studied compounds into different structural groups. Finally, QSAR models were generated to predict *in vitro* hapatic clearance measured with multiple assays for different structural groups; particular attention was paid to generate models compliant with OECD guidelines for QSAR models development and validation i.e. effort was made to generate statistically reliable, and externally predictive models with defined structural applicability domains (AD). These results demonstrate that QSAR methods can predict biotransformation rate-related endpoints which are relevant to improve bioaccumulation assessment and to increase the scientific evaluation of hazard and risk that chemicals may pose to humans and the environment.

WE225

Interpreting OECD 305 Dietary Bioaccumulation Tests with the ADME-B Calculator: BCFs, BMFs and Biotransformation Rates

Y. Lee, Simon Fraser Univeristy / Resource and Environmental Management; F. Gobas, Simon Fraser University / Resource & Environmental Management

Current OECD 305 guidelines for conducting bioaccumulation tests include the option to conduct a dietary bioaccumulation test for assessing a chemical's bioaccumulation behaviour. However, the one-compartment toxicokinetic model that is used to analyze the results of dietary bioaccumulation tests is out-of-step with the current bioaccumulation science and experimental practices and information needs for bioaccumulation and risk assessment. This study presents (i) a two-compartment toxicokinetic modeling framework for describing the bioaccumulation of neutral hydrophobic organic chemicals in fish; and (ii) an associated toxicokinetic analysis tool (ADME-B calculator) for the analysis and interpretation of the results from dietary bioaccumulation test in terms of the adsorption, distribution, metabolism and excretion (ADME) of chemicals for the purpose of bioaccumulation (B) assessment. The model framework and ADME-B calculator were applied to the analysis of 229 OECD-305 dietary bioaccumulation tests involving 166 unique organic chemicals. Bioconcentration and biomagnification factors, as well as somatic and intestinal biotransformation rates were derived from this analysis. The findings indicate that the two-compartment fish toxicokinetic model over has the advantage over the one-compartment fish model is that the effect of the exposure pathway on the bioconcentration and biomagnification factor of biotransforming chemicals can be quantitatively taken into account. This is important for the application of a weight-of-evidence based approach to bioaccumulation assessment where information from both aqueous and dietary bioaccumulation tests needs to be interpreted in terms of the chemical's bioaccumulation potential in the environment.

WE226

Biotransformation of chemicals in different species using in vitro metabolism approaches

K.M. Johanning, KJ Scientific, LLC / dba of Pura Vida Connections LLC; C. Kropf, University of Bern / Centre for Fish an Wildlife Health; H. Segner, University of Bern / Centre for Fish and Wildlife Health; Q. Fontenot, Nicholls State University / Biological Sciences Department; J. Nevarez, Louisiana State University / School of Veterinary Medicine; K. Berg, University of California Davis; A. Long, G. Garcia, KJ Scientific; A. Ferrara, Nicholls State University / Biological Sciences

Biotransformation of chemicals in different species is not only relevant in bioaccumulation assessment but is an area that requires research. Recently, OECD Test Guidelines (TGs) 319A and 319B were approved for *in vitro* metabolism assessment of chemicals using rainbow trout liver S9 and cryopreserved hepatocytes for application in chemical risk assessment. Although these TGs were developed using rainbow trout, the methodology can be adapted and used across species. Aquatic and terrestrial organisms display a wide range of feeding modes, reproductive strategies and live in variety of environments. For the present study we used liver S9 sub-cellular fractions from a variety of organisms including fish (rainbow and brown trout, Russian sturgeon, bowfin, and alligator gar) and tetrapods (American alligator, rat and human). We compared fish species that inhabit different environments such as the alligator gar that resides in high temperature waters (T > 30ºC) with low DO, and a wide range of salinities to rainbow trout, the reference fish that has been used for *in vivo* and *in vitro* metabolism and bioaccumulation studies. Trout, sturgeon, garfish and alligator were maintained for 2 to 4 weeks under corresponding natural temperature and photoperiod regimes prior to euthanasia and liver S9 preparation. Bowfin were obtained from the field and rat and human liver S9 sub-cellular fractions were acquired from commercial sources. Fish were euthanized and livers perfused with a buffered clearing solution (pH = 7.8), excised, homogenized, and centrifuged to obtain the liver S9 sub-cellular fractions according to the OECD TG 319B. Liver S9 fractions of the different fishes were used to perform metabolism studies with a pharmaceutical (diclofenac), pyrene (PAH), a pesticide and to determine conventional enzyme activities (EROD, GST). Our results indicate that there are differences in metabolism when compared to trout. Alligator gar and bowfin EROD and GST activities were similar to rainbow trout and exhibited significant metabolism of pharmaceuticals such as diclofenac. Alligator (reptile) did not metabolized pyrene as expected. It is interesting to note that ancient species such as alligator gar and bowfin diverged from the teleost evolutionary line prior to the teleost genome duplication (TGD), thus these ancient fishes may possess unique adaptations to cope with xenobiotics in a way that others may not.

WE227
Analyzing complex mixtures for bioaccumulation potential using the trout in vitro metabolism assay (OECD TG 319A and 319B): a case study, fir oil (pine oil) a Natural Complex Substance (NCS).
A. Lapczynski, RIFM / Environmental Science; K.M. Johanning, KJ Scientific LLC / dba of Pura Vida Connections LLC; D.T. Salvito, Research Institute for Fragrance Materials (RIFM) / Dept of Environmental Science
Bioaccumulation potential determination using the bioconcentration factor (BCF) is used widely by regulatory agencies (e.g. REACH, ECHA) for the PBT (Persistency, Bioaccumulation and Toxicity) criteria in risk assessment of chemicals. Biotransformation of chemicals is a key component in order to determine if a chemical is enzymatically degraded by organisms in the environment and impacting environmental and human health. We are utilizing the recently approved OECD TG 319A and 319B trout *in vitro* metabolism methodology to assess the bioaccumulative potential of fir (pine) oil. The objectives of the present study are two-fold: a- determine the metabolism of pine oil by assessing biotransformation of 9 main components (alpha-pinene, beta-pinene, camphene, careen, limonene, terpinolene, borneol, borneo acetate, and beta-caryophyllene) b- compare these results with a recent *in vivo* benchmarked fish dietary study of the same fir oil mixture that has been undergoing in McLeod's laboratory at the Stockholm University. In our animal alternative methodology *in vitro* study we are utilizing rainbow trout liver S9 and cryopreserved hepatocytes. The analytical method has been optimized in order to separate and resolved the main components of this mixture for accurate analysis. In addition, individual components have been used to match the identity of the components in the complex mixture of fir oil. These individual components will also be assessed in a subsequent phase of the study for *in vitro* metabolism using the same TG 319A and 319B and compare the results with the behavior of each component in the mixture. The *in vitro* metabolic assay is a powerful tool that can be used to determine BCF of test chemicals and also provides data to build the database information on fragrance materials for fish metabolism and modeling. In addition, this *in vitro* methodology offers the great advantage and flexibility of varying factors at the cellular level in order to obtain a more realistic scenario of the chemicals-enzyme interactions (e.g. inhibition, induction) which is not possible utilizing *in vivo* methodologies.

WE228
Validation of batches of rainbow trout liver S9 sub-cellular fractions (RT-S9) to determine in vitro intrinsic clearance for bioaccumulation assessment
H. Laue, Givaudan Schweiz AG / Fragrances S & T; L. Hostettler, R. Badertscher, Y. Weiner-Sekiya, Givaudan Schweiz AG; A. Natsch, Givaudan Schweiz AG / Fragrances S &T
In vitro-in vivo extrapolation models can be used to predict fish bioaccumulation based on measured *in vitro* biotransformation rates. Two methods to determine *in vitro* intrinsic clearance using hepatocytes and liver S9 sub-cellular fractions (RT-S9) from rainbow trout underwent international validation studies and OECD guidelines have been published. The validation studies showed good transferability and reproducibility of the assays, which were performed on identical batches of biological material obtained from one source. Since these methods are based on primary biological material and not on stable cell lines, and since the biological material is not sourced from a single commercial supplier, variability due to the heterogeneous sources of the biological material must be controlled and minimized. Here we propose a suite of assays to determine phase I and phase II enzyme activities in different batches of RT-S9. Enzyme activities for a total of 9 RT-S9 batches obtained from 4 different sources were characterized. These batches included one batch used in the international validation studies. Model substrates for CYP1A (7-ethoxyresorufin-dealkylation, EROD), uridine diphosphate glucuronosyltransferase (UGT) and glutathione transferase (GST) were applied. Additionally, substrate depletion assays were performed according to the new OECD TG319B with testosterone (CYP3A) and 7-hydroxycoumarin as substrates. The latter was tested with different cofactors to determine sulfotransferase (SULT) and UGT activity. In addition, pyrene (PYR) and cyclohexyl salicylate (CS), two chemicals assessed in the validation studies, were tested. Testosterone depletion, GST- and SULT-activities were similar in the 9 RT-S9 batches tested and differed less than 2-fold. A slightly higher variation was observed for depletion of CS. The highest variations between the batches were found for UGT- and EROD-activities and PYR-depletion. The batches of two commercial suppliers showed comparable activities to the batch used in the international validation study. Based on these data, enzymatic activity ranges are proposed to validate any new batch of trout S9 for key enzymatic activities and, most importantly, to compare new batches directly to the batches used in the international validation studies. This will facilitate comparison of results obtained by different laboratories with the validation exercise and to validate newly generated results obtained with the new OECD guideline.

WE229
Development to measure biotransformation rates of chemicals using hepatopancreas S9 fractions from carp (Cyprinus carpio)
T. Yamazaki, LSI Medience Corporation; T. Niino, LSI Medience Corporation / Toxicological Science Division, Medi-Chem Business Segment; K. Ookubo, K. Oshioka, LSI Medience Corporation
To rapidly assess bioaccumulation potential of chemical substances, *in vitro* testing methods using hepatocytes or liver S9 fractions from rainbow trout were established recently (OECD TG319A&B) since data regarding biotransformation of chemicals in fish improve significantly the prediction of bioaccumulation potential (BCFs : Bioconcentration factors) in fish. However, the application of this method was substantially limited to rainbow trout. Therefore, there is uncertainty regarding the differences in biotransformation rates among fish species. In this study, we addressed to measure *in vitro* biotransformation rates using carp (*Cyprinus carpio*), which have been used for *in vivo* bioaccumulation assessment such as OECD TG305 in Japan. Through compiling in vitro data of carp, the comparison with *in vivo* data will be possible and it will show the accuracy and the reliability of *in vitro* method. Firstly, we prepared hepatopancreas S9 fractions from carp, because of the easiness to prepare and the difficulty in perfusion and separation of hepatocytes. Then, we measured the Phase I and Phase II enzyme activities and the *in vitro* intrinsic clearance ($CL_{INVITRO}$; mL/min/mg S9 protein) for some chemical substances. We also measured that for liver S9 fractions from rainbow trout and compared these data. As the results, the $CL_{INVITRO}$ values of carp were comparable with that of rainbow trout for tested chemicals and show the usefulness to assess the biotransformation ability of chemicals. However, for liver S9 fractions from rainbow trout, there are large differences in $CL_{INVITRO}$ values between measured values and the previously reported values. Then, it could not be concluded that there are differences among fish species in biotransformation of chemicals. Therefore, further research on species differences and lot to lot differences in biotransformation are needed to be adopted as the testing method by risk assessors.

Describing methods for stakeholder identification, engagement, and empowerment on mining projects.
L. Kapustka, LK Consultancy
In the last three decades, considerable progress has been made in efforts to identify, engage, and empower stakeholders in the management of their environment. Standard procedures have been codified, but all too often, only lip-service is given to stakeholder involvement. It is particularly challenging when Indigenous Peoples have an interest in the proceedings. This is in large part do to the linear thinking of most engineering-based projects. Mining operations typically are in remote areas that often include territories occupied or at least used

by Indigenous Peoples. Their knowledge and values deserve special considerations if the Sustainability Goals of the United Nations are to be addressed meaningfully – Atlas for Mapping Mining to the Sustainable (http://unsdsn.org/wp-content/uploads/2016/11/Mapping_Mining_SDGs_An_Atlas.pdf accessed 15 August 2018). In this presentation, I will trace the interconnectedness of methods for stakeholder engagement and environmental management. This will include details of the ASTM Consensus-Based Environmental Decision-making practice, a comparison with other methods such as iCASS, and illustrate how these could be used to inform decisions toward balancing social equity, ecology, and ecnomics of mining projects.

Risk profile tables for transparent and holistic decision-making for pesticide authorisation

C. Bogen, Bayer Ag / Research & Development, Crop Science; C. Mayer, BASF SE / Ecotoxicology; G. Meregalli, Dow AgroSciences Italia s.r.l. / Ecotoxicology; L. Oger, ECPA; V. Ducrot, Bayer Ag / Environmental Safety Ecotoxicology

Risk assessment and risk management are integral parts of the registration process of plant protection products (PPP). Their functional separation is considered best practice, especially in the European Union. The environmental risk assessment (ERA) investigates whether safe use has been demonstrated for a PPP by meeting its specific protection goals (SPG). In 2016, EFSA guidance was published on the development of SPG, relating them to ecosystem services (ESS) and biodiversity, but not to modern agronomic practices. Indeed, such overarching protection goals require decisions by landscape and risk managers, which should also include the consideration of stakeholders and socio-economic consequences of a given option, including up-scaling from local to global conditions. In this context we propose a risk profile table as tool and structural help. This approach aims at providing a transparent overview of relevant aspects for both the ERA and risk management, and to support the decision making process at the risk manager level. The proposed risk profile table is based on the SPG dimensions as per EFSA (2010), which directly relate to the ERA of a specific product. We propose to add further dimensions, e.g. to inform about risk mitigation or landscape management options, and which can be used to ensure safe use of the product in an agriculturally sound context. \n While the risk profile allows a direct comparison of risks versus benefits, their consequences and includes visualizing the suitable level to handle challenges, the next step is for the applicant and regulators, from risk assessors to risk managers, to test this concept for practical implementation.

The Fate, Effects, and Mitigation of Oil Spills on Aquatic and Marine Environments (P)

WE233

Comparative temperature-dependant toxicity of light oil, intermediate oil and diesel oil WAFs alone and mixed with dispersant: sea urchin bioassays

Marigomez, Euskal Herriko Unibertsitatea / Zoology & Animal Cell Biology (Sci & Tech Fac)

Shipping and oil platforms in the North Atlantic and Baltic Sea have been growing during the last years and thus, the risk of oil spills is gaining concern. Different factors such as the type of spilled oil, weather conditions and water temperature can modify the potential toxicity of spill products; So dispersants do, as well. Moreover, dispersants can be toxic themselves and make oil chemicals more available to biota, and though they can contribute to reduce the residence time of the oil in the environment (depending on factors such as the environmental temperature and the oil type) they also cause the concentration of hydrocarbons in water to rise, resulting in enhanced toxicity. Presently, the influence of Finasol OSR52 dispersant on the toxicity of the water accommodated fraction of three oil types, Napthenic North Atlantic (NNA WAF), Intermediate Fuel Oil 180 (IFO180 WAF) and Marine Diesel Oil (MDO WAF) for sea urchin larvae and embryos (*Paracentrotus lividus*) was compared after preparing WAF (oil and oil+Dispersant) at different seawater temperatures (5, 10, 15, 20 and 25°C). Different PAH levels and profiles were recorded in WAF depending on the oil type, the temperature and the presence of dispersant. Developmental alterations and larvae abnormalities were determined, and catalase enzyme activity was analysed in larvae as oxidative stress biomarker. Overall, toxicity was lower for oil WAF than for oil+D WAF at all the studied temperatures. Thus, the presence of dispersant seemingly increased oil toxicity; however, the degree of effect varied with the oil type and the temperature at which WAF was produced.

Thanks to Total Spain for kindly providing the dispersant.

WE234

Critical analysis of oil toxicity testing - recommendations and research needs for standardized and site-specific methods

P.V. Hodson, J. Adams, Queens University / School of Environmental Studies; R.S. Brown, Queens University / Department of Chemistry

A review of laboratory studies assessing biological effects of oil products to fish found a diversity of experimental designs, including differences in experimental designs, procedures for preparing test solutions, characterization of test solutions, and end-points measured. The diversity of test methods limits the comparisons of toxicity among studies and among various oil types and weathering states, contributes to uncertainty in estimated toxicity, and may limit their application in oil spill risk assessments. This review demonstrated the need for standardized tests to generate unbiased estimates of toxicity, and the need for research to identify experimental and ecological factors that determine oil toxicity under site-specific environmental conditions. This presentation provides a rationale for developing standard and site-specific oil toxicity test methods, and specific recommendations and research needs to develop such methods for oils with varying properties. Improved assessments reduce the uncertainty in their use in hazard assessments, a major component of environmental risk assessments of oil spills.

WE235

The impact of microbial degradation of oil spills on toxicity to early life stages of marine fish

B. Hansen, SINTEF Materials and Chemistry / Environment and New Resources; J. Farkas, T. Nordtug, SINTEF Ocean / Environment and New Resources; D. Altin, BioTrix; O.G. Brakstad, SINTEF Ocean / Environment and New Resources

Following acute oil spills in the marine environment, microbial communities will metabolize and ultimately mineralize petrogenic oil components. During this process, intermediate metabolites formed are expected to display lower bioaccumulation potential and acute toxicity to marine organisms due to microbial-facilitated incorporation of chemical functional groups resulting in a general decrease in lipophilicity. However, toxicity and characterization of metabolites are poorly studied. The purpose of the present work was to assess toxicity of water-soluble oil components degraded over a three-week period in cold sea water. Low-energy water accommodated fraction (LEWAF) of a weathered crude oil was prepared with nutrient-amended seawater at 5 °C, kept in the dark, and sampled at 0, 10, 14, and 21 days. Samples were extracted with dichloromethane and they were reconstituted back into sea water for toxicity testing. 4-day exposure experiments were conducted for developing cod (*Gadus morhua*) embryos during a critical period of their heart development. After exposure, embryos were kept in clean seawater and observed until 5 days post hatch, and survival, hatching, morphometric deformations and cardiac function were studied. Although reduced larvae sizes were observed after hatch for all treatments, growth rates were not significantly affected. However, developmental deformations and altered cardiac functions were affected in a concentration-dependent manner for WAFs sampled at all time points, i.e. the expected decrease in sublethal toxicity during the biodegradation period was not observed. This implies that either metabolites formed during microbial degradation of water-soluble oil components display equal toxic potential to their parent compounds, or there are other unidentified compounds contributing to toxicity persistent to a 3-week degradation in sea water. In order to properly understand the impact of oil spills on early life stages of fish, efforts need to be made to identify the toxicity driving components of crude oil. And in order to reliably predict impacts of oil spills using fate and effects modelling, metabolites of petrogenic oil components should be included.

WE236

Marine oil spills in the Arctic: quantitative oil spill risk assessment with limited data and high uncertainties

I. Helle, J. Mäkinen, M. Nevalainen, University of Helsinki / Organismal and Evolutionary Biology Research Programme; M. Afenyo, University of Manitoba / Transport Institute; J. Vanhatalo, University of Helsinki / Organismal and Evolutionary Biology Research Programme

The Arctic is experiencing increasing levels of maritime traffic, as sea ice continues to retreat due to the global climate change. This development raises concerns about accidental oil spills and their impacts on sensitive Arctic marine ecosystems. In order to be able to develop strategies for proactive risk management, we need methods to assess oil spill-induced risks in the Arctic context. However, limited data and high uncertainties typically hinder oil spill risk assessments in the Arctic. Here we present a novel probabilistic approach for ecological oil spill risk assessment for such cases. We define the oil spill risk (OSR) as the proportion of the population that will die due to the spilled oil within two weeks after an accident, and estimate it by combining information on three components: 1) spreading of oil in ice conditions along maritime routes; 2) spatiotemporally varying species' densities; and 3) species-specific vulnerabilities and sensitivities to oil. We use the Kara Sea, the westernmost of the Siberian arctic seas, as a case study to demonstrate our approach. We included five navigation routes, three seasons, and four oil types in the risk assessment, and the assessment endpoints were three arctic marine mammal species present in the Kara Sea, i.e. polar bear, ringed seal, and walrus. The results show that OSR varies between species, oil types, seasons and maritime routes. For instance, for polar bear and ringed seal, spring has the highest and summer the lowest OSR, whereas with walrus summer ranks before autumn and spring. Oil type has also a clear effect on the risk that species face. The study shows that the risk that potential oil spills pose to the Arctic marine ecosystems depends on many factors. It is also evident that the associated uncertainties are large. However, it is important that these uncertainties are displayed explicitly, if the results are to be used in decision-making. Our method is useful, as it provides quantitative risk estimates with explicitly expressed uncertainty estimates, and offers a relatively simple way to make justifiable risk comparisons over large spatial entities such as maritime routes. However, to be truly comprehensive, the analysis should include also other species groups as well as spatiotemporally varying accident probabilities. Despite these limitations, our study offers valuable information to the assessment and management of oil spills risks in the arctic marine areas.

WE237

Evaluating the impact of a simulated diluted bitumen spill on freshwater zooplankton using limnocorrals

T. Black, University of Manitoba / Department of Environment & Geography; S.S. Stoyanovich, University of Ottawa; J. Cederwall, Queens University / Biology; M. Paterson, IISD-Experimental Lakes Area; D.M. Orihel, Queens University / Department of Biology/School of Environmental Studies; V. Palace, IISD-Experimental Lakes Area; B. Hollebone, Environment Canada / Emergencies Science & Technology; J.M. Blais, J. Rodriguez Gil, University of Ottawa / Department of Biology; M.L. Hanson, University of Manitoba / Department of Environment and Geography

A number of international and collaborative reports have outlined key research areas to be addressed surrounding the transportation of oil, specifically diluted bitumen (dilbit), around North America's freshwater ecosystems. These reports concluded the need for whole-ecosystem based research evaluating fate and behaviour, toxicity, and remediation of dilbit spills into freshwater. The Boreal Lake Oil Release Experiment by Additions to Limnocorrals (BOREAL) aimed specifically to address this research need. As part of this whole-ecosystem study, the zooplankton communities were monitored for changes in abundance, community composition, and biomass. The study was conducted in an experimental boreal lake at the IISD-Experimental Lakes Area from May 2018 to September 2018. A total of nine 10-metre diameter, 157-m^3, limnocorrals were deployed to an approximate depth of 1.6-m and treated with different volumes of Cold Lake Winter Blend (CLWB) diluted bitumen (dilbit) in a regression-based design (n=7 treatments, n=2 controls). Nominal dilbit:water ratios ranged between 1:100,000 to 1:1,000 (1.6 L to 160 L of dilbit). Zooplankton was sampled at least weekly starting three weeks prior to oil addition and for 11 weeks post-addition. Preliminary data suggests that dilbit has a direct impact on zooplankton communities – densities approached zero in the two greatest treatments with no recovery apparent as of 11 weeks post-addition. In addition, biomass estimates and an analysis of species-specific changes in zooplankton were performed to understand the wider ecological implications following spills of diluted bitumen. These data will help us understand direct and indirect impacts of oil spills on freshwater biota and to inform management and policy strategies for future construction and expansion of oil transportation infrastructure in North America.

WE238

Simulating diluted bitumen spills: Environmental weathering and submergence in model freshwater systems

J. Rodriguez Gil, University of Ottawa / Department of Biology; S.S. Stoyanovich, University of Ottawa; M.L. Hanson, University of Manitoba / Department of Environment and Geography; B. Hollebone, Environment and Climate Change Canada; D.M. Orihel, Queens University / Department of Biology/School of Environmental Studies; V. Palace, IISD-Experimental Lakes Area; J.M. Blais, University of Ottawa / Department of Biology

The major petroleum product pumped through pipelines in Canada is bitumen, a semi-liquid form of heavy crude that must be diluted with natural gas condensates to facilitate transport. Though diluted bitumen (dilbit) is increasingly transported out of Canada to the global markets, there still exists numerous knowledge gaps in relation to the weathering, fate, behaviour, and environmental effects of a potential dilbit spill into aquatic systems. Here we report the results from a pilot-scale simulated spill of dilbit to freshwater, providing much-needed information in regard to dilbit's behaviour in the environment. The experiment consisted of three outdoor open-air microcosms containing natural lake water and lake sediment, as follows: a high dose (nominal dilbit:water ratio of 1:1000), a low dose (nominal dilbit:water ratio of 1:10,000), and a control (no dilbit), observed over 11 days. Following dilbit application to water, rapid decreases of volatile hydrocarbons in the dilbit slick were observed in the high and low dose treatments within the first 24 hours of the experiment, attributed mainly to evaporation. These changes in chemical composition of residual dilbit coincided with increasing density, viscosity and water uptake. Relatively rapid increases in hydrocarbon concentrations were detected in the water column following the spill, mainly alkylated polycyclic aromatic compounds, which constitute a large proportion of the aromatic fraction of dilbit. Our study provides new in-sights on the environmental fate, behaviour, and risks of dilbit in a freshwater environment. In particular, we are the first to demonstrate the propensity for dilbit to sink under ambient environmental conditions in fresh waters typical of many boreal lakes across the Canadian Shield. In addition to the data on this pilot-scale experiment, preliminary data on our main study conducted in larger (10-m diameter) in-lake mesocosms, will be presented.

WE239

Biological Effects of Chemically Dispersed Crude Oil on Baltic Sea Microbial Communities

A.S. Raitosalo, M. Vikman, H. Miettinen, M. Bomberg, M. Nyyssönen, VTT Technical Research Centre of Finland Ltd

Heavy traffic and transportation of oil makes the Baltic Sea vulnerable to accidental oil spills. Currently mechanical removal is the recommended response method in the Baltic Sea region. However, in some scenarios, mechanical removal can be challenging and some of the spilled oil could remain in the environment. Chemical dispersants are mixtures of surfactants and solvents and are used to treat spilled oil in marine environments. Dispersants break oil slicks into small droplets, which are more readily available for microbial biodegradation. Effects of dispersants on microbial communities and biodegradation rates have not been extensively studied in the Baltic Sea. During this 40-day microcosm study, native microbial communities from the Gulf of Finland were exposed to crude oil, dispersant or their combination. Additional nutrients were not supplied during the study. The experiment was carried out at +10 °C, and samples were collected at days 1, 2, 5, 14 and 40. The amount and expression of genes related to microbial abundance, oil biodegradation and nutrient cycling was assessed by quantitative PCR. High throughput robotics was utilized to study enzymatic activities. The results indicate that microbial response was primarily elevated in samples containing dispersant. Dispersant was degraded almost completely during the study period. However, dispersant application had little effect on overall oil biodegradation. On genetic level, the abundance and expression of alkane hydroxylase gene (*alkB*) was higher in samples with dispersant, whereas the abundance and expression of polycyclic aromatic ring-hydroxylating dioxygenase gene (PAH-RHD) was enhanced also in samples containing crude oil.

WE240

Effects of dispersant on the petroleum hydrocarbon biodegradation and microbial communities in the Baltic Sea

O. Tonteri, Finnish Environment Institute / Marine Research Centre; A. Nousiainen, Finnish Environment Institute SYKE; A. Reunamo, SYKE Marine Research Centre; J. Nuutinen, Finnish Environment Institute / Laboratory Centre; J. Truu, University of Tartu; K.S. Jørgensen, Finnish Environment Institute SYKE / Marine Research Center

Dispersants are chemicals used in oil spill response to increase bioavailability and enhance degradation of petroleum hydrocarbons. Although dispersants have been used in several oil spill accidents, there is little information available from the effectiveness of dispersants at the brackish and cold seawater found in the Gulf of Finland and Baltic Sea. This study investigated the effects of dispersant on petroleum hydrocarbon biodegradation rate, degradation gene abundances and microbial communities found at the Baltic Sea.   Microcosm bottle experiments were conducted at 5 °C for 12 days using naphthenic Northern Sea crude oil and dispersant Finasol 51. Seawater used in the experiment was collected from coastal and open sea area of Gulf of Finland and also from coastal area of North Atlantic. In the experiments crude oil was applied as Water Accommodated Fractions (WAF) and dispersant was applied as Chemically Enhanced Water Accommodated Fractions (CE-WAF). Experiments were conducted with diluted and undiluted WAF and CE-WAF. Oil degradation was assessed by analysing the petroleum hydrocarbons with GC-FID at the beginning and end of the experiment. Microbial biodegradation potential was assessed by qPCR targeting PAH and alkane degradation genes. Highest petroleum hydrocarbon degradation was observed in coastal Baltic Sea seawater without dispersant (degradation 92 %), with dispersant addition the degradation was only 5 %. With North Atlantic seawater the degradation was lower, 59 % without dispersant and no overall degradation with dispersant addition. Coastal Baltic Sea seawater showed higher abundance of alkB, PAH and 16SrRNA compared to coastal North Atlantic Sea, which had similar or slightly higher copy numbers compared to open sea Gulf of Finland seawater. With all experiments there was small difference between alkB and 16SrRNA Compared to PAH degradation gene copy numbers, alkB genes were generally 10^3 times greater, indicating a higher immediate potential for alkane degradation. Based on the results, dispersant addition was not observed to increase biodegradation. Microbes associated with coastal seawater were observed to have higher oil degradation gene abundances.

WE241

The importance of primary and ultimate biodegradation of oil compounds in marine fate and effect models

O.G. Brakstad, SINTEF Ocean / Environment and New Resources; B. Hansen, K.M. McFarlin, T. Størseth, L. Sørensen, SINTEF Ocean / Environmental Technology; T.K. Frost, Equinor AS

Biodegradation is an important fate parameter of oil released to the marine environment. Biodegradation rates, based on experimental data, are included for oil compound groups in the OSCAR oil spill model, and for single compounds in the DREAM model for produced water. However, the models do not separate between primary and ultimate biodegradation. We showed in this study that both primary and ultimate biodegradation of oil fractions may be important to determine in relation to different ecotoxicity endpoints of marine organisms. Acute screening toxicity (Microtox^{TM}) was primarily related to primary biodegradation of oil. However, chronic toxicity to developing cod embryos and larva, in particular craniofacial and jaw deformations, were observed mainly unchanged after > 95% primary biodegradation, while ultimate biodegradation was still < 25%. These chronic effects therefore extended beyond primary degradation and were also associated with degradation products or the persistent unresolved complex mixture (UCM) of the oil. In order to relate oil compound biodegradation to different ecotoxicity endpoints, we therefore investigated both primary and ultimate biodegradation rates of selected single components included as naturally occurring substances in the DREAM model, and which were associated with environmental concern (BTEXs, PAHs and phenol/alkylphenols). Reviews of literature data relevant for biodegradation in marine environments revealed a need for revision of the current data in the DREAM model. There was in particular a substantial lack of relevant marine ultimate biodegradation data of PAHs and alkylphenols. Experiments were therefore performed to determine primary and ultimate biodegradation rates of single PAHs and phenol/alkylphenols. The substances were immobilized to hydrophobic adsorbents (Fluortex^{TM}), which were submerged in natural seawater and incubatded at 20°C for up to 2 months. Primary and ultimate biodegradation were determined by gas chromatographic analyses (GC-MS) and as biochemical oxygen demand (BOD), respectively.The biodegradation data were also comparded to previous data from studies of produced and crude oil biodegradation. These data from the current study may be included as part of the fate prediction in the DREAM model. Further studies are required to identify biodegradation metabolites associated with different acute and chronic ecotoxicity endpoints.

WE242

Short-term effects of diesel oil and dispersant on marine microbial communities in the Baltic Sea surface water in coastal areas and open sea

A. Reunamo, SYKE Marine Research Centre; E.I. Pulkkinen, Finnish Environment Institute SYKE / Marine Research Centre; M. Bomberg, VTT Technical Research Centre of Finland Ltd; K.S. Jørgensen, Finnish Environment Institute SYKE / Marine Research Center

The Baltic Sea is a geologically and biologically unique sea that is highly vulnerable to environmental hazards. This area is constantly subjected to high inputs of hazardous substances due to anthropogenic activities, and the most emphasized threat is the risk of oil spills. The microbiology of the Baltic Sea has not been extensively studied, and most studies have focused on bacteria, leaving archaea and fungi to less attention. In addition to the natural microbial communities of different parts of the Baltic Sea, the effects of diesel oil, and dispersants applied in case of an oil spill, on the microbial communities is yet to be elucidated. This study focuses on comparing the microbial community structure of the Baltic Sea surface water at three distinct locations; the open sea, pristine archipelago, and putatively oil-contaminated coastal water near an oil refinery. In addition, the short-term effects of diesel oil and dispersant on the microbial community of the three locations were studied during a 72-hour experiment. Next generation Ion Torrent sequencing of bacterial V3-V4 and archaeal V4 regions of 16S rDNA and fungal ITS1 regions was used for a community structure analysis. Quantitative polymerase chain reaction (qPCR) was applied to determine the changes in the copy numbers of bacterial 16S rRNA genes and the two genes associated with microbial diesel degradation, i.e. ring-hydroxylating dioxygenases (RHD) and alkane hydroxylases (AlkB). Assessing the natural diesel degradation potential of the Baltic Sea surface water microbiome is of great importance, and the data generated here can potentially be utilized when developing suitable biological oil spill responses in the Baltic Sea area. Research on the Baltic Sea microbiome and the natural diesel oil degradation potential can also be utilized in predicting the degradation rates in different parts of the sea.

WE243

Biomarker responses in mussels (Mytilus edulis) and amphipods (Gammarus oceanicus) from the White Sea exposed to water-accommodated fraction of marine diesel oil

R. Turja, Finnish Environment Institute, SYKE / Marine Research Centre; N. Berezina, Russian Academy of Sciences / Zoological Institute; S.A. Murzina, I. Sukhovskaya, N. Fokina, N. Kantserova, L. Lysenko, Russian Academy of Sciences / Institute of Biology of the Karelian Research Centre; A. Ahvo, Finnish Environment Institute SYKE / Marine Research Centre; K.K. Lehtonen, Finnish Environment Institute / Marine Research Centre

The White Sea (northwest Russia) is an Arctic marine ecosystem and therefore potentially very sensitive to oil pollution. Studies on the impacts of oil on local biota has so far been scarce, although nearby areas are expected to be increasing in marine traffic and oil production activities in the future, thus increasing the risk of oil pollution. The blue mussel *Mytilus edulis* and the crustacean amphipod *Gammarus oceanicus* are common and ecologically important species in local coastal habitats of the whole region. For the current study, these species were collected from a pristine region close to the White Sea Biological Station in Kartesh (Chupa Inlet, Kandalaksha Bay) and exposed in the laboratory to a water-accommodated fraction (WAF) of marine diesel oil for 7 days with a semi-static scheme at the temperature of 10ºC and a salinity of 26, corresponding to a typical range of environmental conditions in the area. Concentration of oil polycyclic aromatic compounds (PAH) in the exposure media was measured continuously using the TRIos Enviroflu-HC optical sensor. Before and after the exposure different tissues or whole organisms were measured for a suite of biomarkers and indicators of physiological condition, including antioxidant defence system (ADS) enzymes, oxidative damage (lipid peroxidation), acetylcholinesterase activity, proteasome- and calpain-dependent proteolysis, and changes in total lipid level, lipid class and fatty acids composition.The results show clear effects in a number of the parameters measured in both species, accompanied by bioaccumulation of PAH compounds in the tissues of the organisms. Acknowledgements: The study was supported by bilateral mobility grants from the Academy of Finland (AF), the AF research project OILRES, and IB KarRC RAS state theme No 0221-2017-0050.

WE244

Geno- and cytotoxic effects of crude oils on the mussel Mytilus spp. from the Baltic Sea

M. Stankevičiūtė, Nature Research Centre; R. Turja, Finnish Environment Institute, SYKE / Marine Research Centre; L. Butrimavičienė, Nature Research Centre / Institute of Ecology; J. Pažusienė, Nature Research Centre; A. Ahvo, Finnish Environment Institute SYKE / Marine Research Centre; K.K. Lehtonen, Finnish Environment Institute / Marine Research Centre; K.S. Jørgensen, Finnish Environment Institute SYKE / Marine Research Center

Oil pollution is a widespread and continuous problem in the marine environment. The Baltic Sea is a sensitive ecosystem where restricted water exchange, brackish water and low temperatures increase the risk of pollution induced impacts in marine organisms. Biological effects of crude oil were assessed by exposing mussels (*Mytilus* spp.) to the water accommodated fraction (WAF) of (1) Russian crude oil for 1 and 7 days (temperature 10°C) and after 6 month recovery period in the sea, and (2) Naphtenic North Sea crude oil at different salinities (5.6 and 15) for 1, 7 and 21 days (temperature 5°C). Geno- and cytotoxicity were evaluated in thegills cells using the nuclear abnormalities assay. Frequencies (in ‰) of eight nuclear abnormalities (NAs, per 1000 cells) were examined. Micronuclei (MN), nuclear buds (NB), nuclear buds on filaments (NBf), bi-nucleated erythrocytes with nucleoplasmic bridge (BNb), and blebbed nuclei cells (BL) were used as genotoxicity (∑Gentox) endpoints. Fragmented-apoptotic (FA), bi-nucleated (BN), and cells with 8-shaped nuclei were assessed as cytotoxicity (∑Cytox) endpoints. WAF and chemically enhanced-WAF (CE-WAF) of Russian crude oil resulted in significantly elevated ∑Gentox levels at 7 days of exposure. Mussels deployed back to the sea in cages for a 6-month recovery period showed significantly elevated ∑Gentox and ∑Cytox levels in both WAF and CE-WAF treatments in comparison to control. Naphtenic North Sea crude oil CE-WAF at the salinities of 5.6 and 15 induced significantly elevated levels of ∑Gentox after each exposure time point (1, 7 and 21 days), whereas in the WAF exposed group they were elevated only after 21 days at 5.6. Significant higher levels of ∑Cytox were observed after 1 and 21 days of exposure, and only at 5.6.To assess the multi-biomarker response of crude oil exposure, the ∑Gentox and ∑Cytox results were supported by the Integrated Biomarker Response index (IBR) calculated using a number of biomarkers, including enzymes of the antioxidant defense system, lipid peroxidation, acetylcholinesterase activity, and condition index measured from mussels. Chemical analysis showed that the exposed mussels efficiently accumulated polycyclic aromatic hydrocarbons (PAHs) and the uptake was higher in treatments with a dispersant. Increased PAH solubility at lower salinity resulted in higher PAH concentrations at the salinity of 5.6 compared to 15, having also an effect on biomarker responses.

WE245

Ecotoxicological effects of untreated and chemically dispersed marine fuels on cell and organism level

M. Gossen, RWTH-Aachen / Environmental Research Institut; S. Johann, H. Hollert, RWTH Aachen University / Institute for Environmental Research; T. Seiler, RWTH Aachen University / Ecosystem Analysis

Within the framework of the EU project "GRACE", various field and laboratory experiments are carried out to assess the effects of oil spills on selected regional relevant and well-developed model species of the Atlantic Ocean and the Baltic Sea. The marine fuel and crude oil toxicity to aquatic organisms is an important topic in ecotoxicology, as increasing oil consumption, exploration and transport pose a high risk for huge and diffuse oil spills. Besides mechanical oil response option also dispersants are used as a chemical means to combat oil spills at sea. Third-generation chemical dispersants are complex mixtures of surfactants, solvents and other additives which allow the oil to spread more widely in the water body and thus degrade more quickly. One method to assess the risk of different kind of oils and dispersed oils in the GRACE project is the investigation of low energy water-accommodated fractions (LEWAF) and chemically enhanced water-accommodated fractions (CEWAF). In the present study two types of marine fuels, IFO180 and MGO, were tested for their acute toxic and genotoxic potential on different biological levels. The chemical dispersant used was FINASOL OSR 52 (Total). The micronucleus test using the zebrafish liver cell line (ZF-L) to assess the genotoxic potential was performed according to the ISO Guideline 21427-2. To investigate the toxicity on organism level the prolonged Fish Embryo Acute Toxicity Test with *Danio rerio* (OECD 236) was performed. Exposure to fuel WAFs led to typical oil-related malformations in embryos commonly described as blue sac disease. Furthermore, the samples showed a genotoxic potential. Results indicate a higher toxicity for the CEWAF treatment of both oil types, which is in agreement with earlier findings

WE246

Is exposure to chemically-dispersed oil more harmful to early stages of the Northern shrimp Pandalus borealis than mechanically-dispersed oil?

M. Arnberg, F.K. Gröner, s. westerlund, S. Ramanand, R. Katrin Beckmann, NORCE Norwegian Research Centre; a. gomiero, International Research Institute of Stavanger / Enviromnent; T. Baussant, NORCE Norwegian Research Centre

Oil pollution in the sea is a major environmental concern, which can drastically affect the marine ecosystem. Oil and gas activities is expanding oil search and recovery in the North Sea, and currently extends their search to Northern latitudes, including the Norwegian and Barents Sea [1, 2]. The current and future O&G development, together with increasing shipping after ice reduction, pose an increasing risk for accidental oil spill particularly in the high north ecosystem. Oil spill responses involve trade-offs, including the usage of dispersants. However, Scientific knowledge is needed to support decision-making and it is suggested to use a Net Environmental Benefits Analysis (NEBA) to decide on the best counteractions to mitigate ecological impacts following spill. This is especially demanded for key planktonic larval stages which are the most critical life traits to pollution events. such as oil.\nHere, larval fitness parameters such as survival and feeding rates of the Northern shrimp, Pandalus borealis larvae were measured in a series of exposure experiments where both mechanically and chemicallydispersed oil were used. Longer-term effects on the ontogenetic development of the northern shrimp larvae were also assessed. To mimic realistic exposure to oil spill, an experimental setup with high energy mixing was employed [3]. Oil and dispersant were added to achieve a dispersion with a total hydrocarbon (THC) concentration in the range of 10-20 mg/L, simulating realistic oil spill concentration shortly after a spill [4]. Additional treatments with oil only, dispersant only and a seawater control were included for comparison [5]. Relatively short exposure incubations (from 1h to 24h) were followed by longer recovery times (10 days) to assess both acute- (mortality) and longer-term effects (feeding, development). The overall aim was to assess the sensitivity and resilience of the Northern shrimp larvae to realistic oil spill mitigation responses, to support NEBA and oil responders for deciding the best options to combat oil and mitigate impacts to the marine environment, should a spill occur in the high north regions.

Applications of Bayesian Network Models for Environmental Risk Assessment and Management (P)

WE247

Use of Bayesian network modelling for assessing the weight of evidence of an AOP network for UV radiation

J. Moe, Norwegian Institute for Water Research (NIVA) / Section for Ecotoxicology and Risk Assessment; K. Tollefsen, NIVA / Ecotoxicology and Risk Assessment; L. Xie, NIVA - Norwegian Institute for Water Research / Environmental Toxicology; Y. Song, Norwegian Institute for Water Research (NIVA) / Ecotoxicology and Risk Assessment

In this study, we use Bayesian network (BN) methodology to evaluate, refine and quantify a conceptual AOP (Adverse Outcome Pathway) model, which describes the adverse effect of UV-B radiation (a non-chemical stressor). This tentative AOP is a complex network linking two molecular initiating events (MIEs: ROS formation and CPD formation) to two adverse outcomes (AOs: reduced survival and fecundity of arthropodes), through nine potential key events. A tentative AOP structure has been developed based on literature studies, and will be evaluated with experimental data. The experiment, *Daphnia* individuals were exposed to UV radiation in 6 different dose-rates in the range 0 - 0.4 w/m2. All variables (the MIEs, KEs and AOs) were measured with three repeated measurements for each dose-rate. The resulting proposed AOP network consists of 10 potential pathways from the stressor to the second adverse outcome (reduced fecundity). This AOP network will be further developed by BN modelling in three main steps: (1) Evaluation and refinement of the proposed AOP structure: using the structure learning capabilities of BN software to suggest the most important key event relationships (i.e. their causal directions and strengths) based on correlations in the dataset, and refining the AOP model accordingly. (2) Quantification of the refined AOP model: quantifying each selected KER as a conditional probability table based on statistical modelling of the experimental data (e.g., regression analysis of dose-response curves). (3) Sensitivity analysis: ranking the pathways of the AOP network according to the strength of their influence on the adverse outcomes. The approach demonstrated here - the combination of expert knowledge, experimental data and advanced modelling methods (Bayesian networks) - is a promising strategy for data-oriented selection of key AOPs and for the identification of knowledge gaps associated with these AOPs.

WE248

Using AOP Bayesian Networks and Conventional Bayesian Networks to Improve Scenario-Based Risk Assessment and Management

L. Burgoon, U.S. Army Engineer Research and Development Center / Environmental Laboratory

Bayesian networks are a tool for studying causal chains to predict either outcomes, or the sequence of events that may have caused an outcome. Recently my collaborators and I have demonstrated how adverse outcome pathways can be converted into Bayesian Networks to facilitate the prediction of adverse outcomes using a minimal set of sufficient key events (MINSSKE). Here, I am combining the AOP Bayesian Networks, which operate at a more mechanistic toxicology level, with more conventional Bayesian Networks, that we use for scenario analysis in risk assessments and risk management decisions. Specifically, I will demonstrate how different climate change scenarios will alter the probabilistic risk of an adverse outcome in sensitive species due to some chemical exposure, where the chemical exposure level and route of exposure change as a function of climate change scenarios. I will demonstrate this work using the fungicide prochloraz, our AOP Bayesian Network for steroidogenesis, and common scenarios for climate conditions that may alter the growth conditions of fungus on crop plants.

WE249

Spatial oil spill risk assessment for threatened coastal biota in the northern Baltic Sea: Combining Bayesian networks, oil spill modeling and biodiversity data

I. Helle, University of Helsinki / Organismal and Evolutionary Biology Research Programme; A. Jolma, Biwatech Ltd; R. Venesjärvi, University of Helsinki

Possible oil accidents pose a risk to marine and coastal biodiversity especially in areas with high maritime traffic density and oil transportation volumes. Spatial oil spill risk assessment can help to manage the risk, for instance, by providing relevant information related to the deployment of oil combating equipment. In this study, we applied a probabilistic method to assess the spatial risk that tanker accidents pose to coastal ecosystems in the northern Baltic Sea. Our approach combined three elements that all had a spatial dimension: (relative) probabilities and other features of tanker accidents in different areas, the stochastic spreading of oil, and the ecological values at stake. We focused on threatened habitat types and species, as they are typically already stressed by other anthropogenic activities, and their recovery can be assumed to be slow and uncertain. We used a Bayesian network (BN) to describe different tanker accident scenarios in a probabilistic manner. The model included six relevant variables needed to describe the accidents, such as location, accident type, spill size, and oil type. The prior distributions for the variables were mainly derived from maritime and port statistics. For the spreading of oil, we used maps calculated with the SpillMod oil spill model that showed the probability of oil to occur in a certain location within 10 days after an accident, given the characteristics of the spill and the prevailing weather conditions. The species and habitat data covered the locations and abundances/areas of threatened species and habitats along the Finnish coastline in the Gulf of Finland and the Archipelago Sea. The results show that spatial oil spill risk varies across the study area, and does not correspond to the frequency of accidents in a given area. In general, the risk is highest in the outer archipelago, and also certain hotspots along the coastline can be identified. Further, the risk is highest for seashore meadows and sandy beaches, which rank high also when species-specific risks are examined. Our study suggests that we should aim for oil spill risk assessments that do not focus only on single factor such as accident probabilities. A major advantage of our approach is the large number of separate oil spill simulations, which are combined by using a BN that offers an explicit way to handle uncertainty related to oil accidents.

WE250

Managing aleatory and epistemic uncertainty in Bayesian Networks

U. Sahlin, Lund University / Centre forr Environmental and Climate Research; I. Raices Cruz, Lund University / Centre for Environmental and Climate Research CEC

Bayesian Networks (BN) are probabilistic causal models with applications in risk, decision and data analysis. A BN is a joint probability distribution of nodes and causal links between them. When the nodes in a BN are categorical random variables (which is often the case), this probability distribution is characterized by probabilities or conditional probabilities. These probabilities can express aleatory uncertainty (variability) or epistemic uncertainty (uncertainty due to lack of knowledge). We claim that both types of uncertainty cannot be considered at the same time in BNs, which is a potential problem when there is a need to separate aleatory from epistemic uncertainty in an assessment. We present and compare several alternatives to overcome this issue: 1) Let probabilities in the BN represent aleatory uncertainty only, specify multiple BNs considering epistemic uncertainty in these parameters and evaluate the impact of this uncertainty on the outcome using sensitivity analysis, 2) Specify aleatory uncertainty in the definition of nodes of the BN and use probabilities for epistemic uncertainty only, 3) expand the BN to a Bayesian model which allows for several levels of uncertainty and uses the probability on relative frequency approach to treat epistemic and aleatory uncertainty, and 4) Use the BN for aleatory uncertainty only and consider epistemic uncertainty by bounds on the probabilities (Credal Net). These alternatives are valid and coherent alternatives to manage aleatory and epistemic uncertainty in applications of data or expert-driven Bayesian Networks for environmental impact or risk assessment.

Examining Behavioural Effects of Chemical Contaminants and Other Stressors on Behaviour, Ecology and Evolution of Wildlife (P)

WE252

Behavioural and ecological responses to chemical pollution

B. Wong, Monash University / School of Biological Sciences

Humans have brought about unprecedented changes to environments worldwide. For many species, behavioural adjustments represent the first response to altered conditions. Such behavioural modifications can potentially improve an organism's prospects of surviving and reproducing in a rapidly changing world. However, not all behavioural responses are beneficial. Human-altered conditions, including the discharge of anthropogenic chemicals into the environment, can undermine the reliability of sexual signals used by animals to assess potential suitors. Environmental pollutants can also impair sensory systems or interfere with physiological processes needed to mount an appropriate behavioural response. An understanding of behaviour could therefore be important in helping to explain why some species are able to survive, or even flourish, under human altered conditions, while others flounder.

WE253

Interaction between carbamazepine toxicity and food limitation in an artificial indoor stream experiment

K. Heye, Goethe University Frankfurt/ Main / Aquatic Toxicology; S. Graumnitz, Dresden University of Technology / Institute of Hydrobiology; M. Rybicki, Dresden University of Technology / Institut für Hydrobiologie; D. Jungmann, Dresden University of Technology / Institute of Hydrobiology; M. Oetken, Goethe University Frankfurt / Aquatic Ecotoxicology; J. Oehlmann, Johann Wolfgang Goethe-Universitat Frankfurt / Aquatic Ecotoxicology

In chronic toxicity tests, single organisms are commonly exposed to a single contaminant under low-stress laboratory conditions. As those experiments reduce the complexity of natural habitats and potentially the sensitivity of organisms, we exposed three aquatic invertebrates to the antiepileptic drug carbamazepine (CBZ) in a multiple stress, higher tier test. The non-biting midge *Chironomus riparius*, the blackworm *Lumbriculus variegatus*, and the New Zealand mud snail *Potamopyrgus antipodarum* were exposed to two concentrations of CBZ (80 and 400 µg/L) with and without the addition of the herbicide terbutryn (TBY, 6 µg/L) in a 32-day artificial indoor stream experiment. TBY was added as a second chemical stressor to reduce the biofilm biomass in the streams and, hence, induce food limitation. Data were analyzed by an analysis of covariance (ANCOVA) with TBY as a covariate. *C. riparius, P. antipodarum,* and in tendencies *L. variegatus* were affected by CBZ in the artificial indoor streams at concentrations of 10 to more than 25 times lower than in previous laboratory studies. *P. antipodarum* was the only organism affected by TBY as a single factor, which significantly reduced the biofilm biomass. The addition of TBY caused a decrease in emergence of *C. riparius* at 80 µg CBZ/L but an interaction between CBZ and TBY was not present according to the ANCOVA. All three organisms were differently affected by CBZ and the multiple stressors in this experiment according to its ecological niche. The environmental hazard for CBZ can be considered as low due to the high effect concentrations of CBZ. Nevertheless, the difference in sensitivity between laboratory and indoor stream experiments by a factor of more than 25 for *P. antipodarum* give reason for concern about a potential underestimation of risk for other, more toxic contaminants.

WE254

Impacts of water pH on the toxicity of fluoxetine on Daphnia magna: a multi-generational study

J. SEO, The University of York / Environment and Geography; A. Boxall, University of York / Environment and Geography Department; K. Choi, Seoul National University / School of Public Health

Fluoxetine (FLX), a selective serotonin reuptake inhibitor (SSRI), has been widely prescribed as anti-depressant. While FLX has been frequently detected in surface waters, sediments and biota, only limited information is available on its *in vivo* toxicity, particularly in invertebrates, under changing water pH. In the present study, the ecotoxicity of FLX (pK_a = 9.8) was investigated in different pH levels (6.8, 8.3, and 9.2) using *Daphnia magna*. Daphnia neonates ((F0) were exposed to 0, solvent control, 31.3, 62.5, 125, 250, 500, or 1000 µg/L for 48 hr and its effects on survivals (EC20, 50 and 75) were determined. Moreover, Daphnia neonates (The first brood daphnids from the chronic tests were discarded and the second brood daphnids (F1) were employed for the multigenerational acute test within 12 hours. F1 neonates were further exposed to 0, solvent control, 31.3, 62.5, 125, 250, or 500 µg/L for 48 hr and their survivals (EC20, 50 and 75) were determined. F0 juveniles exposed to 0 or 55.6 µg/L at 10 d were measured for MDA. After 48 hr of F0 and F1 exposure, the EC50 significantly decreased ($p < 0.05$) at 6.17 µg/L of FLX at all tested pHs. Moreover, after 21 d F0 exposure, the reproduction showed an increasing trend until 55.6 µg/L and significantly decreased at 166.7 µg/L at pH 9.2. F1 neonates showed significantly decreased body length after 21 d exposure to 2.06, 6.17, 18.5 and 55.6 µg/L at pH 9.2. Malformation of F1 daphnids development was also observed at 2.06 µg/L to 500 µg/L. MDA concentration was also demonstrated increasing trends in all pHs and significantly increased at 55.6 µg/L at pH 6.8 and 9.2. Our observation clearly indicates that survival, reproduction, and growth performance in aquatic invertebrate can be adversely affected by FLX and the toxicity increases as water pH increases. A greater amount of uncharged ions from FLX has increased Reactive Oxidative Stress (ROS), MDA, by the ionic speciation at higher pH. Increased MDA concentration affected the mortality of F0 daphnids. Increased F1 daphnids population demonstrated significantly greater toxicity. As a result, the toxicity of FLX has increased acutely, chronically, and multigenerational effects by increasing pH levels. Consequences of longer-term exposure over multi-generations warrant further investigation.

WE255

Evaluating slow-release implants for manipulating pharmaceutical exposures in wildlife

E. McCallum, Swedish University of Agricultural Sciences SLU; D. Cerveny, Umea University; J. Fick, Umea University / Department of Chemistry; T. Brodin, Swedish University of Agricultural Sciences SLU

Recently, scientists have advocated to "scale-up" studies measuring the effects of pharmaceutical pollutants in the wild. Whole-lake experiments are a gold standard for ecotoxicologists looking to assess the effects of chemical contaminants, such as pharmaceuticals, in aquatic ecosystems. However, access to such lakes is limited, exposures can be costly, and they can have potentially long-lasting effects on the exposed environment. Here, we present a method for manipulating internal pharmaceutical exposures in aquatic wildlife. We evaluate the used of two fat-based pharmaceutical carriers (coconut oil and vegetable shortening) for delivering an internal dose of the behaviour-modifying pharmaceutical oxazepam. We implanted roach (Rutilus rutilus) with implants containing a high (50 µg/g), low (25 µg/g), or control (0 µg/g) concentration of oxazepam in the implant. We then measured oxazepam uptake in four tissues (plasma, muscle, liver, and brain) over a month. The two carriers released oxazepam differently: coconut oil delivered a more consistent dose across time, while vegetable shortening released oxazepam rapidly at the start of the exposure period. For both carriers and treatments, brain and liver tissues contained the most oxazepam, while plasma and muscle contained the least. Overall, the method is a promising technique for conducting controlled manipulations of pharmaceuticals in fish. We compare our findings to tissue-specific oxazepam uptake reported in previous waterborne exposure studies, and discuss potential mechanisms (e.g., diffusion) for the differential release of oxazepam from our two fat-based carriers.

WE256

Sublethal behavioral responses of two common larval fish models to Prynesium parvum along a nutrient stoichiometry gradient

R. Steenbeek, Baylor University / Environmental Science; B.N. Hill, Baylor University / Department of Environmental Science; B. Steele, Baylor University / Biomedical Studies; B.W. Brooks, Baylor University / Department of Environmental Science

The magnitude, frequency and duration harmful algae blooms (HABs) appear to be increasing on a global scale. These HAB events result in diverse water quality challenges such as impairment of recreational uses, reduced aesthetics, decreased drinking water quality, lower dissolved oxygen concentrations, and health and ecological risks following the production of toxins. *Prymnesium parvum* causes major kills each year around the world, resulting in appreciable economic losses. Unfortunately, sublethal effects of this emerging threat to water quality are largely unstudied. In the present study, we examined growth and sublethal toxicity of *P. parvum* across a nutrient stoichiometry (N:P) gradient (1:1, 4:1, 8:1, 16:1, 32:1, 64:1, 128:1) while maintaining temperature and salinity conditions representative of conditions associated with inland HABs. Following previously reported methods from our laboratory, we examined acute and sublethal behavioral responses of the fathead minnow and zebrafish models during stationary growth conditions. These toxicity bioassays employed embryo-larval stages and followed standardized experimental guidelines. For behavioral analyses, zebrafish embryos and fathead minnow larvae were exposed for 48 h to dilutions of each N:P treatment level and then were observed with a digital behavioral analysis system.

These analyses included photomotor responses, distance travelled, and stimulatory, refractory and cruising locomotor activity. Our observations identify the importance of understanding sublethal responses to *P. parvum* and demonstrate the usefulness of behavioral responses for HAB events.

WE257

Comparative Behavioral Toxicology in Zebrafish: Individual and Mixture Responses to Nicotine and Bupropion

J.L. Vanderpool, Baylor University / Department of Environmental Science; B. Steele, Baylor University / Biomedical Studies; B.W. Brooks, Baylor University / Department of Environmental Science

Pharmaceuticals are a major group of contaminants of emerging concern that have been detected in surface waters worldwide, yet traditional toxicological endpoints (e.g., mortality, growth) may not capture important mechanism of action (MOA) relevant responses of these chemicals in aquatic biota. Because several pharmaceutical compounds (e.g., antidepressants) are specifically designed to modify behaviors in humans, behavioral responses of non-target species must be considered. Unfortunately, data is routinely lacking on specific behavioral perturbations associated with therapeutic targets in fish species. Nicotine and bupropion are two common pharmaceutical contaminants that differentially interact with nicotinic acetylcholine receptors (nAChRs), and elicit behavioral effects in mammals. Therefore, the current study followed standardized guidelines to identify and compare larval zebrafish behavioral responses between nicotine and bupropion after 96 h exposure. A binary mixture study was then conducted with both nicotine and bupropion following previously published methods. Each compound produced locomotor and photomotor effects in larval zebrafish at levels that were two to four orders of magnitude lower than LC50 values. Nicotine, a nAChR agonist, produced stimulatory responses whereby larval activity dramatically increased at bursting speed thresholds, but bupropion, a nAChR antagonist, elicited refractory responses were larval activity decreased at all effected endpoints. With the mixture study at the 1% LC50 concentration for both compounds, nicotine bursting activity was reduced, and the activity was no longer significantly different from the control. Additionally, behavior was affected significantly at the lowest treatment level of these mixtures (0.25% LC50 nicotine and bupropion). These results indicate that behavioral responses can be useful to examine physiological responses associated with pharmaceutical MOAs at concentrations far below those eliciting mortality. These observations further suggest that behaviors can be leveraged to investigate interactive effects of aquatic contaminants on non-target aquatic species.

WE258

Effects of nanoplastics on fish embryos

M. Oliveira, RMS-TekebBio, LDA; P. Manuel, University of Aveiro / Department of Biology; M. Almeida, I. Domingues, University of Aveiro / department of Biology & CESAM; M.A. Martins, University of Aveiro / Physics Department & CICECO; A.M. Soares, University of Aveiro / department of Biology & CESAM

Small plastic particles have increasingly been detected in aquatic biota, from zooplankton to fish, raising concern for potential effects on aquatic organisms. Once in the environment plastic debris can be fragmented to smaller-sized plastics, including microplastics and nanoplastics. Although an increasing number of studies have been assessing the effects of microplastics to fish, the data concerning nanoplastics can be considered scarce. This study was design to assess the effects of nanoplastics on zebrafish embryos development, swimming behaviour, response to stress and biochemical endpoints associated with oxidative status and energy metabolism. Considering that in the environment organisms are exposed to plastic particles and other environmental contaminants, this study also aimed to assess the role of nanoplastics on the toxicity of other environmental contaminants, to evaluate their protential trojan horse effect/ protective effects.

WE259

Impact of the agricultural pollutant 17β-trenbolone on sequential male mate choice in the guppy (Poecilia reticulata)

M.G. Bertram, P. Tomkins, Monash University / Biological Sciences; M. Saaristo, Monash University / School of Biological Sciences; M. Michelangeli, Monash University; R. Tomkins, Department of Environment and primary Industries; J.M. Martin, B. Wong, Monash University / School of Biological Sciences

Endocrine-disrupting chemicals (EDCs) are of major concern due to their capacity to perturb hormone systems of wildlife at minute exposure concentrations. In this regard, a leading source of EDCs in the environment is run-off of veterinary pharmaceuticals used in agriculture. This includes hormonal growth promotants (HGPs), which are administered to beef livestock in agricultural operations worldwide. Among the most biologically active HGPs is the androgenic steroid 17β-trenbolone, which has repeatedly been detected at low nanograms per litre concentrations in surface waters. In standard reproductive trials (i.e. a male-female pair), recent research has revealed that exposure to 17β-trenbolone can alter mating behaviour in fish. However, in reality, natural mating systems are complex and very little is known about the potential for chemical pollutants, in general, to disrupt behaviour under more complex and ecologically realistic reproductive scenarios, such as sequential mate choice. To address this, we exposed wild-caught adult male guppies to a field-realistic level of 17β-trenbolone (average measured concentration: 2 ng/L) for 21 days and compared the response of exposed and unexposed males to sequentially presented large and small females. Due to a positive size-fecundity relationship, larger females often represent better reproductive value and are generally preferred by males. In the first presentation, regardless of exposure, males demonstrated a preference for larger females by courting these females more often. Further, regardless of female size, exposure was associated with a marginally non-significant increase in male sneaking behaviour. In the second presentation, males from both exposure treatments again demonstrated a preference for greater female size in terms of both courting and sneaking behaviour. Furthermore, exposed fish again performed more frequent sneaking behaviour towards females. We found evidence for sequential male choice, although this was not disrupted by exposure. This is because, regardless of exposure, males 'traded down' by significantly reducing the frequency of their courtship behaviour towards small females if they had previously encountered a large female. Considering the pivotal role that mate choice mechanisms play in population dynamics and broader evolutionary processes, this study highlights the need for a greater understanding of potential impacts of chemical contaminants on sexual selection in wildlife.

WE260

Assessing population-relevant behavior patterns in free-swimming groups of larval zebrafish (Danio rerio)

L. Frese, T. Braunbeck, COS University of Heidelberg / Aquatic Ecology and Toxicology

In order to help identify potential population-relevance of neurotoxic effects on embryos (as revealed in photomotor or locomotor response assays), zebrafish (*Danio rerio*) embryos were exposed to sublethal concentrations of fluoxetine in a 35 d early-life stage test augmented with behavioral assessments. As a known selective serotonin re-uptake inhibitor (SSRI), fluoxetine was chosen as a first model substance. Behavioral analyses of multiple free-swimming fish, however, posed significant technical difficulties, even more so since the zebrafish juveniles observed were very small and not yet fully pigmented. Nevertheless, a promising protocol using groups of 20 fish could be developed to demonstrate more natural behavior patterns than in tests with isolated individuals. A relatively large volume of 8 liters was chosen to allow for natural swarm behavior despite experimental constraints; the large volume also provided ample room for the fish to display spatial preference. Since the swimming tracks of individual fish inevitably cross the tracks of other individuals, individual-based analyses (e.g. of swimming speeds and patterns) had to be abandoned, and the analysis was focused on the distribution of the shoal over time. Manual tracking allowed the analysis [1] of the relative habituation time after stress (novel tank test), [2] of the average distance kept to a potential threat (predator response test) or [3] of the feeding behavior. First results show a clear concentration dependence of all of these endpoints; however, the interpretation of the result required careful consideration of each response since the observations did not allow a simple categorization into "anxiogenic" or "anxiolytic". In some occasions, upon first glance, results even seemed contradictory. Besides the aforementioned behavioral paradigms and the classic early-life stage growth and survival metrics, it should also be possible to quantify swarm coherence and compactness as additional endpoints once the fish can be reliably identified by an appropriate image analysis software.

WE261

Dilute levels of a benzodiazepine (oxazepam) alters important behavioural traits in a common planktivorous fish, (Rutilus rutilus)

T. Brodin, Swedish University of Agricultural Sciences (SLU) / Department of Wildlife, Fish and Environmental Studies; J. Klaminder, Umea University / Ecology and Environmental Science; G. Hellström, Swedish University of Agricultural Sciences SLU; J. Fick, Umea University / Department of Chemistry

Environmental pollution by pharmaceuticals is increasingly recognised as a major threat to aquatic ecosystems worldwide. A complex mix of pharmaceuticals enters waterways via treated wastewater effluent and many remain biochemically active after they reach aquatic systems. However, to date very little is known about the ecological effects that might arise following pharmaceutical contamination of aquatic environments. One group of particular concern is behaviourally modifying pharmaceuticals because seemingly minor changes in behaviour can generate pronounced ecological consequences. Here we show that a benzodiazepine anxiolytic drug (*oxazepam*) alters key behavioural traits in wild roach *(Rutilus rutilus)* at concentrations similar to those encountered in effluent dominated surface waters. Roach exposed to water with high concentrations (280 $\mu g\ l^{-1}$) exhibited increased boldness, while roach in the low treatment (0.84 $\mu g\ l^{-1}$) became bolder and more active compared to control fish. Our results reinforces the notion that anxiolytic drugs could be affecting fish behaviour in natural systems, emphasizing the need for further research on ecological effects of pharmaceuticals in aquatic systems and the development of new tools to incorporate ecologically relevant behavioural endpoints into ecotoxicological risk-assessment.

WE262

Behavioural effects of temperature, predation-risk and anxiolytic exposure on the European perch (Perca fluviatilis)

M. Saaristo, Monash University / School of Biological Sciences; A. Lagesson, Umea University / Department of Ecology and Environmental Science; M.G. Bertram, Monash University / Biological Sciences; J. Fick, Umea University / Department of Chemistry; J. Klaminder, Umea University / Ecology and Environmental Science; B. Wong, Monash University / School of Biological Sciences; T. Brodin, Swedish University of Agricultural Sciences (SLU) / Department of Wildlife, Fish and Environmental Studies
With the ability to resist biodegradation and exert therapeutic effects at low concentrations, pharmaceutical contaminants have become environmental stressors for wildlife. In fact, more than 600 pharmaceutical substances have now been detected in the environment worldwide. Despite increasing research interest in understanding how wildlife responds to pharmaceutical contaminants, the synergistic fitness effects of pharmaceuticals and their interaction with other biotic (e.g. temperature) and biotic (e.g. predation risk) stressors remain unclear. In particular, in aquatic environments, changing temperature due to anthropogenic activity (e.g. seasonal extremes due to climate change), impacts ecosystems at multiple levels of biological organisation. One pharmaceutical contaminant of particular concern is the anxiolytic oxazepam, a psychoactive pharmaceutical that is frequently detected in surface waters globally. Here, using a multi-stressor approach, we investigated effects of 7-day oxazepam exposure (6.5 μg/L) on tendency to shoal (i.e. sociability) in juvenile European perch (*Perca fluviatilis*). The multi-stressor approach was achieved by exposing perch to oxazepam at two temperatures (10 °C and 18 °C), and at two predation risk regimes—generated using chemical cues from the northern pike (*Esox lucius*). Forming shoals provides protection from predation and improves foraging efficiency through information transfer and, if disrupted, has potential to impact the fitness of exposed animals. A standard sociability assay was used to record the amount of time spent near a shoal of size-matched conspecifics. We found that 7-day exposure resulted in a successful uptake of the drug from the water, i.e., oxazepam was measured in perch muscle tissue at 50 ± 17 ng/g (mean ± SD). Results from the sociability assay will be presented and further discussed. Overall, our multi-stressor study is the first to uncover if, and how, exposure to oxazepam alters sociability-related behaviours in wild-caught juvenile fish, and if these alterations are modified by water temperature and perceived predations risk.

WE263
Assessing predator-prey interactions in a chemically altered aquatic environment: The effects of DDT on Xenopus laevis foraging behaviour
J. South, South African Institute for Aquatic Biodiversity; T.L. Botha, N.J. Wolmarans, North-West University / Unit for Environmental Sciences and Management; V. Wepener, North-West University - School of Biological Sciences / School of Biological Sciences; O. Weyl, South African Institute for Aquatic Biodiversity
Behavioural assays are used as a tool to understand ecotoxicological effects on organism functioning, however, this is often not applied in an ecologically relevant context. It is essential to assess the effect of chemical contaminants on behaviours relating to fitness and trophic interactions, thus predator-prey interactions must be incorporated in order to create appropriate hazard risk assessments. Dichlorodiphenyltrichloroethane (DDT) is a controlled substance but is still regularly used as a form of vector control. There is little explicit information on the effect of DDT on animal behaviour and the consequent effects upon trophic interactions. This study uses a 3 x 2 factorial design to assess the interactions of predatory behavioural responses of *Xenopus laevis* towards a vector prey (*Culex* sp. larvae) towards visual-hydromechanical and olfactory prey cues, with regards to factors "DDT exposure" and "prey cue". We also assess the behavioural responses of mosquito larvae when supplied with no threat cue and predator threat cues when exposed to 2 μg/L and 20 μg/L DDT. There was a significant "DDT exposure" x "prey cue" interaction wherein DDT significantly decreased the foraging behaviour of *X. laevis* towards visual-hydromechanical prey cues, however there was no effect of DDT upon *X. laevis* response to olfactory prey cues. Dichlorodiphenyltrichloroethane exposure caused mosquito larvae to appear hyperactive moving significantly more; however there was no difference between DDT concentrations. Mosquito larvae anti-predator response was significantly dampened when exposed to 2 μg/L DDT, however when exposed to 20 μg/L the anti-predator responses were not impaired. Our results indicate a complex interplay in trophic interactions under DDT exposure, wherein effects are mediated depending on species and concentration. There are possible implications regarding reduced anti-predator behaviour in the prey species but also reduced foraging capacity in the predator, therein it is likely that DDT exposure can cause changes in ecosystem energy pathways, resulting in bioaccumulation in higher trophic levels. We demonstrate that in order to quantify effects of pesticides upon trophic interactions it is necessary to consider ecologically relevant behaviours of both predator and prey species.

WE264
Could behavioural disturbances be linked to density depletion of the ragworm Hediste diversicolor populations?
I. Métais, Catholic University of the West / Biology; H. Perrein, Catholic University of the West / MMS; M. Mouloud, A. Chatel, M. Bruneau, Catholic University of the West / UBL Mer Molécules Santé; P. Gillet, Catholic University of the West / Mer Molécules Santé MMS; N. JRAD, LARIS - UCO / Biology; C. Mouneyrac, Université Catholique de lOuest / UBL, Mer Molécules Santé
Evaluating the health status of estuarine areas is a difficult task as they are impacted by mixture of contaminants. Chemical approaches are classically combined to biological and ecological indicators. However, chemical analyses are costly and some contaminants are not yet accessible to analyze. This work aims to demonstrate in *Hediste diversicolor*, a sentinel species of most estuaries, the key role of behavioral biomarkers which may be at the individual level the central link between sub-individual response and population changes in the field. Acetylcholinesterase (AChE), a core biomarker of neurotoxicity, was chosen for its ecological relevance as its inhibition observed in laboratory or field studies can lead to behavioral impairments in organisms exposed to a wide range of contaminants. The sampling site was located on the largest mudflat of the polyhaline domain of the Loire estuary ("Les Brillantes"). Two areas were selected in the upper intertidal (Site 1) and in the middle intertidal (Site 2) zones of the mudflat. Two sampling campaigns were conducted in May 2013 and February 2014, respectively. AChE activity was determined in worms from each site. Burrowing behavior was studied by placing worms on sediment of their site of origin and recording their position every 2 minutes during 30 minutes. Additionally, automated behavioral tests were carried out on worms with the Multifreshwater Biomonitor® (MFB®) allowing the identification of *H. diversicolor* movements (undulation, head movements and feeding activity). Density was determined sorting and counting worms from four sediment samples randomly collected at low tide from both areas (Site 1 and Site 2). The results showed a lower AChE activity, behavioral impairments (burrowing kinetics, body undulation, feeding activity) and a lower density for the worms from Site 2 compared to Site 1. A Spearman positive correlation was determined between AChE activity and MFB results suggesting a link between behavior impairments and AChE activity inhibition. These results allow a first attempt to propose three steps of an adverse outcome pathway from AChE inhibition (molecular interaction), behavior alteration (organism response) leading to density decrease (population response) in *H. diversicolor*. These results bring direct empirical field evidence demonstrating the sensitivity and the central key role of behavioral biomarkers in *H. diversicolor* as biomonitors of estuarine health status assessment.

WE265
Impact of the pharmaceutical sotalol on Gammarus pulex swimming behaviour
V. de Boer, E. Peeters, Wageningen University / Aquatic Ecology and Water Quality Management; I. Roessink, Wageningen Environmental Research / Environmental Risk Assessment
Pharmaceuticals in surface waters have become an environmental concern in recent years. Although acute toxicity does not seem to be an immediate issue the impact of chronic exposure of especially invertebrates to these compounds is poorly understood. In addition, an increasing body of evidence becomes available showing that chronic exposure to pharmaceuticals results in behavioural changes. In order to test the potential impact on aquatic invertebrate behaviour we exposed *Gammarus pulex* individuals to sotalol, a beta-blocker frequently occurring in Dutch surface water monitoring schemes. The amphipods were exposed for 7 days to concentrations ranging from 0.03 to 10 ug/L and were subsequently released in a custom-made flow-through device. Flow velocity in the device could be varied and the velocity that proved to be too strong for the Gammarids, i.e. washing the animal out of the tube, was taken as the final endpoint. *Gammarus* swimming ability decreased at increasing sotalol concentrations with the highest impact on swimming ability observed in the 1 ug/L treatment level. Interestingly, no monotonous response could be observed since swimming ability increased again at higher test concentrations, resulting in an a-typical 'arch-shaped' effect curve. Although these results are in line with previous findings for carbamazepine, ibuprofen and fluoxetine (De Lange et al., 2006) it is not yet clear what the mechanistic explanation or ecological consequences for this phenomenon are.

WE266
Development of high-throughput assays to assess swimming behaviours in Artemia franciscana
S.A. Kohler, University of Portsmouth / Aquatic Biology; A. Ford, University of Portsmouth / Biological Sciences; M.O. Parker, University of Portsmouth
Technological advancements have allowed for a rapid expansion in the use of behavioural endpoints in ecotoxicology. However, the lack of standardisation poses the largest drawback in the widespread use of behavioural assays in environmental risk assessment. It has been shown that there is a trade-off between allowing 'space to behave' and reducing arena size to increase high-throughput analysis for your chosen species. Furthermore, some behaviours are complex and require careful experimental design and vast amounts of data on the baseline unconditioned behaviours of your test organism to allow for appropriate interpretation of results. For example, alterations in phototaxis behaviours may be interpreted as scototaxis, representing an anti-anxiety behaviour. Moreover, these responses have been found to differ between seemingly similar species. In this study we optimised a simple swimming behavioural assay using the brine shrimp *Artemia franciscana*. Sudden transition to light was used as a stimulus to initiate a behavioural response. Multiple parameters were measured using a DanioVision

observation chamber with EthoVision tracking software. Significant differences (P< 0.05) were observed between the swimming speed and escape response to light between arena sizes. *A. franciscana* showed a greater mean velocity when in a larger arena. Some reports in the literature suggest that *Artemia spp* can differ in their phototactic behaviours depending on light intensity. In this study we assessed the effects of low and high lux on swimming behaviours and phototaxis. However, no significant differences (P>0.05) were observed in either endpoint between light intensities. Subsequently, we conducted a fluoxetine exposure (0.001-1μg/L) over 1hour, 1 day and 1 week. Significant effects on velocity were observed after 24 hours of exposure (P>0.05) but not after 1 hour or 1 week. Further experiments to test the repeatability of this experiment are ongoing. The use of artemia in high-throughput behavioural assays seems promising to support environmental risk assessment

WE267

Effects of the antidepressant Venlafaxine on the feeding rate and behaviour of the freshwater amphipod Gammarus pulex

G. Consolandi, University of Portsmouth; A. Ford, University of Portsmouth / Biological Sciences; M. Bloor, University of Portsmouth / School of Earth and Environmental Science

In the last decade the prescribing of antidepressants has increased dramatically. Venlafaxine (VEN) is one of the most commonly detected antidepressants in European streams. Little is known about the potential impact of VEN on non-target aquatic organisms at enviromentally realistic concentrations but it is hypothesised to interfere with behaviour and feeding. We aim to identify if the behaviour and/or feeding rate of *Gammarus pulex* a sensitive freshwater macroinvertebrate was altered when exposed to environmentally realistic concentrations of VEN for 7 days. Specimens of *Gammarus pulex* were kept for 14 days at 15?C under a 12:12 h light:dark cycle. After a 48 h starvation period they were exposed for 7 days to 3 different concentrations of VEN (20 ngl^{-1}, 2 μgl^{-1} and 20 μgl^{-1}). To evaluate the possible alteration on the feeding rate (FR), *Alnus glutinosa* leaves were cut into discs, dried and weighted. The leaf discs were then conditioned in stream water for 14 days, after which time each disc was photographed and given to the organisms. Each organism was provided with 2 discs at a time, that were replaced every 2 - 3 days. The leaves were then re-photographed, dried and weighted again. The before and after photographs were analysed to determine the leaf area consumed, whereas changes in the leaf disc weight were used to calculate the consumed leaf mass. To quantify possible changes in the swimming velocity, *Gammarus* pulex behaviour was recorded after 24 h and 7 days by using a DanioVision™ observation chamber. Data were analysed with a linear mixed effects model (p=< 0.05). *Gammarus pulex* FR was not altered. There was no significant difference between the concentrations in either the consumed leaf mass (F=0.764, p=0.519) or the leaf area consumed (F=2.610, p=0.060). The interaction between treatments and time was not significant (F=0.726, p=0.630; F=1.884, p=0.090). However there was a significant overall change in FR over the length of the experiment, but unrelated to the concentration tested (F=14.742, p=0.000; F=62.221, p=0.000). Alterations in velocity were not significant between the concentrations (F=0.934, p=0.430). A significant interaction was measured between concentration and exposure time (F=26.025, p=0.000), meaning that the organisms velocity was different across the concentrations after 24 h and 7 days. Overall this study showed that VEN may affect *Gammarus pulex* behaviour when exposed to environmentally realistic concentrations for 7 days.

WE268

Behavioural and proteomic responses in Asiatic clams Corbicula fluminea, exposed to crude oil in outdoor artificial rivers, within a multistress context.

M. Alison, Université de Bordeaux / UMR EPOC CNRS; M. Sow, M. Perrigault, University of Bordeaux / UMR EPOC CNRS; C. GELBER, TOTAL S.A.; P. Ciret, University of Bordeaux / UMR EPOC CNRS; C. Lacroix, CEDRE; J. Dalens, C. Weber, TOTAL SA; S. LeFloch, CEDRE; P. Blanc, TOTAL SA; J. Massabuau, University of Bordeaux / UMR EPOC CNRS

Oil industry is a source of disturbance in aquatic ecosystems. Relevant, efficient, and reliable monitoring is essential and requires the use of adapted and specific tools. Robust, autonomous and working by remote control, HFNI (High Frequency Non-Invasive) Valvometry is one possible solution to improve management in natural systems. Its principle is to monitor online, 24/7, behaviour and different life history traits (restlessness, biological rhythms, growth, spawning, mortality…) of abandoned bivalve mollusks. Through distant access, data are automatically readable on the web and allow monitoring them in near real time to research online changes in water quality. To develop and value this biomonitoring instrument in the oil and gas industry it is necessary, to highlight if behavioural responses to crude oil are reliable and discriminating in presence of additional stressors and to explore the relationship between behavioural signals and underlying cellular responses. Looking for basic unifying principles, the behaviour of *Corbicula fluminea* was studied in a multistress context by comparing and coupling the disturbances caused by a crude oil exposure (400 μg/L) in presence and/or absence of noise pollution (cargo noise), barium (100 μg/L) and burst of turbidity. Experiments were conducted in outdoor open-stream mesocosm subjected to natural variations (Artificial Rivers, Lacq, France, TOTAL; 1 month of acclimation and reference, 10 days of exposure, 1 month of recovery; no death). The behavioural response to crude oil was characterized by a decrease of valve opening amplitude and a decrease of valve opening duration. The characteristic behavioral response of bivalves to crude oil exposure was maintained in presence of additional stresses. Furthermore, the proteomic response and the aromatic hydrocarbon bioaccumulation (which remained in the low range) were investigated in gills and adductors muscles of oil-exposed clams. We will discuss the main results and we will conclude that the study of bivalve mollusks behaviour by HFNI Valvometry confirms its biomonitoring potential for the oil and gas industry.

WE269

Analysing zooplankton swimming bahviour with robots and data science

R. Wolf, NIVA - Norwegian Institute for Water Research / Section for Ecotoxicology and Risk Assessment; J. Heuschele, University of Oslo / Section for Aquatic Biology and Toxicology

Zooplankton shows strong behavioural responses to both biotic and abiotic stressors, e.g., avoiding harmful ultraviolet radiation (UVR) by retreating to deeper waters. Anthropogenic pollutants can also influence the swimming behaviour of zooplankton, e.g., *via* info chemical effects. Yet, an effective experimental approach to measure sensible behavioural endpoints remains a challenge. As behaviour is typically extracted from video recordings, the resulting data analysis is not a simple spreadsheet job either. In this study, we provide a framework for analysing and quantifying swimming behaviour of zooplankton, deriving multiple behavioural proxies from the same experiments. As a case study, we use the swimming response of *Daphnia magna* to UVR, both in the absence and presence of a dissolved organic matter (DOM) gradient. DOM causes a characteristic browning of the watercolour with increasing the light absorption of water, especially in the UVR spectrum. Making use of a custom-built, Raspberry Pi-based imaging system, we repeatedly filmed individual *Daphnia magna* neonates over six hours. We examined the video recordings using the OpenCV library to extract individual position data, and calculated motility proxies such as explored area, swimming speed, swimming depth, travelled distance, and swimming time. These were analysed in R using linear mixed-effect models. To account for the complexity and variability of swimming behaviour, not only UVR and DOM were used as explanatory variables, but also the size of the neonates and the time into the experiment, and all possible parameter interactions were included. The results show that increasing DOM generally buffers the strong effects of UVR on swimming behaviour while raising the overall swimming activity independent of UVR exposure. Our findings highlight the complexity of behavioural responses, which traditional ecotoxicological data analysis approaches might miss. We further emphasise the importance of an in-depth data analysis, both to avoid false results, but also to account for the effect sizes of additional factors like body size and experimental duration on behavioural responses. Wolf R, Heuschele J. 2018. Water browning influences the behavioural effects of ultraviolet radiation on zooplankton. Front Ecol Evol 6:26. doi: 10.3389/fevo.2018.00026.

WE270

Effects of Per- and polyfluoroalkyl substances (PFASs) on zebrafish embryo behaviour

F. Menger, Swedish University of Agricultural Sciences; J. Pohl, Swedish University of Agricultural Sciences (SLU) / Department of Biomedical Sciences and Veterinary Public Health; L. Ahrens, Swedish University of Agricultural Sciences SLU / Dept. of Aquatic Sciences and Assessment; G. Carlsson, S. Örn, Swedish University of Agricultural Sciences / Department of Biomedical Sciences and Veterinary Public Health

Per- and polyfluoroalkyl substances (PFASs), a group of omni-present and very persistent environmental pollutants, cause concerns regarding their environmental impact and their risk for human health. The zebrafish (*Danio rerio*) embryo is a robust model organism for the evaluation of the developmental toxicity of chemicals, but also more sensitive endpoints, e.g. behavioural endpoints, have become more popular in recent years. In the present study, zebrafish embryos were used to investigate behaviour alternations caused by PFASs. Special focus was put on the comparison between single substance and mixture effects. First, based on control data, a set of locomotor activity endpoints was defined to establish a normal swimming profile of 6-day-old zebrafish larvae. Then, the behaviour of exposed groups was investigated. In total, nine PFASs plus a PFAS mixture were investigated at seven concentrations ranging from environmentally relevant to acutely toxic levels of certain PFASs. Significant differences were detected in the swimming distance, the movement composition and the reaction to light change of the exposed larvae. In general, toxicity increased with increasing length of the perfluorocarbon-chain and the active group of the PFASs seemed to influence the toxic response. PFAS mixture toxicity generally followed the trends of single substances, but in cases where different toxic responses were observed, mixture toxicity could not be predicted. More complex models are needed to predict the mixture toxicity of PFASs as a simple additive toxicity model is not sufficiently.

WE271

Effect of climate change temperatures on the toxicity of the pesticide fipronil
M. Pino, San Jorge University / Facultad ciencias de la salud; D. Ballestero, Universidad San Jorge; E. Terrado, San Jorge University; J. Urieta, A.M. Mainar, Universidad de Zaragoza; J. Val, Universidad San Jorge
There is a broad consensus in the scientific literature that the most serious effects of global warming are related to a change in average global temperatures. These changes include an increase in the surface water temperature of lakes and streams, especially at high altitudes that occur even faster than the warming of the ocean or atmosphere. Such an increase could have dramatic effects on aquatic ecosystems in the medium and long term. Additionally, pollution as a consequence of human activities, exposes aquatic communities to a scenario of multiple stress. Therefore, there is a growing concern to know how contaminants present in fresh waters will affect these ecosystems in future complex exposure scenarios Fipronil is a phenylpyrazole insecticide widely used as a phytosanitary product and veterinary medicine, due to its great effectivity against a broad spectrum of insects. This insecticide acts by targeting the receptor for c-aminobutyric acid (GABA) and has a higher binding affinity to GABA insect receptors than to mammals. Our study evaluates the impact of fipronil, together with the temperature, on *Daphnia Magna*, an aquatic invertebrate selected as biomarker for freshwater, and also in a fluvial microbial community. We tested the effect of fipronil at three temperatures (18,23 and 28 ^{0}C) on the acute ecotoxicity on *D. magna* and also on the growth and physiological diversity of the river bacterial communities. Results indicate that the toxicity of fipronil is higher the higher the temperature. Fipronil affects both the survival of *D. magna* and the ability of the river bacterial community to metabolize substrates. These results suggest that the toxicity of some pesticides in freshwater ecosystems can be enhanced with the increase of temperatures in the expected range due to climate change. The authors thank the financial support of MINECO-FEDER (CTQ2015-64049-C3-2-R), Gobierno de Aragón-FSE (GATHERS E39_17R) and Cátedra Novaltia.

Does low-level radioactive contamination cause developmental instability in chironomids?
S. Majlesi, V.C. Navarro, University of Eastern Finland; S. Panzuto, Università di Napoli Federico II; J. Naarala, University of Eastern Finland; J. Akkanen, University of Eastern Finland / Department of environmental and biological sciences; J. Sorvari, J. Juutilainen, University of Eastern Finland
There has recently been increasing interest in protecting non-human wildlife from the effects of ionizing radiation. However, only limited data are available on radiation effects on wildlife species and ecosystems, and methods for detecting such effects are not well developed. In this study, we investigated the effects of low-level radioactive contamination on chironomid midges. Developmental effects were evaluated by observing time of emergence of adult insects after exposure of larvae, and by measuring fluctuating asymmetry (FA) in the wings of the adults. FA has been suggested to be a sensitive measure of developmental instability induced by environmental exposures. Larvae of *Chironomus riparius* were grown in controlled laboratory conditions in sediments from two contaminated ponds (higher and lower contamination level) located near an abandoned uranium mine and a reference pond. Artificial sandy sediment was used as an additional control. Wing size measurements were used for assessment of FA. Fish food (TetraMin®) was added at two feeding regimes (12 and 36 μl/beaker/day). Emergence of the adult midges was significantly delayed by both contaminated sediments. However, FA was affected only by the higher contamination level, and only at the lower feeding level. In conclusion, it appears that FA evaluated by wing size measurements is not a more sensitive indicator of developmental effects than time to emergence. **Key words:** Fluctuating asymmetry; Chironomids; Wing measurement; Radioactive contamination

Disinfection Byproducts and Oxidation Byproducts: Analysis, Fate, Toxicity and Treatment (P)

Leucomethylene blue, a selective photometric reagent for chlorine dioxide analysis in water. Part II: the sulphate interference
R. Devesa, Aigues de Barcelona / Chemistry. Laboratory; N. Jiménez, Polytechnic University of Catalonia, Barcelona Tech / Chemical Engineering; A. Garbayo, Agbar, Barcelona Water Company / Analytical Chemistry; F. Estrany, Polytechnic University of Catalonia, Barcelona Tech
Drinking water supply companies have traditionally focused their efforts on providing a product with health guarantees, a safe and clean water. Disinfection has been the main purpose of the water treatment. A broad range of disinfectants and technologies are available. Chlorine dioxide has been increasingly used because of its ability to avoid the formation of trihalomethans (THMs), the most common and well-known disinfection by-products. N,N-Diethyl-p-phenylenediamine (DPD) method has been without any doubt the most common procedure for the analysis of free and combined chlorine (chloramines) and also, chlorine dioxide. While this method easily permits the differentiation between free and combined chlorine, the selectivity of the analysis of chlorine dioxide when chlorine is present has recently been questioned. As a result, this procedure has been removed from Standard Methods (American Water Works Association) and qualified as "reserved" method. Given this circumstance and the need of having a selective method for chlorine dioxide, several UV-VIS spectrophotometric methods have been evaluated by our group. In a previous study (1) leucomethylene blue, a chromophore agent obtained by reduction of methylene blue and scarcely described in the literature for chlorine dioxide analysis, showed good analytical performance. But the measurements were interfered by high concentrations of sulphates. In this study, two alternatives to solve the interference have been evaluated: microfiltration after the precipitation of sulphate with barium chloride and solvent extraction with 1,2-dichloroethane. The filtration method gave better results: first, the measurements presented a good reproducibility; secondly, there was not significant interference by free chlorine, which is frankly important for the water supply monitoring; and third, the method showed a good accuracy with real water samples (relative error below 20 % for chlorine dioxide concentrations between 0 and 1.6 mg/L.). This reagent with this method has revealed to be the best option among the different compounds that we have tested – amaranth, lissamine green, and choro phenol methyl red- in previous studies. (1) Leucomethylene blue: a selective photometric reagent for chlorine dioxide analysis in water. R. Devesa, X. Aldazabal, A. Garbayo, F .Estrany. 28th Annual Meeting of the Society of Environmental Toxicology and Chemistry (SETAC). Rome, Italy, May 2018

Water treatment - A regulatory challenge for crop protection products in the EU
S. Dorn, F. Schnitzler, knoell Germany GmbH
Regulation (EC) No 1107/2009 lays down the rules for the authorisation of crop protection products in Europe with the aim of protecting humans and the environment. It is known that during primary disinfection processes for central water treatment (e.g. ozonation, chlorination) certain active substances included in crop protection products and their metabolites have the potential to form unwanted by-products with e.g. toxic, carcinogenic and genotoxic characteristics. Notwithstanding that the EFSA (European Food Safety Authority), the scientific advisory body of the European Commission, has recently identified data gaps during the approval process of active substances, water treatment processes have not (yet) been implemented in the European data requirements (Reg. 283/2013 or 284/2013) relevant for the authorisation of crop protection products. Further, no guidance document for experimental testing is available. With this information pending, addressing water treatment processes successfully becomes a challenge for applicants of crop protection products. The European Commission states that the applicant shall submit the (confirmatory) information to the European Commission, the Member States and EFSA within two years after adoption of a guidance document on evaluation of the effect of water treatment processes on the nature of residues present in surface- and groundwater. Meanwhile applicants seek to address the issue in their dossiers to authorities in different ways – from simple waiving to the generation of extensive supporting data. Current attempts of addressing ozonation and chlorination for active substances from the third Annex I Renewal programme (AIR 3) are summarized based on publically available data. Following most recent developments in the area, the poster will also review the current activities and issues around the implementation of the upcoming guidance document: Currently water treatment is only addressed at active substance level. It remains largely unclear how the topic can be approached for product registrations and how metabolites can be realistically addressed. With such guidance in place it can be expected that other chemical sectors, e.g. industrial chemicals or pharmaceuticals, would also need to set a spotlight on the topic.

WE275
ECOTOXICOLOGICAL COMPARATIVE EVALUATION BETWEEN CHLORINE AND OZONE DISINFECTION OF MUNICIPAL WASTE WATER PRODUCED IN A CONVENTIONAL ACTIVATED SLUDGE TREATMENT PLANT IN BRAZIL
C.H. Soares, Universidade Federal de Santa Catarina / Biochemistry Department; G. Costa, UFSC; I. Baptista, Universidade Federal de Santa Catarina
The conventional sewage treatment plants need a disinfection process step to comply with the legal standards to dispose the treated waste water on the environment. The chlorine is the most economically attractive option. However, it has a residual effect and potential carcinogenic by-products formation. The ozone is more expensive, but due to its high reactivity it does not present residual effect. (ZIETZSCHMANN,2015), nevertheless it has a known existence of toxic by-product formation (RICHARDSON et al, 2007). The ecotoxicological evaluation is more sensitive and representative of the impact of an effluent the environment. With the aim of assess and measure the ecotoxicology potential, took place the waste water sampling in a treatment plant constituted by an UASB reactor, activated sludge reactor and disinfection via gaseous chlorine. The samples consisted in: raw effluent, decanted, chlorinated and ozonated. In laboratory scale a pilot ozonization reactor was set up to treat the decanted sampled waste water to compare with the chlorine system. To better explanation of the fact, some physical chemical parameters ware measured: total phenol concentration, pH, Conductivity, COD, DBO, Ammonia nitrogen, nitrate, total phosphate, sulfide. The ecotoxicological analysis were made with the following tests and

bioindicators: Acute and chronic test using the micro crustacean *Daphnia magna*, and exposition of *Danio rerio*'s embryos and following's development (the aim was to evaluate the sample's teratogenicity with a higher sensibility). The ozonated samples had better performance as well as on physic-chemical parameters as the phenols, color and organic matter degradation and on ecotoxicological tests, being one of the reasons for lower ecotoxicity probably was the ammoniacal nitrogen (more toxic) conversion to nitrate, less toxic form of nitrogen, promoted by ozone treatment.

WE276

Mapping degradation pathways in advanced oxidation processes with two-dimensional liquid chromatography with an online light-degradation system

M. den Uijl, University of Amsterdam / Van t Hoff Institute for Molecular Sciences, Faculty of Science; P. de Voogt, University of Amsterdam / IBED; B. Pirok, P. Schoenmakers, M. van Bommel, University of Amsterdam / Van t Hoff Institute for Molecular Sciences, Faculty of Science

While advanced oxidation is applied in drinking water treatment, recent studies [REF] indicate that after medium-pressure UV/H_2O_2 treatment mutagenic substance are formed. Due to the complexity of water samples the origin of these mutagenic components is unclear. This problem can be split in two. First, one chromatographic dimension is not able to separate the complex water sample. Secondly, there is no knowledge the photodegradation pathways. This projects aims to solve both of these problems.\n This poster will introduce the TooCOLD project (Toolbox for studying the Chemistry Of Light-induced Degradation), conducted within several institutes at the University of Amsterdam (UvA) and the Free University Amsterdam (VUA). In this project, the complexity of the water samples including the Natural Organic Matter (NOM) will be analysed with two-dimensional liquid chromatography (2DLC) in combination with mass spectrometry. Next to applying 2DLC-HRMS to water-treatment samples, the samples will be subjected to an online-degradation system. After the first-dimension separation, the components will separately be trapped in a photo-degradation cell. In this cell the analytes are continuously illuminated at any desired wavelength(range). In a second separation dimension after the exposure cell the degradation products will be separated and analysed with mass spectrometry and UV. In this way we can establish a link between the degradation products and the starting materials. \n Apart from water research, this 'Toolbox for Studying the Chemistry Of Light-induced Degradation' (TooCOLD) will be applied on samples from cultural heritage and the food industry.

Individual Variation in Ecotoxicological Research: a Change from Unwanted Noise to a Meaningful Endpoint (P)

WE277

Genotype variation in heavy metal tolerance can drive inter- and intra-specific selection amongst Baltic Sea diatoms

B. Andersson, University of Gothenburg; O. Berglund, Lund University / Dept of Biology; H.L. Filipsson, Lund University / Department of Geology; K. Rengefors, Lund University / Department of Biology; A. Godhe, University of Gothenburg / Department of Marine Sciences

The Baltic Sea is one of the most polluted seas in the world. Microalgae are key primary producers in the Baltic Sea, as in other aquatic environments. These organisms have short generation times, flexibility in reproductive strategies, and often high standing genetic variation, which should facilitate rapid evolution. We explored whether evolution and inter-specific competition can lead to modifications in heavy metal tolerance in Baltic Sea microalgae. We used the sediment seedbank to revive individuals from two ecologically important pelagic diatom species, *Skeletonema marinoi*and *Thalassiosira baltica,* at a mining polluted inlet of the Baltic Sea (Gåsfjärden). We investigated if long-term exposure to mining discard has resulted in more heavy metal tolerant diatom individuals, both within and between the two species. We found that, generally, *T. baltica* was more tolerant to silver (Ag) and copper (Cu), whereas *S. marinoi* was more tolerant to cadmium (Cd) and lead (Pb). This suggests that mining discharge can have different effects on the structure of phytoplankton assemblages, depending on the composition of metals. In 72h acute exposure tests we also observed an elevated tolerance to Cd and Cu within the *S. marinoi*population at Gåsfjärden suggesting that the species has evolved heavy metal tolerance at this location. We are currently investigating the mechanism and scale of this evolution using long-term (42 days) artificial selection experiments on assembled *S. marinoi* populations. We use population genomics and physiological measurements of metal-tolerance to assess differences between genetic individuals. Our results add valuable scientific information about the population-wide variance in heavy-metal sensitivity of marine diatoms as well as the evolutionary capacity of this group of globally important primary producers.

WE278

Crude oil has transgenerational effects on phenotypic plasticity and individual variation of metabolic rate of Daphnia magna

K. Anttila, E. Suominen, University of Turku / Biology; M.J. Nikinmaa, University of Turku / Department of Biology

Worldwide animals are under threat of crude oil spills and especially in Baltic Sea the threat is serious. This is because 11% of the global shipping of crude oil happens through Baltic Sea which waterways are shallow and narrow. Although there are several studies of physiological effects of crude oil and its water soluble fractions (WSF) on different organisms, little is known about its long lasting transgenerational effects. In this study we exposed offspring of single *Daphnia magna* to 30%, 10% and 0% (control) WSF for 48h and measured its effect on oxygen consumption rates of animals. The highest exposure caused 50% mortality of the animals and this led to significant reduction in individual variability inside population as compared to other exposures (p=0.008). There were no significant differences in the mean oxygen consumption rates between animals from different exposures (p>0.05). However, the reduction of individual variability in 30% WSF exposure was reflected in the oxygen consumption rates in the next two generations. The offspring of animals exposed to 30% WSF had significantly higher oxygen consumption rates than the offspring from other groups (p< 0.001 in both F1 and F2 generation), which showed reduced oxygen consumption rates as compared to parental individuals (p=0.003 in control animals and p=0.004 in 10% WSF-exposed animals). As conclusion, the reduction in individual variability after WSF exposure could make the animals vulnerable to other environmental hazards since the buffer capacity in the population lowers. The exposure also had transgenerational effect by elevating oxygen consumption rate, i.e. animals are spending more energy for the same activities. This could have long lasting negative effect on the fitness of the whole population especially if the variability between individuals is reduced.

WE279

Transgenerational effects of crude oil and heat shock on the mortality and oxygen consumption rate of Daphnia magna

J. Eklund, M.J. Nikinmaa, University of Turku / Department of Biology; K. Anttila, University of Turku / Biology

Baltic Sea is a compact area with heavy shipping activity, and since around 160 million metric tons of oil are transported annually, the risk of a major oil tanker spill is ever-present. Since climate change will raise sea temperatures forcing organisms to adapt or die, it is important to determine how the combined stress of oil exposure and rising temperature affects organisms. We studied *Daphnia magna*, since with its parthenogenetic reproduction and short generation time, we could easily follow the effects of exposures on the next generation, after the oil exposure is over. Our hypothesis is that the combined oil exposure and heat shock will lower the viability of *D. magna* and the effects are transferred to next generation. The first generation (F0) of the fleas was exposed to oil water soluble fraction (WSF) concentrations of 0 % (control), 10 % and 30 % for 24 hours, and the day after that to 30 °C heat shock for 24 hours (with 20 °C as control). We measured the mortality and oxygen consumption rate of *D. magna* after both exposures. We left the first generation to reproduce, measuring the number of offspring (F1-generation) and their oxygen consumption rate, while continuing to monitor the F0 mortality. Both 30% WSF exposure and heat shock alone caused mortalities in F0-generation, but the mortality after heat shock was more than doubled in the population that received both treatments, when compared to population that experienced only WSF 30 % exposure (40 % vs. 13 %, respectively). Exposure to WSF 30 % and heat shock caused a significant decrease in oxygen consumption rate in F0-population (p< 0.001). We also found that the WSF and heat shock exposures had significant interacting effects on the oxygen consumption rates of the next generation. For the WSF 30 % + No-heat shock –F1 population, oxygen consumption rate was increased (p=< 0.001) compared to WSF-control + No-heat shock, but no similar effect was seen in WSF 10 % + No-heat shock. In the heat-shock F1 population, WSF caused a decrease in oxygen consumption rate compared to WSF-control + heat shock (p=< 0.001 in both WSF concentrations) along with a decrease in individual variation. We conclude that the lowered oxygen consumption rate in F1 generations of parents that are exposed to WSF and heat shock is a response to stress, which together with the reduced variation could have negative effects on populations exposed to both oil and increased temperatures.

WE280

Phenotypic plasticity of thermal and copper tolerance in three-spined sticklebacks (Gasterosteus aculeatus) from natural and thermally polluted areas.

G. Mottola, University of Turku / Department of Biology; A. Vasemägi, Swedish University of Agricultural Sciences / Department of Aquatic Resources; M.J. Nikinmaa, University of Turku / Department of Biology; K. Anttila, University of Turku / Biology

Climate change will increase the frequency and duration of extreme thermal events as has been seen during summer 2018 in the whole northern hemisphere. These heat waves have led to mass fish death events around the world. Moreover, the presence of a certain pollutant might further compromise the ability of ectotherms to respond to these sudden temperature changes. The capacity of fish to cope with an anthropized environment can be exerted throughout a mechanism of phenotypic plasticity. There are, however, only few studies how fish that have experienced long term (decades) increase of temperature in their habitat are able to respond to both heat waves and presence of pollutants, such as heavy metals.

The capacity of individuals to change their tolerance will, nevertheless, define survival capability of entire populations. Here, we evaluate the thermal plasticity of critical thermal maximum (CTmax) in six populations of three-spined sticklebacks exposed to copper (100 μg/L) for one week, in laboratory conditions. Populations were from coastline and from areas that have been warmed by ~10°C by nuclear power plants (NPP) for four decades in Finland. According to results the decades of warming has not increased the thermal tolerance of sticklebacks. Surprisingly, all the individuals from each population were able to increase their tolerance after copper exposure by ~1°C ($p < 0{,}001$). Further molecular studies will be conducted about the molecular response of Heat Shock Proteins. We propose that decades of warming has not reduced the capacity of three-spined sticklebacks to respond to environmental contamination. Yet, they possess some phenotypic plasticity to respond to copper exposures.

WE281

Characterising within-species individuality in the escape response of a marine amphipod

S.A. Kohler, University of Portsmouth / Aquatic Biology; A. Ford, University of Portsmouth / Biological Sciences; M.O. Parker, University of Portsmouth

Animal behaviours are increasingly recognised as a useful endpoint in ecotoxicological studies, as they can provide a link between the ecological and biochemical effects of compounds. However, within-species variation can impact the results of behavioural assays. Studies on fish have shown that classification into bold and timid individuals prior to exposure, allowed for more accurate interpretation on the effects of exposure to behavioural modifying compounds. Currently, there is paucity of data on baseline unconditioned behaviours in aquatic invertebrates. Previous studies in our labs have shown behavioural data to be highly variable and potentially complicated by behavioural phenotypes. We have shown that the marine amphipod *Echinogammarus marinus* is negatively phototactic, however when stimulated by light, individual responses can vary from 'responders' to 'non-responders'. In this study, the baseline unconditioned response of 70 *E. marinus* to sudden exposure to light was measured in a DanioVision observation chamber with EthoVision tracking software. The software recorded data every 0.033 seconds and mean velocity was used as a measure of swimming activity, the initial 2 seconds of response to sudden light stimulus was measured providing 60 data points per organism. Individuals of *E. marinus* exhibited different responses to light, with organisms showing either an increase or decrease in swimming activity. *E. marinus* are an intertidal species which are predated upon by different organisms at low or high tide. This difference in response may be an evolutionary adaptation to dealing with mixed predators which hunt using different sensor cues. Our work suggests that pre-organising your organisms into positive or negative response groups may reduce noise in behavioural data for ecotoxicological studies. The role of phenotypic plasticity and interpretation of behaviours in ecotoxicology are discussed

WE282

Analysis of inter-individual variability in locomotor activity of larval zebrafish as a basis to improve neurotoxicity testing of chemicals

J.A. Fitzgerald, K.T. Kirla, C.M. vom Berg, Eawag - Swiss federal Institute of Aquatic Science and Technology / Environmental Toxicology

Many environmental contaminants, such as pharmaceuticals, pesticides and heavy metals, have been shown to interfere with the nervous system of different species including humans and fish, thereby creating deficiencies in sensation and behavior. Behavior is the integrated output of multisensory, neuroendocrine and neuromuscular signals and is an important, ecologically relevant and very sensitive endpoint of toxicity measurement. In aquatic toxicology, the analysis of locomotor behavior of chemically exposed zebrafish larvae has become a prominent method for the assessment of neurotoxicity, because of the easy-to-handle, high-throughput and automated manner of testing. However, the detection of group differences can be hampered by high inter-individual variability among larval zebrafish. Therefore, the aim of this study was to investigate behavioral inter- and intra-individual variability in zebrafish larvae as a basis to better estimate effects of chemicals on behavioral responses. We assessed the variability of locomotor behavior in larval zebrafish from 5 to 7 days post fertilization for some frequently used protocols (spontaneous swimming, light/dark phases, tapping stimuli) and collected physiological and morphological data of the individual larvae in order to explore whether they correlate with locomotor activity. Our results show that the variability in locomotor activity is lowest during dark phases, but for morphological parameters (length of the larva, size of the swim bladder, size of the yolk) and cardiophysiological measurements (heart rate), there was no correlation with individual locomotor activity. When looking into consistency of activity of the individuals, we found that during dark phases, activity levels correlated well between measurements taken in the morning and afternoon of each day and the activity of individual larvae was highly consistent between day 6 and 7. Overall, our study indicates that taking the variability of locomotor activity into account will improve the evaluation of chemical effects on behavioral responses of larval zebrafish and has the potential to reduce the number of animals to be used for neurotoxicity testing. These results might also offer new insights into mechanisms of toxicity considering that every individual's response to a chemical differs based on their genetic make-up.

WE283

Local genetic adaptation to pesticide use in organic and conventional agriculture

R.A. Almeida, P. Lemmens, R. Ekelson, KU Leuven / Laboratory of Aquatic Ecology Evolution and Conservation; L. De Meester, KU Leuven / Department of Biology

The impact of organic farming is expected to differ from that of conventional farming. Organic farming has therefore been highly promoted under the current EU Common Agricultural Policy. To date, most comparative studies on the impact of organic and conventional agriculture focus on the agricultural land itself, on terrestrial ecosystems, or on rivers. Yet, small farmland ponds harbor much of the regional aquatic biodiversity and are key providers of vital ecosystem services. We will present the first results from a common garden experiment testing to what extent organic and conventional agriculture differentially affect local genetic adaptation of a non-target, sentinel species, the water flea *Daphnia magna*. *Daphnia* are key grazers in lentic waterbodies, and thus contribute strongly to the ecological integrity and ecosystem services of farmland ponds. Earlier investigation demonstrates that *Daphnia* populations can genetically adapt to pesticide use in agricultural areas. We collected multiple clones from different populations (n=7) of *Daphnia magna* from ponds located in conventional agriculture, organic agriculture and natures reserves. The collected clones were cultured under laboratory conditions for at least two generations to minimize interference from maternal effects. A common garden experiment was used to quantify the sensitivity of *D. magna* populations to two pesticides typically used in conventional (Chlorpyrifos and Imidacloprid) and two pesticides used in organic agriculture (Pyrethrine and Copper Sulfate). The EC_{50} value for the different populations and pesticides was determined by exposing juveniles (< 24h old) to eight different concentrations of each pesticide for 48h. The results of this study will provide important insight on the genetic consequences of agriculture on non-target species and can be highly relevant for policies focusing on the development of more sustainable agricultural schemes.

WE284

Effect of test medium components on metals toxicity in microalgae

G. Pascual, Tohoku University / Civil and Environmental Engineering; D. Sano, Tohoku University / Department of Frontier Science for Advanced Environment; O. Nishimura, Tohoku University / Department of Civil and Environmental Engineering

Metals happen naturally in the environment, however, anthropogenic activities highly contribute to increasing their concentration in aquatic ecosystems, becoming water pollution one of the biggest concerns around the world. The toxicity assessments following standardized guidelines are indispensable for water quality regulation and environmental risk assessment. However, reported values of critical concentration of toxicity such as the median effective concentration (EC50) are inconsistent, even the same testing species were used. One of the reasons for this wide variation in reported in previous studies can be attributed to the conditions of test media. Media with high nutrients concentrations are commonly used in assessments using microalgae, but such nutrients amounts are not observed in natural environments. Moreover, the chemical interaction of nutrients and tested metal may also affect the outputs of toxicity assessment. The purpose of this research was to evaluate the effect of copper (Cu), lead (Pb) and zinc (Zn) on microalgae *Pseudokirchneriella subcapitata*, using three different types of culture media, including Bold Basal Medium (BBM), OECD medium and AAP medium. The assessment was carried according to the OECD guideline. Algae were exposed to the metals for three days using a borosilicate flask, and pH was adjusted to 6.5. The fluorescence intensity at 435/685 nm of excitation/emission wavelength was measured every day to follow the algae growth. The specific growth rate was estimated using the formula provided in the OECD guideline and EC50 estimated using the log-logistic dose-response curve. The estimated EC50 values using OECD, BBM and AAP media were 38.5 μg/L, >3000 μg/L and 95.5 μg/L, respectively for Cu, >3000 μg/L, >3000 μg/L and 117.8 μg/L, respectively for Pb, and 155.4 μg/L, >3000 μg/L and 146.2 μg/L for Zn. These results indicate that Pb is apparently less toxic than Cu and Zn. The BBM medium gave extremely high EC50 (>3000 μg/L) for all tested metal species, which also allowed higher growth rate of the microalgae because of the highest nutrient concentrations among the used test media. The EC50 value of Cu was higher in the OECD medium than AAP medium, but the opposite result was obtained for Zn. This means that components of the test media influence to the metals toxicity. Further research should be done to determine the real metal toxicity on the microalgae growth, considering the effect of the chemicals in the test media.

Contaminated Sediments: an Understudied Environmental Compartment (P)

TH001

Persistent Organic Pollutants in sediments from rivers in Moldova

A. Ivanova, The Institute of Zoology of Moldova / Laboratory of Hydrobiology

and Ecotoxicology; L. Ahrens, Swedish University of Agricultural Sciences SLU / Dept. of Aquatic Sciences and Assessment; K. Wiberg, Swedish University of Agricultural Sciences / Department of Aquatic Sciences and Assessment; A. Dahlberg, Swedish University of Agricultural Science / Department of Aquatic Sciences and Assessment

Being predominantly an agricultural country, Republic of Moldova has extensively used organochlorine pesticides in the past, compounds which nowadays are banned and listed as persistent organic pollutants (POPs) under the Stockholm Convention. There are limited data in the open literature on POPs in aquatic ecosystems from Moldova. Sediments act as a sink for various chemicals but can also serve as a source for dispersal of POPs to the surrounding ecosystems. In this study, hexachlorobenzene (HCB), 20 polychlorinated biphenyls (PCBs), dichlorodiphenyltrichloroethane (DDT) and its transformation products (DDE and DDD) were analysed in sediments collected from the two main rivers in Moldova (Dniester and Prut River). The sediments were sampled at a depth of 0-5 cm at 14 different sites during the summer of 2017. The sediment samples (*n*=14), which consisted of three pooled subsamples (per sampling site), were Soxhlet extracted, cleaned-up using several steps, and finally analysed using gas chromatography coupled to mass-spectrometry (GC-MS/MS).The concentrations profiles were generally $?_6$DDTs ≥ $?_{20}$PCBs ≥ HCB in both rivers. The average concentration of HCB was 0.2 ng g^{-1} dw in the Dniester River and 0.080 ng g^{-1} dw in the Prut River. The highest concentration of HCB was found at Soroca sampling site (0.98 ng g^{-1} dw, Dniester River) and at Giurgiulesti sampling site (0.14 ng g^{-1} dw, Prut River). The average concentration of $?_{20}$PCBs was 2.4 ng g^{-1} dw in the Dniester River and 0.74 ng g^{-1} dw in the Prut River, with the highest concentration at Goieni sampling site (9.2 ng g^{-1} dw, Dniester River) and Leuseni (1.5 ng g^{-1} dw, Prut River). DDT and its transformation products were found in all samples. The concentrations of $?_6$DDTs ranged from 1.1 to 52 ng g^{-1} dw in the Dniester River and 3.5 to 89 ng g^{-1} dw in the Prut River, with maximum values at Goieni and Leuseni. *p,p'*-DDE and *p,p'*-DDD were the predominant compounds and constituted 56% and 26% of $?_6$DDTs in the Dniester River and 47% and 33% in the Prut River, respectively. The predominance of transformation product reflects historical use of DDT and indicates significant agricultural input in the past in Moldova. Five sites from the Dniester River showed levels of $?_4$DDT that could cause chronic effect on sediment dwelling organism at long term exposure, according to Norwegian environmental quality standards. Our study suggests that further monitoring of POPs in aquatic ecosystems in Moldova is needed. \n \n

TH002

Application of artificial neural network (ANN)-self-organizing map for the categorization of sediment contaminated by PAHs in Serbian's stretch of Danube River

M. Brboric, University of Novi Sad Faculty of Technical Sciences / Department of Environmental Engineering and Occupational Safety and Health; B. Vrana, Masaryk University, Faculty of Science, RECETOX / RECETOX Research Centre for Toxic Compounds in the Environment; B. Stepanov, University of Novi Sad, Faculty of Technical Sciences / Department of Environmental Engineering and Occupational Safety and Health; S. Pap, Environmental Research Institute, North Highland College, University of the Highlands and Islands / Environmental Contamination and Ecological Health; M. Vojinovic Miloradov, J. Radonić, M. Turk Sekulić, University of Novi Sad Faculty of Technical Sciences / Department of Environmental Engineering and Occupational Safety and Health

The Kohonen self-organizing map (SOM) is a type of Artificial neural networks (ANNs) that uses unsupervised learning for data training to classify and adequately recognize patterns embedded in the input data space. In this study, SOM–ANN was used for recognizing spatial patterns in polluted areas by unificating physico-chemical, ecotoxicological and toxicokinetic variables in the identification of contamination sources and similarities in the quality of the sediment samples. Ten Danube sediment samples contaminated with 16 priority polycyclic aromatic hydrocarbons (PAHs) were quantified by gas chromatography–mass spectrometry. The total concentration of 16 PAHs ranged from 99.48 to 520.48 ng/g, with a mean (median) concentration of 271.86 ng/g (235.37 ng/g). Individual PAH analysis showed that PAHs with four to six rings were the most frequently detected isomers and accounted 85% of the total PAHs concentrations. Correlations and relationships between the samples and the variables were determined by comparing the component planes with similar patterns of the self-organizing map (Fig 1). The SOM network was trained using a 7 × 7 map. The results have highlighted the dependencies between the different PAHs and the classification of studied sediments into four classes with similar pollution levels. The first (Nap, Acy, Ace, Fl) and second pattern (Phe and Ant) were dominated by LMW PAH contaminants, which are likely released from similar petrogenic sources. The third pattern including Flu, Pyr, B(a)A, and Chr, which are HMW PAHs commonly discharged from coal combustion. The final pattern comprises B(b)F, B(k)F, IP, and B(g,h,i)P, which are also HMW PAHs from pyrogenic sources. Principal component analysis (PCA) and hierarchical classification of SOM maps (SOM AHC) were also used for validating the obtained results. The proposed methodologies and results obtained in this paper provided valuable assessment using the SOM visualization capabilities and highlighted zones of priority that might require additional investigations and also provide productive pathway for effective decision making and remedial actions.

TH003

Polychlorinated biphenyls and naphthalenes in sediments of a contaminated river in Finland: Levels, sources and bioavailability

J. Koistinen, University of Helsinki / Tvärminne Zoological Station; A. Sormunen, Mikkeli University of Applied Sciences / Environmental Technology; M. Verta, S. Herve, Finnish Environment Institute; P. Ruokojärvi, National Institute for Health and Welfare / Department of Health Security; J.V. Kukkonen, University of Jyvaskyla / Biological and Environmental Science

The pollution of a Finnish river, the River Kymijoki, with polychlorinated biphenyls (PCBs) and naphthalenes (PCNs) was investigated by sediment data. This river descends to the Gulf of Finland and has been a secondary source of pollutants to the Baltic Sea due to contamination via several plants, including pulp mills, a chlor-alkali plant and a former chlorophenol plant. Variable levels were measured for the PCBs (from 12 to 390 µg/kg dry weight, dw) and PCNs (from 0.83 to 13 µg/kg dw) in surface sediments, which had been collected from different locations of the river, the PCBs being more abundant than the PCNs in all sites. The levels of both pollutant groups exceeded those measured in the Finnish coast of the Baltic Sea. Analyses of a core from the vicinity of the chlor-alkali and a former chlorophenol plant revealed that historical burden may constitute a significant source for both the PCBs and PCNs in the river. Different spatial distribution of the PCNs compared to that of the PCBs and differences in congener profiles in surface sediments with those of technical formulations suggested that there have been multiple sources for both pollutants to the River Kymijoki. The chlor-alkali plant was considered one source of the PCBs and PCNs, either via the process or use of technical formulations, while elevated levels of the PCBs in the lower reaches of the river could possibly be explained by other industrial processes or leaks of formulations from electrical equipment used earlier in plants. The comparison of the surface sediment data to the data of mussels incubated in this river pointed to low potential for the accumulation of the PCBs and PCNs from sediment to aquatic biota. The continuous transport of pollutants in sediments downstream and into the Gulf of Finland in the Baltic Sea, however, has to be kept in mind.

TH004

Spatio-temporal exposure of Plant Protection Products in OECD 218/219 sediment test systems - Modelling and measurements

K. Hammel, Bayer AG, Crop Science Division / Environmental Safety; A. Dorn, RWTH Aachen University / Institute of Environmental Research; P. Dalkmann, Bayer AG Crop Science Division / Environmental Safety; E. Bruns, Bayer AG Crop Science Division / Ecotoxicology; D. Faber, Bayer AG, Crop Science Division / Environmental Safety Ecotoxicology

Sediment toxicity testing is currently revised under the premise to improve quality and consistency of regulatory risk assessments. In 2015, EFSA has published a scientific opinion on risk assessment for sediment organisms where sediment-spiked (OECD 218) and water-spiked test systems (OECD 219) are considered to study chronic effects on sediment organisms. Prominent test organisms are Chironomids, aquatic insects which live in and on soft sediments. Usually specific mean concentrations of the overlying water or over the entire sediment are used to derive effect endpoints. However, due to the design of these studies initially large gradients between the exposure in the overlying water and in the sediment layer are established. As a consequence, substantial temporal and spatial dynamics of local concentrations have to be expected, especially in the vicinity of the interface beween water and sediment where the Chironomids larvae are supposed to live (observations made in several internal studies). Following up previous work (Hammel et al, 2018) we simulated the transport and the redistribution of four active ingredients of plant protection products with the mechanistic model TOXSWA. Studying a number of compounds from high to low mobility (with Koc from zero to several thousand) and spiking either overlying water or sediment allowed a comprehensive analysis of compound- and test-specific local concentrations in such test systems and their temporal behaviour. The results of the simulations are compared with measured sediment concentrations in three depths (see contribution submitted by Dorn et al.). Main findings are that both, compound mobility and mode of spiking have a major impact on local concentrations. Presuming that chironomids live in the upper millimetres of the sediment their exposure can be very different from the average concentration depending on substance mobility and test design. This approach allows to identify the ecotoxicologically relevant exposure which should be considered for the derivation of effect endpoints of chironomids. It also allows to set water- and sediment-spiked studies for a specific substance into context because in both studies the underlying dose-response should be the same. New insights of the relevant ecotoxicological exposure pathway of Chironomus riparius in OECD 218/219 tests

D. Faber, Bayer AG, Crop Science Division / BAG-RD-CS-EnSA-Ecotoxicology; K. Hammel, P. Dalkmann, Bayer AG Crop Science Division / Environmental Safety; V. Herno, Bayer SAS; E. Bruns, Bayer AG, Division Bayer CropScience / Ecotoxicology; A. Dorn, RWTH Aachen University / Institute of Environmental Research
The European Food Saftey Authority (EFSA) published in 2015 a scientific opinion on environmental risk assessment for sediment organisms. This includes a discussion on how regulatory acceptable concentrations for sediment organisms could be derived and what is the relevant exposure pathway for test organisms such as *Chironomus riparius*. To challenge the assumption that pore water over the entire sediment layer is a relevant route of exposure for *C. riparius*, we conducted over the past two years several studies in-line with OECD 218/219 to investigate the spatio-temporal behaviour of different compounds in the water-sediment system. The compounds differed in their physico-chemical characteristics like the logKow. In the studies, analytical measurements were performed at different times for the overlying water and in 3 sediment core samples divided into 3 x 5 mm-layers each for the total sediment and the respective pore water concentration. This improvement of the sampling allowed us to have a closer look at the local concentrations at different times in the test system. In parallel, the measurements were compared with predictions by TOXSWA model. Furthermore, it was investigated where the *C. riparius* larvae live in this system prepared with artificial sediment. The approach and first results were already presented at the SETAC in Brussels 2017 (Herno, V. et al.) and in Rome 2018 (Hammel, K. et al.). The new results show, that *C. riparius* larvae live in the upper first mm of the sediment and are therefore predominantely exposed to a concentration comparable to the overlying water instead of the average pore water concentrations of the sediment layer. The analytically measured and predicted TOXSWA concentrations show that the compound mobility and the mode of spiking have a major impact on the local concentrations in the system (see contribution submitted by Dorn et al. & Hammel et al). Taking this into consideration it is important to combine the living behaviour of the test organism with the local concentration of the compound to predict the relevant ecotoxicological exposure pathway and to base further regulatory decisions on these circumstances. Herno, V. et al., (2017): Pore water – The relevant exposure pathway for sediment risk assessment? Setac Europe 2017 Hammel, K. et al., (2018): Spatio-temporal exposure of Plant Protection Products in OECD 219 sediment test systems - Comparison of model results with measurements. Effects of bioturbation on the freely dissolved hydrophobic organic chemical contribution in sediment cores of the German Bight

A. Kreutzer, HAW Hamburg; N. Nabo, G. Witt, HAW Hamburg / Department of Environmental Engineering
Marine muddy sediments store a large amount of legacy hydrophobic organic chemicals (HOCs), such as polycyclic aromatic hydrocarbons (PAHs) and polychlorinated biphenyls (PCBs). The primary emissions to the environment of many HOCs have been reduced as a result of strict regulations. Undisturbed sediment serve as sink for HOCs and exhibit a normal distributed chemical profile according to the historical input of HOCs in the environment. For example, the PCB concentration first increases with depths until a maximum is reached and then decreases again with depths according to the temporal industrial use. The release of HOCs from the sediments to water and biota pose a risk of negative effects on the local ecosystem. Especially the benthic community is directly exposed to organic pollutants in the sediment. However, the reworking activities of benthic organisms, a process called bioturbation, can enhance the sediment-to-water flux of HOCs. The organisms' activities disturb the sediment profile and mobilize the chemicals from deeper layers. Beside the chemical analysis of the total sediment concentration (C_{total}), the determination of the freely dissolved pore water concentration (C_{free}) is more crucial since it accurately reflect the bioavailable fraction. Based on C_{free}, the chemical activity (a) can be determined, which describes the potential for ecologically relevant spontaneous processes such as diffusion, bioconcentration and baseline toxicity. In this study, C_{total} and C_{free} of sediment cores from the German Bight (North Sea) were investigated. Recent advances in equilibrium passive sampling methods (EPSMs) offer a promising alternative to the measurement of C_{total} and support improved risk-based decision making since bioavailability of sediment contaminants can be directly quantified via C_{free}. Currently, freely dissolved concentration will establish as an important endpoint for sediment quality and risk assessment (Mayer et al. 2014). The determination of C_{free} of PAHs and PCBs in sediment pore water was performed using solid phase microextraction (SPME) according to Witt et al. (2009). Furthermore, the community bioturbation potential (BPc) was determined according to Queirós et al. (2013) after benthos analysis. Finally, C_{free} and C_{total} were correlated with the bioturbation potential to identify whether there is a mobilization and redistribution of HOCs in the sediment cores caused by bioturbation.

TH007

The Effect of Organic Carbon on the Availability of Cobalt in Sediments

G. Woodward, ADAS Gleadthorpe; C. Peacock, University of Leeds / School of Earth and Environment; A. Otero-Farina, University of Lorraine; O. Thompson, National Nuclear Laboratory; I. Burke, University of Leeds
Cobalt is produced as a waste product in a number of industries and therefore has the potential to leak into the environment. It is possible it would then contaminate the environment depending on the conditions of the system, such as pH and relative content of cation sorbing phases. We investigated Co sorption to the common sediment and soil constituents ferrihydrite, kaolinite, humic acid, ferrihydrite-HA and kaolinite-HA organo-mineral composites, and three natural sediments with a range of organic carbon contents. Sorption batch experiments, synchrotron X-ray absorption spectroscopy (EXAFS), and thermodynamic surface complexation modelling were used to develop our understanding of the system and determine whether Co behavior in complex systems could be modelled assuming linear additivity of Co sorption to the end-member phases. Sorption to each of the sorbents increased with pH. Sorption to the organo-mineral composites was found to be intermediate between the end-member phases, displaying enhanced sorption respective to the mineral phase at low-mid pH. Sorption to the natural sediments increased with increasing organic carbon. EXAFS analysis shows that at mid-high pH Co sorbs to each of the end-member phases and the organo-mineral composites via inner-sphere bidentate binuclear surface complexes. Our molecularly constrained thermodynamic surface complexation models for Co sorption to ferrihydrite, kaolinite, HA, ferrihydrite-HA, kaolinite-HA, and three natural sediments show that Co sorption to complex systems cannot be modelled assuming linear additivity of Co sorption to the end-member phases.

SEDIMENT RESUSPENSION EVENTS - THE IMPACT OF CLIMATE CHANGE ON SEDIMENT-BOUND METALS: Geochemistry

S. DeSisto, P. Huntsman, CanmetMINING, Natural Resources Canada; C. Rickwood, Natural Resources Canada
Sediments play an important role as sinks for sequestering contaminants from local ecosystems. However, under future climate change scenarios, more frequent and intense precipitation events may lead to remobilization of sediments and an increase in the flux of contaminants to the local ecosystem. Sudbury, Ontario has been exposed to decades of smelter emissions that have released metal(loid)-bearing particulate matter, which has accumulated in lake bottom sediments. The present study aimed to investigate the influence of resuspension on the fate and effect of metals in Sudbury area lake sediments. This poster outlines the approach and results of investigations into physical-geochemical factors that could influence metal dissociation from particulate matter. To assess mobility of metals, core resuspensions and shaker flask tests were conducted. Results indicated that sediment disturbances, such as would occur during intense storm events, produce a range of geochemical changes and element behavior that differ from control samples that experienced no resuspension. In addition mineralogy and sequential extraction data provided explanations for these geochemical changes, highlighting the importance of a weight of evidence approach to understanding metal fate in a changing climate.

TH009

Assessing bioavailability and toxicity of dual metal-contaminated sediments to early life stages of medaka (Oryzias latipes) fish

C. Lee, National Taiwan University / Department of Agricultural Chemistry; P. Chen, National Taiwan University / Agricultural Chemistry
In the river system, sediment is considered as a long-term source of contaminants for aquatic organisms due to its high accumulating capacity. Among all contaminants, heavy metals are of high concern because of their non-biodegradable nature. The bioavailability of these metals may be affected by sediment properties, transportation behavior between sediment-water system and physiology of aquatic organisms. To understand the chemical and biological interaction of sediment-bound contaminants to the aquatic life, this study used the whole-sediment exposure method with intermittent water renewal system to evaluate the bioavailability and toxicity of two heavy metals [i.e. lead (Pb) and copper (Cu)]. The early life stage (ELS) fish of medaka (*Oryzias latipes*) embryos and larvae were exposed to a variety of Pb- and Cu-spiked sediments with different physicochemical properties. The acute mortality and sub-lethal (e.g. malformation, growth and bioaccumulation) were recorded simultaneously during sediment exposures. In addition, several analytical approaches were used to assess the bioavailability of these two metals and the correlation with observed toxic effects. It was observed that embryos and larvae had different toxic responses to these metals with embryos having higher tolerance than larvae. For the metal concentrations (Cu and Pb) in sediment higher than 300 mg/kg each, the survival rates of larvae were significantly lower than that of the control group. In addition, the larval morphology (i.e. body length and body weight) decreased with increased metal concentrations. The heavy metals were also bioaccumulated in larvae with increased concentration in sediments. We will further evaluate whether Chelex-100 resin extraction method can be an effective method in predicting the bioavailability of sediment Cu and Pb to medaka fish.

TH010

The ecotoxicity of Emamectin Benzoate to benthic marine organisms

D. Leverett, WCA-Environment Ltd; M. Fox, Scymaris Ltd / Ecotoxicology; J.

Smith, Scottish Salmon Producers Organisation; C. Doig, EPP / Ecotoxicology
Emamectin Benzoate (EMB) has been authorised in Scotland for use as a veterinary medicine to control sea lice in farmed salmon for almost 20 years. EMB partitions rapidly to sediments and, in the marine environment, its mode of action targets crustacean sea lice species. The non-target species expected to be most affected by environmental EMB exposure are therefore benthic crustaceans living near salmon sea pens. While short term sediment ecotoxicity data on marine organisms are available for EMB, it has not been possible to develop a reliable sediment Environmental Quality Standard (EQS) for benthic marine organisms because the only long-term sediment ecotoxicity data available was for a freshwater species (*Chironomus riparius*) and potential differences in sensitivity to EMB between marine and freshwater benthic species could not be resolved. In order to fill this data gap in the EMB ecotoxicity dataset, a programme of new long-term testing with marine sediment species was carried out during 2017/2018, which comprised the following tests: 10-day static toxicity of EMB to the lugworm (*Arenicola marina*) (endpoints covering mortality and feeding). 28-day semi-static toxicity of EMB to the amphipod (*Leptocheirus plumulosus*) (endpoints covering mortality, growth and reproduction). 75-day semi-static toxicity of EMB to the amphipod (*Corophium volutator*) (endpoints covering mortality, growth and reproduction). All of the studies involved the exposure of test organisms directly to sediment spiked with EMB, and the chemical verification of sediment EMB exposure concentrations. The results of these studies indicated that EMB was much less toxic to marine benthic organisms, and particularly benthic crustaceans, than expected. Mean measured sediment ‘no effect’ concentrations ranged from 12.9 µg/L for 10-day *Arenicola marina* feeding behaviour (casting) to greater than 61.3 µg/L for 75-day growth and reproduction in *Corophium volutator*. We will present the full results of this sediment ecotoxicity testing programme, as well as discussing the implications of the results with respect to the derivation of an updated sediment EQS for EMB.

TH011
Identifying non-target toxicants in sediment using effect-directed analysis with a multiple-level endpoint approach
F. Cheng, Jinan University / School of Environment; H. Li, Jinan University; J. You, Jinan University / School of Environment
Identifying causal relationship between sediment contamination and ecological responses is challenging. Bioaccessibility-based XAD extraction and multiple cell-based bioassays were incorporated into effect-directed analysis (EDA) to identify sediment-bound toxicants, with a special consideration of bioaccessibility and toxicity pathways. The XAD extracts of sediment samples from urban waterways in Guangzhou, China were screened using cell viability bioassays with cell lines from four organs. Pronounced effects were noted in the bioassays with SH-SY5Y and MCF7 cell lines, thus neurotoxicity and estrogenic effects were focused in next-step EDA using 35 normal phase liquid chromatography fractions. In addition to cell viability, reactive oxygen species and estrogenic receptor activity were applied as subcellular endpoints for neurotoxicity and estrogenic effect pathway directed bioassays, respectively. Suspect toxicants were identified in active fractions using GC/MS. Toxicity confirmation was performed by evaluating toxicity contributions of identified toxicants to proposed pathways. Cypermethrin and fipronil sulfone were found as the major contributors to neurotoxicity, while nonylphenol explained most of estrogenic activity in the test sediments. The finding of neurotoxicants was consistent with previous *in vivo* EDAs in the same area, suggesting that considering bioavailability and toxicity pathways in screening testing improved environmental relevance for *in vitro* EDA.

TH012
Developing novel sediment toxicity bioassays with Hediste diversicolor polychaete coelomocytes
N. Garcia-Velasco, University of the Basque Country UPV/EHU / Dept. Zoology and Animal Cell Biology, Research Centre for Experimental Marine Biology and Biotechnology; E. Urionabarrenetxea, University of the Basque Country / Zoology and Animal Cell Biology, Research Centre for Experimental Marine Biology and Biotechnology; A. de Diego, University of the Basque Country UPV/EHU / Dept. Izagirre, University of the Basque Country UPV/EHU / CBET Research Group Dept Zoology and Animal Cell Biology Faculty of Science and Technology and Research Centre for Experimental Marine Biology and Biotechnology PIE; A. Gredilla, University of the Basque Country UPV/EHU / Dept. Applied Chemistry; J. Carrero, O. Liñero, University of the Basque Country UPV/EHU / Dept. Analytical Chemistry; I. Marigomez, Euskal Herriko Unibertsitatea / Zoology & Animal Cell Biology (Sci & Tech Fac); M. Soto, University of the Basque Country / Zoology and Animal Cell Biology, Research Centre for Experimental Marine Biology and Biotechnology PIEUPVEHU
The contamination of estuarine sediments after decades of uncontrolled industrial exploitation and urban wastes release is a critical issue that can affect ecosystems health. The ancient pollutants in sediments can pose an environmental risk especially when the physico-chemical conditions of sediments are altered. Hence, a proper assessment of the potential adverse effects of contaminated sediments is crucial. Nowadays, the study of the pollutant levels in sediments is receiving increasing attention, but still the information regarding their effects is scarce. These effects could be assessed by means of toxicity bioassays applied in ecologically relevant species. Among them, the polychaete *Hediste diversicolor* has been characterized by its abundance in sediments and by its capacity to accumulate pollutants. Therefore, it could be considered as a sentinel organism for sediment toxicity assessment. In addition, coelomocytes have become a target system in ecotoxicology due to their capacity to predict impairments caused by pollutants at longer exposure levels. The aim of this work is to develop accurate sediment toxicity test with the coelomocytes of *H. diversicolor*. First, cell retrieval procedures and coelomocyte subpopulation identification were addressed. Primary cultures of coelomocytes were exposed to a range of model (Triton X-100, $CdCl_2$) and novel (Ag NPs) pollutants, and to elutriates coming from real sediments (collected in Bilbao estuary). After different time exposures (1-24h), coelomocyte viability (Calcein-AM) and mortality (PI) were assessed through microplate and flow cytometric analysis. Coelomocytes were extruded by electric stimulation (9V) using PBS adjusted to the salinity of ragworms coelomic fluid (0.17M NaCl) and passed through 40µm strainer to avoid gametes. Coelomocyte population was composed by two major cell groups, amoebocytes and eleocytes. Both subpopulations showed gradual responses after exposure to the different pollutants, being Calcein AM viability test more sensitive and responsive endpoint than IP. According to the cytotoxicity measured in coelomocytes and to the chemical analysis performed in the elutriates of real sediments, a pollution gradient of the sampling points was established. The obtained results prove the usefulness and the potential of *in vitro* toxicity test with *H. diversicolor* coelomocytes for the assessment of polluted sediments.Ack: Basque Gov (IT810-13), Univ. Basque Country and MINECO (CTM2017-87766-R).

TH013
Toxicity evaluations of sediment collected in the Osaka Bay, Japan using medaka embryos
S. Uno, Kagoshima University / Faculty of Fisheries; E. Kokushi, Kagoshima University / Education and Research Center for Marine Resources and Environment; M. Kawano, Kagoshima University
Chemicals discharged through the human activities have been carried to the sea area by river water, rainfall, and other factors, and then are settled on sediments finally. They have been possibly affecting benthic animals individually or multiply. But their actual conditions in the field are almost unknown. We have been developing new method using fish embryos for the evaluation of sediment toxicities collected from the field. Because the embryos are kept on the polluted sediment with slight amount of pore water and without overlying water, this method can evaluate the toxicities in sediment alone. Osaka Bay is located at the eastern end of the Seto Inland Sea, and is enclosed by Osaka and Hyogo Prefectures, which are a couple of the most densely populated areas in Japan. The bay is surrounded by the island of Honshu and Awaji Island, and is classified as an enclosed coastal sea with only two narrow entrances. This limits water exchange in the bay, and possibly leads to increase risk of marine pollution with heavy traffic together with the presence of large industrial plants. There have been no examinations on the sediment toxicities obtained from the Osaka bay to aquatic organisms. In the present study, we collected the field sediments over 20 locations along the shoreline of the Osaka bay from 2014 to 2016, and evaluated the sediment toxicities using the embryos of Japanese medaka (*Oryzias latipes*). The dried sediment samples were rinsed with an embryo raring mediums. Ten embryos were embedded in half of them in the each sediments, which is laid at a glass petri dish with 35 mm of diameter, and were developed on the sediment in an incubator set at 23°C for 7 days post-fertilization. In the period, the rearing water was not added to the dishes. Three dishes contained the sediment were prepared as sampling site (n=3). An embryo was then individually transferred in a hole of 48-well microplates containing dechlorinated tap water, and kept until 3 days after hatching. The toxicities were evaluated with their developing condition, mortality, hatching days, abnormality in embryo, and malformation in hatching larvae. Only 60% embryos exposed to sediments collected at the mouth of Yodo river were hatched. Their mortality was only 3%, but they had not been able to hatch. For other sites, we could not almost observe the deformity in the embryos and hatching larvae. However, sediments from some sites decreased hatching rates and delayed their hatch.

TH014
Assessment of chronic toxicity of REE-enriched sediments from a prospective mining area on Myriophyllum alterniflorum
K. Mehennaoui, Laboratoire Interdisciplinaire des Environnements Continentaux (LIEC) UMR 7360 CNRS; E.M. Gross, University of Lorraine / Laboratoire Interdisciplinaire des Ecosystemes Continentaux; L. Minguez, LIEC Université de Lorraine CNRS / Laboratoire Interdisciplinaire des Environnements Continentaux, CNRS UMR 7360; A. Romero-Freire, Oceanography department, Marine Biogeochemistry; L. Giamberini, Université de Lorraine, CNRS UMR 7360 / LIEC, CNRS
Rare earth elements (REE) are strategic compounds increasingly used in emerging technologies. The future exploitation of areas with high REE contents play a strategic geopolitical role around the world. Opening new mining areas contribute to increased REE mobility and will influence their fate in the environment. Hence,

establishing baseline ecotoxicity of REE in prospective mining areas will be crucial to monitor the potential REE enrichment in the surrounding environments. Despite the growing number of studies on REE toxicity, their effects on aquatic organisms is not fully understood. Moreover, their effects on organisms living in the sediments and more specifically aquatic plants, remain scare. Hence, the aim of the current study is to assess the chronic toxicity of naturally REE-enriched sediments on the submerged growing *Myriophyllum alterniflorum.* Every two weeks, effects on growth, pigment and phenolic compound content and dry matter content are assessed along with uptake and translocation of REE to various plant parts. The experiment is performed in a water-sediment system. Six cm-long apical shoot sections of *M. alterniflorum* from axenic cultures are used as model organisms for the present study. Plants are exposed to two REE-enriched sediments for 6 weeks; namely N2 and B4, and a control sediment established based on the characteristics of the natural sediments. N2 and B4, were collected in North Quebec, Canada. They were selected based on their parent materials. The physico-chemical analyses on sediments showed that B4 contains the highest amount of REE and has the highest fine grain fraction. The first results on exposed plants show that both sediments lead to a growth inhibition in term of length and fresh biomass. Interestingly, the plants exposed to REE-enriched sediments present longer roots than those of the control sediment. This could be linked to a lack of nutrients in the contaminated sediments, or interactions between REE and plant nutrients. These results may also indicate a phyto-available fraction of REE from the sediments that leads to significant changes in plant growth behavior, and may also hint on a potential transfer of REE through the food web chain. Further analyses are ongoing to better define the baseline ecotoxicity of REE on *M. alterniflorum*. The present study provides first insights on REE behavior between sediments and plants, and their potential chronic toxicity on aquatic organisms around prospective mining areas.

TH015

Microbiological biotests for sediment risk assessment - A question of reproducibility and reliability

S. Heise, Hamburg University of Applied Sciences / Life Sciences; S. Faetsch, Hamburg University of Applied Sciences (HAW); S. Warmuth, N. Wittig, Hamburg University of Applied Sciences HAW

Use of microbiological biotests in sediment risk assessment is controversial in Europe. While some countries have implemented them in their decision making frameworks, managers in other countries are doubtful regarding reliability and certainty of ecotoxicological results, and to what extent they can support well-informed decision. Questions that are often raised are those on reproducibility of biotest results and their variability compared to chemical data. In this study, data are gathered on sediment cores that were taken biweekly at two sites in the Elbe river catchment. Analyzing the ecotoxicological depth profile with different test systems were supposed to provide information on a)Reproducibility of ecotoxicological answers to sediments collected at different times from the same site, and b)variability of biotest data and reliability of the different biotests with regard to ecotoxicological thresholds. Sediment cores of up to 80 cm length were taken 3 times every 2 weeks from the same location. The core was divided horizontally into slices of 1.5 to 3 cm thickness. Analysis: Vertical element profiles were determined by portable XRAF to identify comparable layers in the various cores from the same location. Biotesting: Algae growth inhibition assay with *Raphidocelis subcapitata* (AGI), luminescence bacteria test with *Allivibrio fischeri* (LBT) (both tests on elutriates) and the bacterial sediment contact assay with *Arthrobacter globiformis* (BCT) were carried out applying a miniaturized protocol. Locations: a) the "Alte Süderelbe", a sidearm of the Elbe river which is not tidally influenced, Febrary/March 2017. b) a small harbor upstream of Hamburg (Hohendeicher Hafen), September, October 2018. Samples were taken from a wooden swimming pier without boat traffic Currently, only the study of the Alte Süderelbe is completed. Results from Hohendeicher Hafen will be finalized by December 2018. Ecotox data from Alte Süderelbe sediments showed good agreement between the different corer and point towards good reproducibility of AGI and LBT data. (BCT was only performed on Hohendeicher Hafen sediments). There were, however, strong differences in the data on the upper sediment layer that may be due to disturbances of the surface during sampling which had been done wading into the river. For the second study, samples were taken from the pier, reducing the amount of resuspension. Data from both sites will be shown and discussed at the conference.

TH016

SEDIMENT RESUSPENSION EVENTS - THE IMPACT OF CLIMATE CHANGE ON SEDIMENT-BOUND METALS: Toxicity

C. Rickwood, Natural Resources Canada; S. DeSisto, CanmetMINING Natural Resources Canada; E. Suominen, University of Ottawa; P. Huntsman, CanmetMINING, Natural Resources Canada

Association of trace elements to particulate matter reduces bioavailability and hence toxicity for most metals. However, investigations into the fate and effect of metals associated with particulates during erosion or resuspension events (e.g. during heavy rainfall) is lacking. Future climate change scenarios predict more frequent and intense precipitation events that could lead to remobilization of sediments and an increase in metal dissociation from particulate matter resulting in increased bioavailability and toxicity for aquatic organisms. Sudbury, Ontario has been exposed to decades of smelter emissions that have released metal(loid)-bearing particulate matter, which has accumulated in lake bottom sediments. The present study aimed to investigate the lethality and bioavailability of metals to aquatic invertebrates following exposure to field collected water and sediments samples from Sudbury area lakes. To assess toxicity, a novel sediment resuspension test was developed to measure lethality and bioavailability of metals to *Daphnia magna.* In addition, a standard *Chironomus dilutus* sediment test was conducted to compare toxicity and bioavailability. Results showed that survival rates differed amongst sites and that bioaccumulation of certain metals varied between tests and sites. Results suggest that sediment resuspensions can affect metal bioavailability, resulting in increased bioaccumulation and toxicity in aquatic primary consumers. Based on these preliminary results, further investigation is needed to better understand the environmental impact of climate change on contaminated sediments.

TH017

Impact of agricultural practices on sediment quality of small streams in Switzerland

A. Schneeweiss, Swiss Centre for Applied Ecotoxicology; M. Casado-Martinez, Centre Ecotox; C. Thiemann, M. Wildi, Swiss Centre for Applied Ecotoxicology; m. Pintado-Herrera, University of Cadiz / Department of PhysicalChemistry; P. Lara-Martin, University of Cadiz / Physical Chemistry; B.J. Ferrari, I. Werner, Swiss Centre for Applied Ecotoxicology

In Switzerland, the National Surface Water Quality Monitoring Program "NAWA" documents and evaluates the status and development of surface waters. This program includes a large network of monitoring stations for long-term continuous measurements (TREND) and a focused program at selected sites (SPEZ). In the framework of the NAWA SPEZ program, two studies on the contamination of small to medium sized streams by plant protection products were conducted in 2012 and 2015 [1,2,3]. The first campaigns showed that the concentrations of several insecticides, herbicides and fungicides measured in the surface water exceeded the corresponding environmental quality standards [2,3]. Based on physico-chemical properties of some plant protection products (low water solubility, hydrophobicity) it is highly likely that they are present in sediments too. However, the occurrence and concentrations of pesticide residues in sediments of surface water bodies in Switzerland and their impact to the benthic fauna and flora are yet largely unknown. In parallel to the NAWA SPEZ project 2017, which studies surface water quality in relation to the application of plant protection products in five small streams surrounded by agricultural land, the Ecotox Centre studied sediment contamination and the potential adverse effects of these contaminated sediments using a battery of sediment-contact tests. Considering potential temporal variability in pesticide use, the study was conducted during a whole season, from March to October, with monthly sampling. The concentrations of several plant protection products targeted in this study exceeded existing sediment quality guidelines, indicating a potential risk to benthic invertebrates in sediment and suspended matter samples collected for at least one of the sampling months. Depending on the sampling site the mixture risk was mainly dominated by the organophosphate insecticide chlorpyrifos or by pyrethroid insecticides. The results of the toxicity tests showed adverse effects on benthic organisms (*H.incongruens, C.riparius, C.elegans*) at some sites but the measured endpoints showed large temporal variability for a same site. [1] BAFU 2013: NAWA – Nationale Beobachtung Oberflächengewässerqualität. Konzept Fliessgewässer. Bundesamt für Umwelt, Bern. Umwelt-Wissen Nr. 1327: 72 S. [2] Wittmer et al. (2014). TH018

Reducing uncertainty in sediment contact testing by considering natural variability and harmonizing control sediments

U. Feiler, Federal Institute of Hydrology; S. Heise, Hamburg University of Applied Sciences / Life Sciences; M. Brinke, Federal Institute of Hydrology / Biochemistry and Ecotoxicology; G. Reifferscheid, German Federal Institute of Hydrology; B.J. Ferrari, Swiss Centre for Applied Ecotoxicology; M. Casado-Martinez, Centre Ecotox; H. Hollert, RWTH Aachen University / Institute for Environmental Research; S. Höss, Ecossa / Animal Ecology

Introduction: Sediment contact tests (SCT) aim to assess the toxicity of anthropogenic contaminants in whole sediments introduced into water bodies. However, environmental samples do not only differ in their quantity and quality of contamination, but also in terms of their geochemical properties, such as grain size distribution or content of organic matter. These sediment properties might also affect the test organisms and thus impede the interpretation of toxicity data, e.g. by producing false-positive results. This has already been shown for various benthic organisms in freshwater sediments (Ankley et al. (1994) Environ. Toxicol. Chem. 13: 627–635; Höss et al. (2010) Environ Poll 158: 2999–3010). Attempts to account for the variability of test results of SCTs in form of thresholds or corridors for tolerable inhibitory effects (Höss et al. (2010) Environ Poll 158: 2999–3010) might lead to false-negative results and an underestimation of risk. Therefore, we want to present a strategy, how to reduce uncertainty in sediment contact testing for a more reliable risk assessment. Methods: Nine different SCTs

(*Arthrobacter* test, ISO/CD 10872; *Myriophyllum* test, ISO 16191; *Heterocypris* test, ISO 14371; *Caenorhabditis* test, ISO 10872; *Chironomus* test, AFNOR T90-339-1; *Hyalella* test, ISO 16303; *Tubifex* test, OECD 225; *Danio* test, ISO 15088, adapted) with organisms from various trophic and organizational levels will be applied to a selection of min. 30 reference sediments, in order to investigate the species-specific variability due to differences in geo-physico-chemical properties of lowly contaminated freshwater sediments. The project comprises two work packages: In WP1, a common field-collected sediment will be defined as control sediment for all test systems. In WP2, min. 30 lowly contaminated sediments from rivers and lakes will be tested with all sediment contact tests. Sediments will be selected according to following criteria: sites should be in a (very) good ecological and chemical status; chemical contamination is below 2 x TEC for each substance (SQGs according to De Deckere et al. (2011) J Soil Sed 11:504-517); sediments show a gradient of texture and organic content. Variability of test results will be analyzed statistically in order to derive reliable and safe toxicity thresholds. Aimed Results: (1) A common natural control sediment will allow comparison of test results among all SCTs. (2) Revision of endpoint-specific toxicity thresholds will ensure environmental safety.

TH019

Contaminated marine sediments in the Nordic countries; review of remediation approaches. Report from the CONSENS project

A.P. Lehoux, Uppsala University; K. Petersen, Norwegian Institute for Water Research; M. Schaanning, NIVA - Norwegian Institute for Water Research; M.T. Leppänen, Finnish Environment Institute SYKE; I. Snowball, Uppsala University; M. Olsen, NIVA - Norwegian Institute for Water Research

Introduction: For the last two decades, an increasing awareness of legacy contaminated sediments has been seen. Contaminated sediments have been recognized as a source of contamination in aquatic food chains, and the concerns regarding ecological and human health risks continue to grow. Worldwide, a number of sites have been identified and assigned priority for remediation. However, governance and regulatory instruments vary between countries. The Nordic Council of Ministers have recognized the need to compile knowledge of remediation strategies and to evaluate the different approaches within the Nordic countries, to ensure that the best possible measures are taken in the future. A new report presents a status of regulatory framework and sediment management in Norway, Sweden, Finland and Denmark. Further, the report gives an overview of remediation approaches, and presents experience from some well-documented remediation sites within the Nordic countries. **Methods:** A literature review has been carried out by a group of Nordic scientists, which allows for a unique comparison between the Nordic countries. Information and data on regulations, contamination and remediation are not easy obtained as most reports and official documents have been written in Nordic languages, and information can be spread out between many government authorities. Typically, surveys and monitoring of remediation sites are not published in scientific peer review journals. **Results and discussion:** The review shows the inequality in national remediation strategies and prioritizing between the Nordic countries. While Norway has included contaminated sediments in the country's priorities since almost 30 years, Finland has not yet started any remedial action on polluted marine sediments. Remediation approaches includes traditional methods like dredging that has been extensively used for navigation purposes and to maintain sailing depths whereas isolation capping has been conducted in a few sites in Norway, and is under consideration in Sweden. The use of active materials is still in it's infancy. There is not a lot of documentation on post-remediation monitoring, though this phase appears to be very important in order to evaluate the efficiency and improve the techniques. Criteria for deciding upon remediation approaches should include efficiency, adverse effects, costs and benefits of the different approaches.

TH020

Establishing Cleanup Levels for Contaminated Sediment Sites in Norway Based on Bioavailability

M. Olsen, NIVA - Norwegian Institute for Water Research; R. Gardner, Anchor GEA; M. Schaanning, K. Næs, NIVA Norwegian Institute for Water Research

Introduction Traditionally, cleanup strategies have focused on removal or capping of contaminated sediments in order to reduce the sediment concentrations within the biologically active zone, even though the risk for exposure is more related to porewater concentrations than to total sediment concentrations. Recently, activated carbon (AC) and other active materials have been shown to reduce the bioavailability of various contaminants in aquatic sediment, measured as reduced porewater concentrations and reduced flux from sediment to water. The use of AC may reduce the thickness of the capping layer to a few centimeters (thin-layer capping), thus also potentially reducing remedial action costs. However, the use of AC may not meet standard sediment cleanup goals as AC does not destroy contaminants, it sequesters them. This paper presents three examples of Norwegian remedial action plans where proposed sediment cleanup levels have been based on reducing bioavailability rather than sediment concentrations. Materials and methods For all three sites, the proposed cleanup levels are based on bioavailability (porewater concentrations) and ecological risk reduction rather than total sediment concentrations. In the Mosjøen site, the remedial action was completed in 2017; action is pending at the other two sites. The approach for assessing risk, establishing site-specific cleanup levels and assessing remedial technology feasibility is presented. Results and discussion Tier 1 sediment cleanup levels established in Norway are based on screening levels ranging from natural background to severe impairment. Cleanup levels are usually set to level 2. Higher cleanup levels can be accepted if Tier 2 and 3 studies are performed; Tier 3 cleanup levels are based on bioavailability and site-specific conditions. In the Mosjøen site, Norwegian authorities have accepted a Tier 3 sediment cleanup level that is based on site-specific partitioning studies and is protective of porewater and surface water quality. However, for the two other sites Norwegian authorities have not yet accepted proposed similar approaches, which focus on risk reduction and the use of thin AC capping as a thick isolation cap alternative. Conclusions Potential ecological impacts associated with different remedial technologies must be taken into consideration when proposing cleanup strategies focused on risk reduction.

Laboratory and Field-Based Assessment of the Effects of Sediment Cover Materials on Zinc Flux, Bioavailability, and Toxicity

G. Burton, University of Michigan / School for Environment and Sustainability; K. Thiamkeelakul, University of Michigan; E.C. Cervi, University of Michigan / SEAS; M. Hudson, EA Engineering, Science, and Technology, Inc., PBC / Water and Natural Resources; S. Nedrich, A. Rentschler, University of Michigan; S.S. Brown, Dow / Environmental Remediation & Restoration

A former mining site in the southern United States has been the subject of extensive remediation and restoration for the past few years, with significant focus on disconnecting mine spoils from groundwater and managing the quantity and quality of runoff. An investigation was conducted to compare the efficacy of selected cover materials for decreasing Zn dissolution during periods when the hypolimnion is anoxic and acidic (pH=5.5). Cover materials were selected based on laboratory batch testing and included gravel, AquaBlok, limestone, and limestone + bonechar, gravel + limestone, and gravel + bentonite clay + limestone. Field studies employed Limnocorrals (LC) to isolate the water columns above various cover treatments. Simultaneous in-situ and ex-situ toxicity tests were conducted using *Daphnia magna*, *Hyalella azteca*, and *Chironomus dilutus*. Test organisms were protected from temperature shock by pre-acclimating over 24 h and then deploying the test chambers in a Toxicity Assessment Container System (TACS). Test organisms were exposed to surficial sediments and overlying water in the reference (no cover) LC and in LCs containing surficial sediments plus cover materials. Ex-situ testing was conducted in waters and/or sediment cores collected from adjacent each LC. These exposures were conducted at corresponding in-situ temperatures (15 to 19 °C). Laboratory tests involved a series of acute to short-term chronic toxicity tests using site waters and sediment cores. Results from in-situ testing demonstrated the usefulness of the TACS and provided similar results to the ex-situ testing. Overall, there were no differences in biological responses/endpoints between treatments involving sediment cover materials, and this was true in both the field and laboratory tests. This was likely due to the fact that dissolved Zn in the surface water were below-threshold levels. All cover materials successfully reduced Zn release from the sediment, although some may be less effective under certain hydrologic conditions. While gravel + limestone stopped Zn dissolution, the addition of bentonite clay created an additional impermeable barrier. Gravel + clay + limestone were the optimal cover for controlling pH and restricting Zn dissolution/release. This field and lab based weight-of-evidence study provided for more effective decision-making, with reduced uncertainty, than standard laboratory and chemistry-only approaches.

Adverse biological effects of activated carbon amendment are dependent on particle size and the test organism

R.A. Rämö, Stockholm University / Dept of Ecology, Environment and Plant Sciences (D; J.M. Honkanen, Stockholm University / Dept of Ecology, Environment and Plant Sciences; J. Gunnarsson, Stockholm University / Department of Ecology, Envionment and Plant Sciences (DEEP)

Thin-layer capping with activated carbon (AC) is an *in situ* method for remediation of contaminated sediments. Though efficient in binding hydrophobic organic contaminants and reducing bioavailability, studies have reported adverse effects on benthic organisms, such as weight loss, reduced feeding rates, and mortality. These effects have been associated with dose and particle size of AC, with finer particles and higher doses causing more severe effects. The aim of this study was to compare adverse effects of powdered AC (PAC) and granular AC (GAC) on two deposit feeding marine benthic invertebrates: the bivalve *Limecola balthica* and the polychaete *Marenzelleria spp*. Five different particle sizes, ranging from 15 μm to 1700 μm, were tested: three PACs and two GACs. Both organisms are capable of ingesting PAC, but not GAC. Organisms and sediment were collected from a non-polluted site in the Baltic Sea. Thin layer caps (ca 2 mm) of AC were applied at a relatively low dose (600 g?m^{-2}), and after 3 months, animals were fed a pulse of ^{14}C-labeled diatom plankton, then gut purged, weighed for dry weight, and measured for ^{14}C uptake and lipid content. A significant loss of weight and strongly reduced ^{14}C uptake occurred in the polychaetae *Marenzelleria spp*. in response to all three PACs. There were, however, no increase in mortality or decrease in lipid content. GAC had a positive effect on ^{14}C uptake by the polychaete when GAC treatments were pooled and compared statistically to control. AC was not observed to affect the bivalve *Limecola balthica*: neither PAC nor GAC treatments significantly affected survival, dry weight, ^{14}C uptake, or lipid content of the bivalve. Our results confirm previous studies on freshwater species, which have found that adverse effects are dependent on particle size of AC. Furthermore, we show that effects are species-dependent and connected to ingestion: the polychaete was strongly adversely affected by ingestible powdered AC, whereas non-ingestible granular AC had some positive effect. This study highlights the risks to benthic communities when using powdered AC for sediment remediation and the importance of selecting appropriate test organisms when evaluating biological effects on benthic organisms. Results from this study strengthen the hypothesis that adverse effects of AC on benthic organisms are caused by reduced feeding or reduced assimilation of food by the organism, rather than nutrient sorption to AC outside the organism.

The Indoor Environment: Emerging Contaminant Identification, Analysis and Quantification for Exposure Assessment (P)

TH024
Analyses of chlorinated paraffins and pesticides in the indoor environment for human exposure assessment
I. Van der Veen, S. Brandsma, VU University Amsterdam / Environment & Health; S.J. Harrad, The University of Birmingham; G. Poma, University of Antwerp, Toxicological Center / Toxicological Center; C. Christia, University of Antwerp; A. Covaci, University of Antwerp / Toxicological Center; C. de Wit, Stockholm University ACES; N. Wemken, National University of Ireland Galway / School of Physics & the Ryan Institute; M. Coggins, National University of Ireland Galway; M. Lamoree, VU University Amsterdam / Department Environment & Health; P.E. Leonards, VU University Amsterdam / Environment & Health
Daily, people spend a lot of time indoors, either at work in offices or at home. In the indoor environment they are exposed to a variety of compounds, released from furniture, carpets, electronic devices, insulation or construction materials by a combination of evaporation and abrasion. Within the SHINE (Target and non-target Screening of cHemicals in the Indoor enviroNment for human Exposure assessment) project, target analyses and non-target screening were performed on indoor dust and air samples for the presence and concentrations of emerging compounds of different compound classes, such as phosphate flame retardants (PFRs), new and legacy brominated flame retardants (BFRs), chlorinated paraffins (CPs), hexabromocyclododecanes (HBCDs), per- and polyfluoroalkyl substances (PFASs), novel plasticizers and pesticides. These results will be used in existing human exposure models to predict the internal human exposure for a set of emerging substances in EU populations. Here, the results for concentrations of 15 pesticides, and short-, medium- and long chain CPs in dust samples from daycare centers, offices and houses from Sweden, Ireland, Belgium and The Netherlands are presented. Results showed that pesticides as well as short, medium and long chain CPs were detected in indoor dust. The highest concentrations of pesticides were found for permethrin, which had also the highest detection rate. The highest concentrations of CPs were detected for MCCPs. Dust from houses of The Netherlands were less contaminated with pesticides and CPs than houses from Belgium, Ireland and Sweden.

TH025
An assessment of the exposure of the Irish population to selected brominated flame retardants via indoor air and dust
N. Wemken, National University of Ireland Galway / School of Physics & the Ryan Institute; D. Drage, University of Birmingham / School of Geography, Earth & Environmental Sciences; M.A. Abdallah, University of Birmingham / Division of Environmental Health and Risk Management College of Life and Environmental Sciences; S.J. Harrad, The University of Birmingham; M. Coggins, National University of Ireland Galway
Polybrominated diphenyl ethers (PBDEs), hexabromocycododecane (HBCDD)–POP-BFRs –and decabromodiphenyl ethane (DBDPE) were measured in air and dust samples from Irish indoor microenvironments (MEs). HBCDD and PBDEs were used as flame retardants in a variety of soft furnishings, building insulation foams, electronic and electrical goods. Human exposure to POP-BFRs have been shown to cause many adverse health effects and coupled with evidence of their bioaccumulation potential and persistence, has resulted in their ban or use restrictions under the Stockholm Convention. Legislative restrictions have created a market demand for replacement flame retardants, such as DBDPE. This study reports for the first time the estimated exposure of Irish adults and toddlers to POP-BFRs via dust ingestion and air inhalation from several MEs. Samples were collected from Irish homes, cars, offices and primary school classrooms (n=30 per ME) between 2016-2017. Air samples were collected using a sorbent (XAD-3) impregnated polyurethane foam disk, extracted via pressurised liquid extraction using an ASE-350. Dust samples were collected by vacuuming floor surfaces, extracted via a combination of vortexing and ultrasoncation and purified on SPE cartridges, concentrated and analysed via GC-EI/MS or LC-MS/MS. Dust samples collected from Irish offices and schools contained relatively low concentrations of BDE-209 (median: 3500 ng/g; median:8100 ng/g resp.), compared to levels in homes and cars (median: 13000 ng/g, median: 26000 ng/g resp.). Highest concentrations of DBDPE were observed in schools (median: 10000 ng/g). The highest BDE-209 air concentrations were detected in samples collected from schools (median: 410 pg/m^3), followed by homes, offices and cars (median: 410 pg/m^3; median: 240 pg/m^3; median: 200 pg/m^3 resp.). The highest concentration of DBDPE in air samples (7000 pg/m^3) was detected in homes. This study reports concentrations in indoor air and dust of DBDPE and to the authors' knowledge the first air concentration data for PBDEs, HBCDDs, and DBDPE in primary school class rooms. Concentrations of DBDPE in dust samples for all our studied MEs are substantially higher than those previously reported internationally.Our data suggests the widespread use in Ireland of BDE-209 and its replacement DBDPE. Estimates of exposure via air inhalation and dust ingestion for both Irish adults and toddlers to DBDPE and BDE-209 exceed reported exposure estimates for the UK population.

TH026
Evaluating the RAIDAR-ICE model with monitoring and biomonitoring data
J.A. Arnot, ARC Arnot Research & Consulting / Adjunct Professor, Department of Physical & Environmental Science/Department of Pharmacology and Toxicology; L. Li, University of Toronto, Scarborough / Department of Environmental Sciences; K. De Brouwere, VITO NV / Health; L. Geerts, VITO NV; M. Lamoree, VU University, Department Environment & Health / Department Environment & Health
Humans are exposed to a wide variety of chemicals that originate in "near-field" environments (i.e., indoors) as a part of building materials, consumer goods and articles, and products used daily, e.g., household products, personal care products. Measured data are emerging through various monitoring and biomonitoring projects and programs. For example, the Cefic-LRI SHINE project is conducting targeted and non-targeted analyses of dust and air samples in indoor environments coupled with a literature review for biomonitoring data for the target chemicals (e.g., flame retardants, pesticides, plasticizers). Mechanistic, mass-balance, multi-media models serve as powerful tools to understand important exposure pathways and to predict exposures in the absence of measured data for human health assessment. Such models that link external exposures with internal exposures can also be used to integrate monitoring data (air, dust, surface concentrations) with biomonitoring data (blood, urine). There is a need to test (evaluate) exposure models to foster confidence in their application in regulatory programs in both data rich and data poor contexts. The Risk Assessment IDentification And Ranking – Indoor and Consumer Exposure (RAIDAR-ICE) model combines and indoor fate model with a toxicokinetic model to simulate chemical exposures from direct (e.g., personal care products) and indirect (e.g., vaporization of chemicals from building materials) sources of chemicals. It simulates human exposure from the near-field environment through inhalation of indoor air, dermal absorption, non-dietary object-hand-mouth contact. In this study we evaluate the RAIDAR-ICE model with existing and emerging monitoring and biomonitoring datasets for a range of chemicals, including new data obtained in the SHINE project. The case study chemicals comprise a broad range of use categories, partitioning properties, and biotransformation half-lives.

TH027
Li-BIM, an agent-based model to quantify human exposure variability in residential indoors
A. Micolier, University of Bordeaux; F. Taillandier, University of Bordeaux / I2M GCE; G. Sonnemann, University of Bordeaux / The Life Cycle Group CyVi; O. Jolliet, University of Michigan / Department of Environmental Health Sciences, School of Public Health
New building design and renovation standards tend to increase airtightness and use of newer materials to meet current environmental challenges. This leads to confined spaces in which building chemicals that have been released in the indoor air of the dwelling accumulate. Their residence time is highly affected by physical removal from occupants activities such as vacuum cleaning, windows opening. Occupants are exposed to indoor chemicals through near-field exposure pathways that affect significantly the indoor fate of chemicals. Therefore, human exposure and chemical fate concerns should be addressed together with the question the occupants as a contributor for and a receiver of indoor pollution. This approach implies a substantial focus on the heterogeneity in human profiles and activities which are key drivers for quantifying human exposure in indoor environments. Statistical analysis from biomonitoring data or field surveys can provide valuable information to account for exposure variability. However, the lack of data for the vast majority of chemicals or a wide range of households' archetypes turns out to be a stumbling block for achieving accurate exposure prediction. To faces these limitations, Artificial Intelligence techniques are promising in describing

dynamics mainly driven by human behaviors and among them, the agent-based approach is particularly well suited to model human cognition. Therefore, we propose an agent-based modeling of the building-occupants' interaction to assess the impact of the occupants' behavior on the chemicals fate as well as the occupants' exposure to the resulting indoor chemicals. The model is structured around an agent-based model, Li-BIM (Live in BIM), simulating the occupants' behaviour in residential dwellings. A twofold scale has been set up at the household and the individual level to characterize the occupants with a set of attributes likely to influence their activity pattern and physiological parameters. Each of the resulting 270 profiles and their indoor exposure is simulated during a whole year in a low-energy dwelling. At the time of the conference, K-mean clustering algorithm will be applied to identify several households' archetypes representative of the exposure variability. This study will offer a better understanding of exposure patterns and paves the way to support the design of healthier building indoors with targeted guidance to specific households' archetypes.

TH028

Higher levels of halogenated flame retardants on handheld than non-handheld electronic devices

C. Yang, University of Toronto / Department of Earth Sciences; S.R. Jilkova, Research Centre for Toxic Compounds in the Environment, Faculty of Science, Masaryk University / Research Centre for Toxic Compounds in the Environment (RECETOX); L. Melymuk, Masaryk University, Faculty of Science, RECETOX / Research Centre for Toxic Compounds in the Environment (RECETOX); S.A. Harris, Cancer Care Ontario & University of Toronto / Population Health and Prevention & Occupational Cancer Research Centre & Dalla Lana School of Public Health; L. Jantunen, Environment and Climate Change Canada / Centre for Atmospheric Research Experiments & Department of Earth Sciences; M.L. Diamond, University of Toronto / Department of Earth Sciences

Flame retardants (FRs), particularly halogenated flame retardants (HFRs) have been widely added to electronic products and are consistently detected in indoor environments around the world. FRs move from products to dust, air and also to humans, and many have evidence of toxicity. It is thus important to better understand the factors controlling FR emissions from consumer products, FR distribution in the indoor environment, and the resulting human exposure pathways. Here, HFRs were measured in floor dust, air and surface wipes of electronic devices, and wipes of participants hands in 51 Canadian homes. Target compounds were 14 polybrominated diphenyl ethers (PBDEs) and 10 novel halogenated flame retardants (NFRs). Ancillary data on house characteristics, participant lifestyle and electronic products were also collected. Our goals were to: 1) evaluate the relationship between HFR levels in the various indoor matrices; 2) identify differences in distributions and patterns of legacy (e.g., PBDEs) vs. their replacement NFRs; 3) evaluate associations between measured indoor levels with information on housing characteristics and consumer product use; and 4) to assess exposure routes of HFRs to humans. Hand-held electronics (e.g., tablets and cell phones) had higher concentrations of a wide range of HFRs as compared to non-hand-held devices and none had a distinct profile, suggesting that their surfaces are behaving both as a source of FRs and a sink for HFRs from other indoor sources. DBDPE, followed by BDE-209 were exceptions with the highest concentrations in TV wipes, which is consistent with more stringent flammability standards for these devices. The number of TVs in the household correlated with the mass fraction of DBDPE in dust; lower levels were found in homes with no TV, indicating the impact of TV flammability standards. HFR concentrations on hands were correlated with dust mass fractions, but less so with air concentrations. Several HFRs wiped from hands were correlated with those wiped from laptop surfaces. Hand and dust samples were dominated by BDE47, 99 and 209, and DBDPE whereas air concentrations were dominated by BDE47 and 99, TBP-AE, PBBz, PBT and EH-TBB. Air mixing was related to lower levels of some HFRs whereas higher levels were measured in separate (poorly mixed) zones. These results suggest that handheld devices could be a pathway for exposure and also indicate the impact of higher TV flammability standards on household HFR levels.

TH029

Occurrence of 18 plasticizers and their alternatives in indoor dust from France: levels and preliminary assessment of children exposure.

A. Cortéjade, CNRS / Intitute of Analytical Sciences; F. Lafay, E. Vulliet, CNRS / Institut of Analytical Sciences; C. Baduel, CNRS IGE UMR 5001, Univ. Grenoble / The Institute for Geosciences and Environmental research

Indoor dust is an important sink of semi-volatile organic compounds (SVOCs). Plasticizers, a group of ubiquitous SVOCs, are present in many consumer products, including building materials, household appliances, food packaging, toys, furniture and personal care products. Some of the classical plasticizers have been banned in Europe due to their adverse effects on human health leading to the introduction of alternatives on the market. Human exposure to these compounds is of concern, especially during the critical period of development (early ages). As spending a considerable time indoor, children are often subject to a high risk of chemical exposure, through indoor dust ingestion, mouthing of toys or other consumer products as well as indoor air inhalation. In this context, a selective, sensitive and multi-residue method was developed to analyze 18 plasticizers, including bisphenols, banned phthalates and their new alternatives. Target chemicals in indoor dust samples were extracted using a solid–liquid extraction method and then purified by a solid-phase clean up step. The extracts were then analyzed using liquid and gas chromatography coupled to mass spectrometry (LC-MS/MS and GC-MS). The developed methodology was fully validated and good performances were obtained in terms of sensitivity, precision, recovery (60-100%), and matrix effect (

TH030

Thermal desorption coupled to GC/MSMS for the quntification of organic pollutants in indoor air and dust

M. MILLET, University of Strasbourg (UdS) / Chemistry; A. Sonnette, University of Strasbourg CNRS; L. Alleman, P. Coddeville, IMT Lille; O. Delhomme, University of Lorraine

An analytical method coupling thermal desorption and GC/MSMS was developed for the simultaneous quantification of multi-class organic pollutants including pesticides, phtalates, phenols, HAPs and PCBs in indoor air and dust. Indoor ais samples were collected by using Tenax passive samplers on a 15 days basis and indoor dust was sampled by aspiration on a new sampling head aquipped with a SiC foam for the collection of dust and potential release of molecules from dust to air during aspiration. These foam were extracted by Accelarated Sovent extraction by using acetonitrile at 150°C/1500psi and solvent extract was evaporated to & mL into a fume hood. 100 μL of the dust extract was then deposited on a Tenax tube and internal standard and 10 μL MtBSTFA was added as a derivatisation agent for the GC analysis of some pasticides and phenols. Tube was than extracted by thermal desorption and molecules were quantified by GC-MSMS. Passive sampling tubes were introduce onto an empty thermal desorption tube and internal standards and MtBSTFA were added. They were also desorbed by thermal desorption and quantified by GC/MSMS. Application of thermal desorption to indoor dust extracts permits to decrease strongly sensistivity to a factor of about 50 in comparson to liquid injection and the matrix effect is also reduced. With this method, it is possible, by coupling derivatisation with thermal desorption and GC/MSMS, to quantify many different compounds in one run with good sensistivity and specificity. Detection limits about 0.1 ng were achieved for many compounds. Details of this analytical method and its application to real samples were presented.

Potential for toxicity and depuration of a dairy wastewater in a basin with different soil uses

D.C. Silva, Universidade Federal do Sul e Sudeste do Pará / Instituto de Estudos do Xingu; L. Queiroz, Universidade de Sao Paulo / Departamento de Biotecnologia; R. Marassi, University of São Paulo USP / Departamento de Biotecnologia; C. Araujo, Consejo Superior de Investigaciones Científicas / Department Ecology and Coastal Management; M.B. Neto, University of São Paulo / Departamento de Ciencias Básicas e Ambientais; G. Silva, Universidade Federal Fluminense / Escola de Engenharia Industrial e Metalurgica; S.C. Silva, University of Sao Paulo - USP / Department of Ecology; L. Gomes, University of São Paulo USP / Departamento de Biotecnologia; T. Bazzan, Universidade Estadual Paulista UNESP / Faculdade de Engenharia de Guaratinguetá; F. Silva, University of São Paulo USP / Departamento de Biotecnologia; M. Pompêo, University of São Paulo / Departamento de Ecologia e Evolução; T. Paiva, University of Sao Paulo - USP / Biotecnology

Knowing the environmental risk that the presence of pollutants causes to aquatic organisms can provide information to prevent it. In this work, the acute toxicity and the effect of the depuration of a dairy wastewater in three points of the Pitingui river (Roseira-SP, Brazil), were studied in order to understand the relation between water quality, the potential of depuration of dairy wastewater and its toxicity. The dairy wastewater was collected in a cooperative in Rio de Janeiro (Brazil). The river water samples were collected during the months of March (rainy season) and June (dry season) in three points: P_1 (near to the source), P_2 (close to a slightly urbanized zone with sanitary effluent discharge) and P_3 (close to a rural area with monocultures). The potential toxic of the dairy wastewater was evaluated by acute assays with the fish *Danio rerio,* that were exposed for 96 h (n=2) to different concentrations: 1, 5, 10, 40 and 70% (effluent diluted with river water samples, P_1, P_2 and P_3). The depuration tests were evaluated by the respirometric method using the BOD EVO sensor system (VELP Scientifica, Italy). Dairy wastewater samples were diluted to 5 and 10% with river water samples (P_1, P_2 and P_3). During assays, the system was maintained with 15

measurement points (n=2) by 168 h. The effluent presented high concentration of Soluble Chemical Oxygen Demand, Total Chemical Oxygen Demand and Total Biochemical Oxygen Demand with 1,544 ± 38 mg·L^{-1}, 5,209 ± 113 mg·L^{-1} and 2,540 ± 297 mg·L^{-1}, respectively, and high nutrient concentration with 100 ± 6 mg·L^{-1} of Total Kjeldahl Nitrogen and 33 ± 3 mg·L^{-1} of Total Phosphorus. Acute toxicity was observed only in the samples taken during the dry period: LC50 of 36.36 ± 4.33% and 24.92 ± 2.42% for P_1 and P_2, respectively. The depuration was higher for samples from the dry period than from the rainy period, where the depuration curves for the 10% of dilution presented a significant difference among river water samples. In this case, P_3 and P_2 depuration potentials were higher than to P_1. Thus, dairy wastewater showed high impact manly in the dry period, that P_2 has higher toxicity potential and depuration potential at short time assay, that is, even with higher clearance potential, the remaining concentration in P2 was toxic to fish. These results were obtained probably due to the lower flow of the river, additionally to organic load discharge for P_2 of 30 mg SCOD L^{-1}, which was not observed for P_1 and P_2.

TH033

Impact of a wastewater treatment plant upgrade on amphipods and other macroinvertebrates: individual and community responses.

K. Peschke, Tübingen University / Animal Physiological Ecology; H. Köhler, University of Tuebingen / Animal Physiological Ecology; K. Wurm, GÖL Water Ecology Laboratory Starzach; R. Triebskorn, University of Tuebingen / Animal Physiological Ecology

Effluents from wastewater treatment plants (WWTPs) are known as major point sources for the release of contaminants into aquatic environments. Particularly municipal WWTPs equipped with secondary and tertiary treatment steps do not or only partially remove micropollutants which can cause short- or long-term adverse effects in aquatic organisms even at low concentration levels. One possibility to reduce the input of micropollutants into the water cycle is the upgrading of WWTPs with an additional purification stage using, e.g., ozonation or powdered activated carbon. The current work is integrated into the BMBF project "SchussenAktiv*plus*", an ecotoxicological research project conducted at two tributaries of Lake Constance, the rivers Schussen and Argen, in Southern Germany. At the Schussen, a powdered activated carbon stage has been established at the WWTP Langwiese, Ravensburg, in winter 2013. Our part of the project focuses on assessing the overall health status of gammarids and the integrity of the macrozoobenthic community in the rivers Schussen and, in parallel, at the river Argen. Investigations upstream and downstream of this WWTP as well as prior and subsequent to the installation of the WWTP upgrade provides information of the impact of the effluent on the test organisms as well as of the efficiency of the new carbon purification step at this WWTP with respect to the health of aquatic wildlife. Our investigations with gammarids showed that the sex ratio and the fecundity had been affected by the effluent of the WWTP Langwiese prior to the installation of an additional treatment step. The WWTP effluent negatively influenced also the macrozoobenthos community with respect to the abundance of all macrozoobenthic taxa and, particularly, the so-called “sensitive” taxa. Subsequent to the upgrade, gammarids collected at the downstream site did no longer differ from gammarids collected upstream of the WWTP with respect to the investigated health parameters. Furthermore, the total numbers of macrozoobenthic taxa and sensitive taxa were found to be increased at the downstream site after the upgrade of the WWTP. On the basis of our results we conclude that additional wastewater treatment on the basis of activated charcoal is highly efficient to reduce toxicity of the WWTP effluent, and thus, is an efficient tool to improve invertebrate health and community integrity, and to sustainably protect aquatic ecosystems.

TH034

Multi-biomarker responses in a common freshwater mussel (Anodonta anatina) after laboratory exposure to industrial wastewater

G.M. Ekelund Ugge, Lund University / Department of Biology; A. Jonsson, University of Skövde / Department of Bioscience; O. Berglund, Lund University / Dept of Biology

The freshwater mussel *Anodonta anatina* is abundant in most Swedish freshwater ecosystem types and is distributed over most of Europe. As a stationary filter feeder, it is a promising candidate for exposure studies both in the laboratory and in the field. In the present study, we chose *A. anatina* as a model for studying molecular stress biomarkers of aquatic pollution. There is a lacking understanding of natural variation in gene expression and enzymatic activities commonly used as biomarkers in other species. To address variation and stress responses in an environmentally relevant exposure scenario, a laboratory experiment was performed. Mussels were collected local-ly in southern Sweden on a location free from point source pollution, and acclimatized to laboratory conditions for four weeks. A 96 h experiment was performed, in which mussels were exposed to wastewater from a Swedish chemical industry (n=16) or to a control treatment (n=16). Digestive glands and gills were extracted, and gene expression and enzymatic activity will be assessed for a panel of stress biomarkers. Preliminary data will address (i) natural variation in gene expression/ enzyme activity, and (ii) biomarker responses to industrial pollution. Results will subsequently be used to design of a follow-up field experiment to test and predict marker responses *in situ*. Ultimately, the aim is to identify biomarkers that can provide early warnings of exposure to pollution as well as be used to predict adverse effects on higher biological levels.

TH035

Developing biomarkers of sewage effluent exposure in the freshwater amphipod Gammarus fossarum

D.R. Caputo, University of Portsmouth / Biological Sciences; S. Robson, University of Portsmouth / School of Pharmacy & Biomedical Science; N. Munz, Swiss Federal Institute of Aquatic Science and Technology; I. Werner, Swiss Centre for Applied Ecotoxicology / Department of Anatomy Physiology and Cell Biology; A. Ford, University of Portsmouth / Biological Sciences

Chemicals coming from sewage effluents, can be detected in the aquatic environment in very low concentrations. Attempts to monitor dysfunctions in invertebrates using orthologous genes in fish have produced inconsistent results. Gammarids have been shown as very sensitive to pollution. Particularly in Swiss rivers they have been shown to bioaccumulate a wide range of chemicals, both polar and non-polar. However, to date no reliable molecular markers are available in these species. The aim of this study is to provide a set of new transcriptomic markers in *Gammarus fossarum*. After in-field validations, the new biomarkers could be used to evaluate the state of aquatic ecological niches and the efficiency of wastewater treatment plants (WWTPs). Amphipods were sampled from a Swiss freshwater stream in September 2017, using a standard kick-net method. Sampling was performed 50 m upstream and 50 m downstream of the WWTP. For the transcriptomics analysis, 5 distinct pools were used, each consisting of 5 amphipods, as biological replicates. Sampling was conducted for both males and females, to get a total of 20 samples of total RNA. The RNA samples were sequenced by HiSeq 2500 platform. A subsample of amphipods was fixed to record population markers and potential intersexuality phenotypes. A differential gene expression analysis was conducted to identify differentially expressed genes between up- and downstream populations. A chemical analysis of some of the most common pesticides and pharmaceuticals found in river waters, for both surface water and amphipods was also performed using online SPE LC-HRMS. Chemical analysis revealed higher concentrations in water and amphipod samples at downstream site compared to upstream, for most of the chemicals. The sequencing analysis showed a total of 87 and 56 differentially expressed genes between up and downstream populations for males and females, respectively. Despite male and female gene lists showing little overlap, a gene ontology analysis showed an enrichment in stress response genes in both lists. The presence of consistent molecular changes between up- and downstream populations seems evident, suggesting sub-lethal effects on the amphipods, triggered by the complex chemical mixture found in the water stream. None of the molecular changes observed downstream were evident in the population data. Therefore, the relationship between the transcriptomics data and phenotypic data needs to be further elucidated.

TH036

Effects of a Swiss sewage effluent on the population structure of the freshwater amphipod Gammarus fossarum

D.R. Caputo, University of Portsmouth / Biological Sciences; S. Robson, University of Portsmouth / School of Pharmacy & Biomedical Science; N. Munz, Swiss Federal Institute of Aquatic Science and Technology; A. Love, University of Portsmouth / School of Biological Sciences; A. Ford, University of Portsmouth / Biological Sciences

The prevalence of chemicals in lotic habitats is a concern, with the main source of these contaminants being effluent from waste water treatment plants (WWTPs). The impact of many chemicals on amphipods has already been identified. However, considering their long and extensive use in ecotoxicology, it is surprising to find that the literature on this aspect appears to be contentious. The reason for this could be attributed to the rate of variability in the biology and ecology of the gammarids species. For example, the differences in environmental conditions among different countries and phenotypic variability in responses to natural and anthropogenic perturbations. The aim of this study is to investigate the changes in population parameters between amphipods sampled up- and downstream of an industrial WWTP. These data coupled with a chemical knowledge of the stream water will give a deeper understanding on the effects on gammarids in response to exposure to specific chemicals. Amphipods were sampled from a Swiss stream in Sep 2017 and 2018, using a standard kick-net method. Sampling was performed 50 m downstream and 50 m upstream of the WWTP. Sampling was conducted for both males and females, to get a total of 609 amphipods in 2017 and 196 in 2018. A chemical analysis of 58 compounds including common pesticides and pharmaceuticals found in river waters, for both surface water and amphipods was also performed in Sep 2017 using SPE-LC-HRMS. Size, sex ratio and number of eggs of the amphipods of both samplings were recorded. No significant differences in any population parameters were found between up- and downstream populations despite previous transcriptomics and metabolomics studies suggesting impacts on the cellular biology of downstream populations. Chemical analyses revealed higher concentrations in water and amphipod samples at downstream site, for most of the chemicals. Higher bioaccumulation factors in gammarids sampled at downstream site for 6 substances were also found. Considering the differences in chemical concentrations between up- and downstream sites, these data show that the effects of a chronic exposure could be not visible simply looking at macroscopic features. In fact, none of the differences observed in a previous transcriptomics analysis were evident in the population data. In addition, environmental conditions in different sampling periods could hide changes in population parameters of amphipods coming from different samplings.

TH037

Cytotoxicity on brown mussels exposed to cocaine environmental concentrations

M. Fontes, UNIVERSIDADE ESTADUAL PAULISTA - UNESP; L. Maranho, Universidade Santa Cecilia / Departamento de Ciências do Mar; B. Barbosa Moreno, Federal University of Sao Paulo; B. de Campos, UNIVERSIDADE ESTADUAL PAULISTA - UNESP; C. Nobre, São Paulo State University - UNESP Biosciences institute - São Vicente, SP - Brazil; C.D. Seabra Pereira, São Paulo Federal University / Marine Science

Illicit drugs consumption increased worldwide which produce not only social and health problems but might also generate environmental impacts. Such compounds have been identified as contaminants of emerging concern continuously released into the environment via Wastewater Treatment Plants (WTPs). Previous studies showed that cocaine induced negative effects on non-target freshwater organisms. However, there is a lack of knowledge regarding the cocaine concentrations in marine environment as well as toxicity . This study aimed to investigate the lysosomal membrane stability (LMS) on haemolymph of brown mussels *Perna perna*through Neutral Red Retention Time (NRRT) assay to identify cocaine cytotoxicity. Mussels were exposed up to 168h to different concentrations of cocaine (0,2 μg/L; 2 μg/L; 10 μg/L) based on those found in a tropical coastal zone (Santos Bay, Brazil). Our results reported a decreased of lysossomal membrane stability in mussels exposed to all concentrations tested. These data indicate that cocaine constitute a potential hazard for marine biota and suggest the regularly monitoring of illicit drugs in coastal waters. Further ecotoxicological studies are recommended to better understand the mechanism of action of this compound on marine biota.

TH038

Efficiency of three different wastewater treatment techniques to reduce pesticide loads in agricultural waters: an ecotoxicological evaluation with Gammarus fossarum

F. Seitz, Inst. for Environmental Sciences / Institute for Environmental Sciences; R. Rosenfeldt, University of Koblenz-Landau, iES Landau, Institute for Environmental Sciences / Institute for Environmental Sciences; J.P. Zubrod, G. Lohff, University of Koblenz-Landau / Institute for Environmental Sciences; B. Altmayer, W. Dachtler, M. Twertek, State Education and Research Center of Viticulture, Horticulture and Rural Development / Institute of Plant Protection; R. Schulz, University of Koblenz-Landau / Institute for Environmental Sciences

Plant protection products (PPPs) that are applied to safeguard yields can unintentionally enter the aquatic environment, for instance as wastewater resulting from the cleaning of agricultural machinery. This may contradict main targets of the EU Water Framework Directive, that aim to increase the overall surface water quality. Different wastewater treatment techniques exist that can be applied at such point sources to reduce PPP concentrations and thus their impact on aquatic ecosystems and the services they provide. As different treatment procedures are available, the selection of an environmental friendly, and efficient method is of high interest. The latter aspect is part of the present work, which is embedded within the EU Interreg project PHOTOPUR. In this context, we evaluated three methods: i) photocatalysis, ii) ozonation, and iii) the application of activated carbon, for their efficiency to reduce the ecotoxicological potential of five model PPPs (myclobutanil, glyphosate, pyrimethanil, folpet and boscalid) by involving a key species in the ecosystem functioning of heterotroph small water systems. For this purpose, the feeding activity of the amphipod shredder *Gammarus fossarum* on preconditioned black alder leaves was investigated during 7d exposures to increasing concentrations of the model PPPs that were previously treated by i), ii), or iii). Using the feeding activity of the gammarids as sublethal endpoint, dose-response relationships for each PPP-treatment method combination was evaluated. Preliminary results indicate, that while all methods tested have a positive effect on the water quality by decreasing the toxicity of the PPPs for the amphipods, efficiency of the methods differed. For instance, for pyrimethanil the highest mitigation potential was demonstrated using activated carbon. The currently ongoing biotests with *Gammarus*, with the remaining (un-)treated PPPs and their mixtures, will provide a comprehensive picture of the methods' efficiencies, which will be additionally supplemented with analytical PPP quantifications.

TH039

Ecotoxicological assessment of freely bioavailable, polar pollutants in Swedish streams

T. Seiler, J. Kunze, RWTH Aachen University / Ecosystem Analysis; L. Ahrens, Swedish University of Agricultural Sciences SLU / Dept. of Aquatic Sciences and Assessment; P. Gago-Ferrero, Catalan Institute for Water Research ICRA; K. Smith, R. Ottermanns, H. Hollert, RWTH Aachen University / Institute for Environmental Research

The impacts of WWTP effluents are widely studied, whereas possible effects caused by effluents emitted from onsite sewage treatment facilities (OSSFs) are mostly neglected up to now. Since about 20 % of Swedish households are connected to OSSFs, we conducted a study with the aim to assess the impact of OSSF effluents on water quality, in comparison to small and large-scale WWTPs. POCIS with Oasis® HLB were deployed at seven sampling sites within the catchment area of the Fyris River, its tributaries, and Lake Ekoln near Uppsala, Sweden. \n Three rural sampling sites were exclusively impacted by OSSFs in tributaries of the Fyris River, whereas the other sites were mainly impacted by WWTPs, and a mixture of other sources. Sampling was conducted in four different sampling campaigns between November 2014 and September 2015 covering four different seasons. Extracts from the samplers were investigated using target analysis for 74 MPs including pharmaceuticals, personal care products, pesticides, artificial sweeteners and perfluoroalkyl substances (PFASs). Cytotoxicity was assessed with the MTT assay, and dioxin-like activity with the micro-EROD activity assay. The lyticase assisted yeast estrogen screen assay (LYES) was used to detect estrogenicity. Eight selected samples were further tested with Danio rerio embryos and larvae for embryotoxicity (FET), for behavior change in a light-transition test, and for oxidative stress in a fluorescence assay. \n Cytotoxicity was only found at one OSSF site in June 2015. EROD-activity was detected in eight samples for different sampling campaigns, including Lake Ekoln estuary, the small-scale WWTP, one OSSF site and the large-scale WWTP. Estrogen activity occurred at the small-scale WWTP and at one OSSF site for different campaigns. No embryotoxicity could be detected in selected samples, but significant changes in behaviour of zebrafish larvae were observed for the small and the large WWTP, two OSSF sites, and the estuary for different campaigns. Finally, oxidative stress was detected for the small WWTP and one OSSF. \n Multivariate statistics revealed a strong difference between the large-scale WWTP and the other sampling sites, with distinct grouping of pharmaceuticals and PFASs. Furthermore, about 50 % of the variance in the substance patterns could be explained by the size of the treatment plant and the water flow rate. This study shows that the emissions of OSSFs can have an adverse effect on the nearby aquatic ecosystem.

TH040

The acute impact of entrainment passage through coastal marine cooling water systems on planktonic organisms

S. Davis, Cefas / Ecotoxicology; D. Sheahan, Cefas Lowestoft Laboratory / Ecotoxicology

Many global industries generate heat as part of their intrinsic processes, these include power generation, desalination, oil refineries, steelworks, and the manufacture of chemicals. To remove excess heat, they require industrial scale cooling systems. Water is the most commonly used coolant, often used in a once through system, whereby it is pumped from source into the industrial unit, used as a coolant and is consequently heated above ambient temperatures, before being transferred back to source, thus removing the surplus heat. Of the water-cooled systems, when available, seawater is advantageous over freshwater, due to its increased abundance relative to freshwater, and a general reduction in legislation governing thermal and chemical discharges, which are often present concerning freshwater sources (Pugh *et al*., 2005). Although these systems are protected by various screens, which stop larger organisms and detritus entering the system, small planktonic organisms will likely be entrained into the system. Entrained material typically includes permanent members of the plankton community (holoplanktonic organisms) such as copepods, and temporary members (meroplanktonic organisms) such as fish eggs and larvae. Except for a paper by Bamber and Seaby (2004) there are few peer reviewed studies examining the impacts of entrainment on locally abundant, ecologically and commercially important species, which may be vulnerable to entrainment. Thus, it is often assumed that there will be 100 % mortality of all entrained organisms. The Entrainment Mimic Unit (EMU) simulates, as realistically as is practically possible, the full range of physical and chemical conditions experienced by entrained organisms during passage through a generic once through cooling water system. It exposes test organisms to increases in pressure and temperature, mechanical damage and biocide application. Following passage through the EMU any mortality is determined 24 hours post simulation. Several temperate fish and invertebrate species were selected for EMU studies based upon their relative commercial and ecological importance. These included both holoplanktonic and meroplanktonic organisms, which are likely to be susceptible to entrainment. These studies showed differences in entrainment induced mortality according species, life stage and season.

TH041

Ecotoxicological impact of semi-open horticultural systems on irrigation water quality

M.E. Gomes Santos, University of Porto / DGAOT; R. Pereira, University of Porto / GreenUPorto and Faculty of Sciences, Universidade do Porto; S. Carvalho, University of Porto / DGAOT

World horticulture is facing major problems due to water scarcity, either by its low abundance or by the degradation of its quality. Inefficient irrigation methods

and excessive use of Plant Protection Products (PPPs) are amongst the main reasons causing this phenomenom. This must be overcome, not only because growers have to maintain their farms profitable in a long term, but also because of environmental issues. Irrigation efficiency is largely improved in closed soilless systems, where drainage is recirculated to further irrigate the same crop. Nevertheless, open (free drainage) and semi-open systems (reuse of drainage to irrigate secondary crops) are still very common and often they even predominate in many regions. This leads to drainage release into the environment, which causes pollution on soil and water bodies since they contain considerable amounts of nutrients and PPPs. Assessing the environmental impact of those systems on irrigation water quality is therefore imperative. Here we assessed the impact of semi-open systems on the quality of drainages collected from a fruit crop (strawberry) and an ornamental crop (rose), through ecotoxicological assays using the aquatic species *Daphnia magna* (cladocerans), *Vibrio fischeri* (marine bacteria) and *Raphidocelis subcapitata* (green algae). Samples were collected immediately after draining at the substrates and from the reservoirs of both growers. High toxicity of the drainages to *D. magna* (immobilisation test) was found for both strawberry (reservoir: $EC_{50\text{-}48h}$=11%; from the substrate: $EC_{50\text{-}48h}$=48%) and rose (from two reservoirs: $EC_{50\text{-}48h}$=18% and 21%; from the substrate: $EC_{50\text{-}48h}$=8%). The algae *R. subcapitata* was generally not affected on its growth, but inhibition was found for drainages from the substrate of rose (EC_{20}=63%). The bioluminescence of *V. fischeri* was stimulated by the drainages from both rose and strawberry cultivation systems. It is concluded that the drainages from soilless systems affect aquatic organisms, but in a variable extent. For a better environmental performance of soilless cultivation, it is stressed here the importance of preventing drainages to be released into the environment.
Keywords: drainage, ecotoxicity, soilless horticulture.

TH042
The ready biodegradability of woven and non-woven wet wipes in aerated and sealed bottle test systems
R. Commander, E. Pratt, Scymaris Ltd / Environmental Fate
In recent years wet wipes have been used as a convenient method of cleaning and disinfecting for a variety of applications (baby wipes, make-up removal, household cleaning), this study looks at whether there is any difference between the biodegradation of woven and non-woven wipes and whether any difference in biodegradation is observed in aerated and sealed bottle ready biodegradation test systems. The OECD series of environmental fate tests have a number of different methods to determine ready biodegradation. Some of the differences are: Aerating test media vs sealed bottles; Biodegradation measurement: CO_2 evolution; oxygen consumption; dissolved organic carbon; Test substance concentration; Test media concentration; Test volume. The OECD 301B and OECD 310 were chosen as both use carbon measurements to determine biodegradation, but the OECD 301B is an aerated test system while the OECD 310 is a sealed test system. Both studies can be continued up to 60 days if 60% biodegradation was not reached within 28 days. Ready biodegradation tests (OECD 301B and OECD 310) were performed using the same batch of activated sludge from a sewage treatment plant treating predominantly domestic sewage to determine whether any difference in biodegradability was observed with an aerated system and closed bottle system and whether there is a difference between woven and non-woven wipes. The tests were performed on dry wipes without solvent to prevent any anti-microbial action from any residual solvent. Study Study type Test substance concentration (mg/L) TFS concentration (mg/L) Test volume (mL) Temperature (°C) OECD 301B Aerated 20 mg DOC/L 30 1 - 3 L 20 - 21 OECD 310 Sealed bottle 20 mg C/L 30 100 mL 20 - 21 We will present the full results of this ready biodegradation testing programme, as well as discussing the implications of the results.
Keywords: Wet wipes; ready biodegradation; waste water; personal care product

TH043
Determination of Heavy Metal Concentration in Treated and Untreated Wastewater from Two Treatment Plants in Maluti-a-Phofung Municipality
M. Moloi, University of the Free State / Zoology & Entomology
Wastewater, the grey and black water from the industry and households, is a complex mixture of heavy metals, organic and inorganic compounds which may be very detrimental to the aquatic systems if not treated adequately. The wastewater treatment plants therefore work to treat and remove these contaminants to create reusable water that can re-join the water cycle with minimal impact on the environment. Over the years, the status of the wastewater treatment plants in South Africa have deteriorated thereby compromising the quality of the receiving streams and their ecosystems. This study therefore focused on assessing the wastewater treatment works in the Maluti-a-Phofung area for heavy metal pollution of the treated effluent. The water was sampled from the Phuthaditjhaba WWTP and the Harrismith WWTP and analysed for heavy metals (Fe, Mg, Mn, Zn, Cu, Cr, Ni, Pb, Co, As, Cd) using Induced Coupled Plasma Mass Spectrometry (ICP-MS) with LGC Multi-element Standard as the quantifying standard. Results showed that there was no significant difference ($P > 0.005$) in the concentration of heavy metals in influents when compared with effluents for both water treatments plants, indicating the inability of both treatment plants to properly remove metal contaminants. Furthermore, there was no significant difference in the heavy metals concentrations in the final effluent from the Phuthaditjhaba WWTP when compared to the effluent from the Harrismith WWTP. This thus indicate that these treatment plants discharge an effluent with heavy metals concentrations that may lead to ecosystem harm and affect the quality of the receiving streams.

TH044
Long-term monitoring and trend analysis of cyclic volatile methylsiloxanes (cVMS) in aquatic environments impacted by wastewater effluent
J. Kim, The Dow Chemical Company / Toxicology and Environmental Research and Consulting; J.A. Durham, Dow Corning Corporation / Toxicology and Environmental Research Consulting; R.M. Seston, Hyla Environmental Consulting, LLC / Toxicology, Environmental Research & Consulting; C. Mund, T. Böhmer, Evonik Nutrition & Care GmbH; N. Meguriya, Shin-Etsu
Cyclic volatile methylsiloxanes (cVMS) are widely used in industrial, personal care, and household applications. Because wastewater represents the major post-use disposal route for cVMS, the Silicone Industry Associations in North America, Europe, and Japan initiated a global monitoring program on major cVMS species in surface sediment and aquatic biota: octamethylcyclotetrasiloxane (D4), decamethylcyclopentasiloxane (D5), and dodecamethylcyclohexasiloxane (D6). Aquatic environments that were selected as study areas for the monitoring program were impacted by municipal wastewater effluents and included Lake Pepin (USA), Lake Ontario (on the border between Canada and the USA), Oslofjord (Norway), and Tokyo Bay (Japan). The target objective of the monitoring program was to determine if cVMS concentrations were stable or changing, based on detecting with 80% power (β=0.20) a statistically significant (α=0.05) annual rate of change of ±6% per year (net change of -27% to 34%). Target matrices for each study area include surface sediments, a high trophic level piscivorous fish, and several low trophic level forage fish and benthic invertebrates near the base of the food chain of the predator. The first project period was from 2011 and 2016. Generally concentrations of cVMS in biota and sediment showed decreasing trends over the period, but the statistical power was relatively weak in many cases. Thus considering the yearly variations, concentrations of cVMS in biota and sediment have been stable or decreasing in most monitoring locations based on the statistical criteria aforementioned. This presentation will discuss more details of monitoring data and their trends over the project period by location and species.

TH045
Distribution of rare earth element concentrations in leachate originating from electronic waste disposal
M. Makombe, V.S. Somerset, CPUT / Chemistry
Rare Earth Elements (REEs) form critical elements required in technological accessories. Their presence in electronic waste gives leads to environmental pollution. Therefore, there is a constant necessity for accurate data and reliable fast analytical methods. This review discusses and compares the methods given for the determination of rare earth elements and heavy metals in electronic waste and other associated environments. Classical analytical methods such as mineral acid dissolution and alkaline fusion are commonly employed. Various instrumental techniques that have been used recently includes electrothermal vaporiser or laser ablation accessory connected to ICP-MS or ICP-OES, X-ray Fluorescence and electro-analytical techniques. These methods of analysis including their accuracy, limit of detection (LOD) and limit of quantification (LOQ) are compared and discussed. These methods of analysis including their accuracy, limit of detection (LOD) and limit of quantification (LOQ) are compared and discussed. This study further investigates the preparation, dissolution methods and instrumental techniques with a focus on rare earth elements in electronic waste and its disposal into the environment.

TH046
Metals and Radionuclides: assessment of molecular effects of combined exposures using HepG2 cells as biological model
A. Campos, University of Porto / GreenUPorto and Faculty of Sciences Universidade do Porto; R. Pereira, Faculdade de Ciências da Universidade do Porto / Biology; A.S. Vaz, University of Aveiro / Biology Department and CESAM; F. Carvalho, M. Malta, J. oliveira, Instituto Superior Técnico / C2TN; J. Lourenco, Department of Biology & CESAM - University of Aveiro / department of Biology & CESAM; S. Mendo, University of Aveiro / Department of Biology CESAM
The uranium mining legacy in Portugal (and in other parts of the world) had a significant impact in the environment and in human populations in the nearby areas. The residues produced are rich in metals and radionuclides and thus are a source of exposure to low levels of ionizing radiation. In addition, exposure to metals like zinc, manganese, iron, nickel etc, besides uranium also occur. In order to evaluate the genotoxic effects in human cells when exposed to a mixture of metals and low dose ionizing radiation, we exposed HEPG2 cells at different concentrations of a uranium mine effluent, for 96 hours. The time and concentrations of exposure were selected considering the concentration gradient of a uranium mine effluent discharge along a stream and water runoff from the mine ponds. Preliminary tests were performed to ensure that only sublethal damage was induced to the cells. Comet assay was employed to assess DNA damageand qPCR

was used to determine alterations in the gene expression of selected tumour suppressor genes and oncogenes. The comet assay results showed that effluent concentrations higher than 5% induce significant loss of DNA integrity and that DNA damage increased at higher concentrations. As for the gene expression analysis, results showed a significant under-expression of the tumour suppressors genes *TP53, ATM*and the fibroblastic growth factor *FGF2*and a significant overexpression of growth arrest and DNA-damage-inducible*GADD45A*gene. The data gathered demonstrates that the exposure to metals and radionuclides simultaneously promoted genotoxic effects in HEPG2 cells. As with other studies, our results reinforce the idea of a negative impact of a multi-stress environment such as uranium mines on the environment, more specifically on animals and humans living in the immediate vicinity. Keywords: Metals, radionuclides, DNA damage, gene expression alterations

TH047

Supporting water management strategies in mining using ecological risk assessment (MSc Thesis)

M.M. Malinen, - / Department of environmental and biological sciences; S. Nieminen, Geological Survey of Finland; M. Kolehmainen, University of Eastern Finland; J. Akkanen, University of Eastern Finland / Department of environmental and biological sciences; K. Väänänen, University of Eastern Finland / department of e

The aim of this research is to assess the usability of ecological risk assessment for improving water management strategies in gold mining. The case study of ecological risk assessment of Kittilä gold mine is carried out to discover the possible ecological impacts of the mine discharge waters on the receiving rivers as well as to possibly predict the future impacts on the rivers after the mine expansion is conducted and new permit regulation limits for water discharge are set. The data applied in this study includes both monitoring data from the Kittilä gold mine (Agnico Eagle Finland Oy) and data gained through sampling. The environmental sampling conducted for this study included water, benthic fauna and sediment samples. The samples were taken from Seurujoki River, upstream and downstream from the mining site, and Loukinen River, downstream from the mining site. The concentrations of elements in the waters of the studied rivers were compared to national and international guidelines and Predicted No Effect Concentrations (PNECs), which are derived using and the Species Sensitivity Distributions drawn according to data from US EPA Ecotox database. The results suggest that the slight decrease in benthos diversity in Seurujoki and Loukinen Rivers could be caused by the mine waste water effluent, the ecological state of them still remaining mostly good. The impacts on water and sediment quality are quite local. There was indication of most significant elements of the mine discharge being SO4, Sb and Ni considering potential ecological risk. Ecological risk assessment tools appear to be useful in supporting gold mine water management strategies. It helps in utilization of the monitoring data: i.e. allocating the load to the possible effects and operations to improve water treatment and management. However, implementing site-specific guideline concentrations for example by the use of SSD would require more toxicity data.

TH048

Lessons from a multi-biomarker study in rivers: insight into challenges for biomonitoring

L. Lafay, A. Bourgeault, EDF R&D / LNHE

In ecotoxicology, biomarkers are common tools that help to detect exposure or effect of substances on organisms. They are now used as part of regulatory monitoring on marine environment (Marine Strategy Framework Directive). In French marine ecosystems, for instance, the 2012-17-12 Decree on the definition of good ecological status of marine waters requires the measurement of 5 biomarkers on bivalves and/or fishes. On the other hand, in freshwater ecosystems, the Water Framework Directive (WFD) does not currently require biomarkers measurement, and only refers to them as a method that can be used to complement an environmental monitoring strategy. Questions remain about the interpretation of biomarker responses in freshwater ecosystems. This study aims to assess the spatiotemporal variability of biomarkers response when applied to freshwater streams. To achieve so, a set of 7 biomarkers was measured on European chub (*Squalius cephalus*) in September, 2016 during the environmental monitoring of the fish compartment in French rivers; fish were caught on streams where EDF (*Électricité de France*) electricity production sites are located. From molecular to individual scale, genotoxicity (comet assay, DNA adduct, micronucleus), neurotoxicity (AChE activity), and immunotoxicity (lysosomal integrity), as well as endocrine disruption (vitellogenin dosage), biotransformation (EROD activity) and development indices were accounted for. These biomarkers were selected in accordance with the European Technical Report on Aquatic Effect-Based Monitoring Tools (2014). This work provides insight into challenges for biomonitoring, and especially into the determination of reference values (or control values) and on the natural biological variation that can make the interpretation challenging. A focus is also made on the interpretation of the biomarker responses with an integrative index, which enables the processing of a set of biomarkers responses into one single score: the Integrated Biomarker Response (IBR). The pros and cons of two IBR versions will be weighed up to offer a critical review of this methodology when it comes to ecotoxicological assessment.

Complex responses of a biofilm to sewage outflow: a mesocosm approach

l. sabater, CSIC-IDAEA / Department of Environmental Chemistry; N. Montemurro, Water and Soil Quality Research Group Department of Environmental Chemistry IDAEA CSIC; A. Ginebreda, Institute of Environmental Assessment and Water Research IDAEA CSIC / Department of Environmental Chemistry; S. Perez, Water and Soil Quality Research Group Department of Environmental Chemistry IDAEA CSIC / IDAEA Environmental Chemistry; D. Barceló, Catalan Institute for Water Research ICRA - Department of Environmental Chemistry, IDAEA-CSIC / Department of Environmental Chemistry

Wastewater effluents represent the primary source of anthropogenic chemicals such as pharmaceuticals, personal care products, metals, and nutrients into the environment. Since they are not completely removed during the conventional wastewater treatment processes, they may pose a potential risk to the freshwater ecosystems. Whereas nutrients at certain concentrations may have a subsidy effect on biofilms, organic pollutants may have a stress effect. Thus, their combination can bring unexpected and contrasting effects in rivers. Of particular importance is to understand and assess how biofilms respond to chemical pollution and subsequently recover. Owing to the number of uncontrollable factors acting on rivers a way to evaluate the effect of wastewater effluent on natural systems is to study it under controlled and simplified conditions in a mesocosm scale experiment. We exposed twenty-four artificial streams to a range of WWTP effluent concentrations, from no effluent to pure effluent, during 34 days, followed by 22 days of recovery under no effluent conditions. Pollution load associated to the WWTP effluent was characterized analyzing physical-chemical parameters (pH, dissolved oxygen, and conductivity), nutrients, organic matter, heavy metals and personal care products and pharmaceuticals (i.e. ß-blockers, antibiotics, psychiatric drugs, anti-inflammatories…) as representatives of organic microcontaminants pollution in the water phase. The effects of chemicals on the biofilms were measured by means of structural (variations of biomass) and functional variables (such as the photosynthetic efficiency or the extracellular enzymatic activities). The overall observed response of biofilms to the wastewater gradient was fast and nonlinear in most of the analysed variables.

Acknowledgements - The research leading to these results has received funding from the European Communities 7th Framework Programme under Grant Agreement No. 603629-ENV-2013-6.2.1-Globaqua.

TH050

Tiered framework for environmental risk assessment of industrial wastewater effluent discharges

C. Di Paolo, Shell International / Ecosystem Analysis (ESA); A. Lindgren, Shell Technology Centre Amsterdam; M.G. Smit, Shell International

Industrial wastewater effluent discharges are undergoing increasing scrutiny and present challenges for environmental risk assessment due to complex and dynamic composition. Although tools and methods for assessing effluents and their potential hazardous properties have improved, the sampling and laboratory testing of effluent discharges is limited by logistical issues related to often remote and not easily accessible locations. In this project, a solution to this challenge was evaluated through the application of a tiered framework to quickly and effectively prioritise wastewater effluents for which further investigations are required. Discharges from a set of industrial sites with different production profiles as well as distinct wastewater treatment facilities were investigated. A set of screening methods was applied as the first tier in the assessment framework to provide information on the inherent hazardous properties of the effluent (persistence, bioaccumulation and toxicity). This toolbox consisted of: (i) the *in vitro* Microtox toxicity test, which measures toxicity in terms of changes in the bioluminescence of bacteria; (ii) a biomimetic solid phase microextraction coupled with gas chromatography (SPME-GC), to assess potentially bioaccumulative substances; (iii) target chemical analysis, to quantify a list of relevant compounds according to national and international (e.g. OSPAR) regulations; and (iv) Quantitative Structure Activity Modelling (QSAR), to estimate the toxicity of the identified components to aquatic organisms. In addition, the effects of aging on the toxicity and SPME-GC profiles was investigated through an experimental setup. Preliminary results indicate that the Microtox, SPME-GC and chemical analysis profiles vary considerably between the different industrial sites. Furthermore, after aging of samples, not always the reduction in the SPME-GC total area was correlated with a reduction in the toxic effects. Currently, wastewater effluents and respective sites are being evaluated regarding on the need to proceed to higher tier investigations, which can include Whole Effluent Toxicity testing and 3D-dispersion models. As an outcome of this project, it is foreseen that environmental risk assessment will be improved by the incorporation of effluent-specific science-based criteria, supporting decision-making in the context of local and international regulations, and ultimately promoting the protection of human and environmental health.

TH051

Effect of Differing Regulatory Guidance on Predicted No Effect

Concentrations (PNECS) for Active Pharmaceutical Ingredients in Industrial Wastewater Discharges

N.D. Forsberg, ARCADIS US Inc / Environmental and Molecular Toxicology; E.L. Osborn, ARCADIS US Inc; B.H. Magee, ARCADIS; P.D. Anderson, ARCADIS US Inc; N. Parke, Eli Lilly and Company / Global HSE - Environmental Affairs

Wastewater discharge permits may not specifically regulate chemicals that are unique to the pharmaceutical and animal healthcare industries, such as active pharmaceutical ingredients (APIs). Release of these chemicals has the potential to adversely affect the environment in areas downstream of the discharge. The potential for such effects can be assessed by developing predicted no effect concentrations (PNECs) for APIs and applying them to the downstream locations where exposures could potentially occur. The absence of a globally harmonized approach for the derivation and application PNECs can lead to substantial differences in the conclusions of risk assessments. To explore this issue, PNECs for aquatic organisms, wildlife, and humans were calculated for a variety of APIs spanning several therapeutic classes using two approaches: U.S. EPA's Great Lakes Initiative (40 CFR 132) and the European Union's Water Frame Work Directive (2000/60/EC) methods for deriving water quality standards. PNECs were calculated for several receptor-exposure scenario combinations, including acute and chronic exposure for aquatic organisms, chronic exposure for wildlife, and chronic exposure for humans associated with drinking water and recreational exposure scenarios. The results were variable within a therapeutic class, with PNECs that varied by 2,500-fold on average across both calculation methods and the previously described receptor-exposure scenarios. A sensitivity analysis was performed to evaluate the influence of the input variables and uncertainty in the underlying datasets on the calculated acceptable concentrations. Additionally, PNECs calculated using principles of the VICH's GL36(R) guideline for establishing microbiological acceptable daily intakes for antibiotics are compared with antibiotic resistance-based PNECs that have been published in the literature for several APIs. The effect of using US and EU-based approaches for evaluating the dilution capacity of receiving waters on the calculation of acceptable daily water discharges will also be discussed.

TH052

Biofilm communities as indicators of ecological impacts caused by treated and untreated abandoned mine effluents

L. Proia, BETA Technological Center - UVic / Aquatic Ecology and Ecotoxicology; L. Vendrell, Universitat de Vic Universitat Central de Catalunya / BETA Technology Centre Aquatic Ecology Group; M. Abril, M. Ricart, J. Colon, S. Ponsá, L. Llenas, Universitat de Vic Universitat Central de Catalunya / BETA Technological Centre

Mining activities have been performed since the Bronze Age and produce huge amounts of waste because the ore is a small fraction of the total volume of the mined material. Wastes produced by mining may reach surface waters both directly by effluent discharge and/or indirectly by seepage through embankments. About the 70% of the metal and salt mines in EU countries are classified as "abandoned" and represent an uncontrolled source of chronic pollution to receiving freshwater bodies because of the lack of any regulation about wastewaters treatment. The specific hazards posed by chemical stressors harboured in mine effluents to the aquatic environment mainly depend on its fate which influence its bioavailability and ecotoxicity. Biofilms are complex microbialcommunities with a relevant role in aquatic ecosystem functioning that are considered as effective bioindicator of ecological impacts and are recognized as necessary target within the Water Framework Directive. This study aims to evaluate the efficiency of an innovative treatment technology based on membranes and electrocoagulation (developed in the framework of the Life DEMINE project) for the reduction of the ecological impacts generated by metals and salts abandoned mines. Twodifferent experiments have been carried out under controlled conditions in microcosms to evaluate the ecological impacts of a) metal and b) salt mine effluents treated with different technologies using natural biofilm communities as bioindicators. Specifically we compared the behavior of control biofilm communities with the responses observed after a two weeks addition of water coming from mine effluents untreated (U) and treated with membranes (M), Electrocoagulation (E), Electrocoagulation after membranes (F) and a mix of water coming from M and F that would be the final effluent (EF) of the innovative technology developed. Untreted mine effluents (U) significanlty affected river biofilms by reducing its photosynthetic efficiency and phosphorus uptake rates whereas treated effluents barely provoked biological responses that, when observed, were generally recovered. Finally, the metal mine untreated effluent caused significant changes of the phototrophic biofilm compartment which shifted from diatom to green alge dominated community. This study demonstrated that the innovative technology developed in the Life DEMINE project significantly reduces the ecological impacts caused by abandoned mine effluents on biofilms.

The Omega-3 Index of macrophytes to improve the assessment of the treatment performance of constructed wetlands receiving treated wastewater

M. LE GUEDARD, LEB AQUITAINE TRANSFERT-ADERA / LEB AQUITAINE TRANSFERT; J. BESSOULE, UMR CNRS 5200-Laboratoire de Biogenèse Membranaire; C. Boutin, Irstea Lyon; H. Budzinski, University of Bordeaux / EPOC LPTC UMR5805 CNRS; M. Coquery, Irstea Centre de Lyon - Villeurbanne / Unité de Recherche Milieux Aquatiques, Ecologie et Pollutions (MAEP); N. Forquet, C. Miège, S. Papias, R. Clément, J. Choubert, Irstea Lyon

Effluents from wastewater treatment plants (WWTP) contain chemicals that are not removed (metals, pharmaceuticals, hormones...) and are therefore considered as a source of pollution for the aquatic environment. Constructed wetlands receiving treated wastewater (CWtw), built between the WWTP and the receiving environment, can help to limit the impact of WWTP discharge on the natural environment. Currently, the methods used to evaluate the treatment performance of these processes are mainly based on physicochemical parameters. However, the wide variety of contaminants that can be encountered and their variable concentrations over time (sometimes below the limit of detection of equipment) constitute a limit of the use of such tools. Moreover, these methods do not provide information on the toxic impact of the treated water on the recipient ecosystem that is one expectation of the WFD. Biological tools that provide a global response to toxic impact of contaminants on the ecosystem can fill this gap. The Omega-3 Index, a standardized biological tool that has been proven it worth to assess soil quality (ISO/CID 21479), could be also used to assess water quality. In this context, the Omega-3 Index of reed leaves was tested as a biological tool to assess the treatment performance of CWtw and, as a consequence, the improvement of water quality. This biological tool was implemented on the experimental sites of the MARGUERITTES and BIOTRYTIS projects located in the suburb of Nimes and Bordeaux Métropole. These projects aimed at studying the functioning and the real efficiency for the removal of major pollutants and micropollutants of CWtw with different configurations (ponds, meadows, ditches built with soil and adsorbing materials). The Omega-3 index, measuring on reed leaves harvested upstream and downstream a pond-CWtw, highlighted that the reeds are more stressed upstream than downstream and therefore suggests that the upstream soil retain more phytotoxic compounds. It also showed that the reeds are more stressed on CWtw built with absorbing materials than those constructed with soil (meadows and ditches). Furthermore, the omega-3 index was found to be correlated to the water quality improvement determined by the classical biochemical parameters (BOD, TSS…) and some micropollutant contents. From a regulatory standpoint, this biological tool can help to better evaluate the treatment performance of CWtw and to assess the complex effects of pollutants.

TH054

PLEUROTUS OSTREATUS IN DEGRADATION OF SELECTED PHARMACEUTICALS: STUDY ON REMOVAL ABILITY, TOXICITY AND POSSIBLE METABOLITES

B.M. Kozka, J. Giebułtowcz, G. Nałęcz-Jawecki, J. Turło, M. Klimaszewska, Medical University of Warsaw

Active pharmaceutical ingredients (API), present in effluents from wastewater treatment plants, constitute a serious problem discussed throughout the world [1]. When the effluents are introduced to the surface water, the API can exert a toxic effect both to the aquatic environment, biosystems basing on aquatic life and human [2]. In order to minimize the risk of the toxic effects, novel methods of the wastewater treatment should be applied. One of the method could be the application in the biological treatment of wastewater the organisms, that could remove API, like fungus from *Basidiomycota* [3]. The first aim of our study was to determine the ability of fungus from *Basidomycota* named as *Pleurotus ostreatus* to degrade selected API (n = 8). The second aim was to compare the toxicity of pre-cultivation and after-cultivation medium. At the last step we proposed metabolites as products of the degradation process carried out by *P.ostreatus*. The *P. ostreatus* cultures were carried out for five days in Sabouraud Dextrose Broth medium. API were quantified by validated LC-MS method. The toxicity was determined by bioassay based on *Spirostomum ambiguum* and *Vibrio fischeri.* **The metabolites were found using Compound Discoverer software. The obtained results showed that *P. ostreatus* is able to degrade majority of examined compounds. The toxicity of after-cultivation medium was lower than \n pre-cultivation medium. The detected metabolites were mostly products of oxygenation or demethylation reactions. To conclude, *P. ostreatus* can be useful in degradation of pharmaceuticals. Moreover, obtained results suggest its utility to wastewater treatment. <strong> References** Desbiolles F, Malleret L, Tiliacos C, Wong-Wah-Chung P, Laffont-Schwob I. 2018. *Occurrence and ecotoxicological assessment of pharmaceuticals: Is there a risk for the Mediterranean aquatic environment?*. Purification with Moringa oleifera of a pretreated wastewater from the Chinampera Zone of México city

N. Infante, Cinvestav Unidad Merida / Biotechnology; R. Rodríguez, CINVESTAV-IPN / Applied Biotechnology

Water is the fundamental element for the proper functioning of ecosystems in the "Chinampera" Zone which was cataloged as Natural and Cultural Heritage of Humanity by UNESCO since 1987. However, water is contaminated with pathogenic microorganisms, endocrine disruptors (including organochlorine pesticides), heavy metals and high salinity due to traditional agricultural activities. Therefore, the development and application of sustainable technologies is required to conserve and use the water resource in agricultural activities. In this project, the processes by which the contaminants can be removed from the seeds of *Moringa oleifera* and their effect on the water quality, in the improvement of a Xochimilco "apantle" will be investigated. The properties of the extract of *M. oleifera* seeds related to the removal of pathogenic microorganisms and endocrine disruptors were evaluated. *Escherichia coli* was isolated from wastewater of Xochimilco, and was considered as a model of pathogenic microorganisms, and *Pseudomonas putida* as a representative microorganism that degrades organic compounds; Lindane was used as a model for organochlorine pesticides. Based on the exploratory results, it was determined that the extract seeds presented characteristics of a surface agent, giving a positive emulsification index ($E_{24\%}$) and a decrease in surface tension (ΔTS). A critical micelle concentration (CMC) of 700 and 1500 ppm of the dehydrated seed extract was determined at 105°C and natural with a ΔTS= 18 and 20 mN/m and ($E_{24\%}$) of 30 and 17%, respectively. Both with 0.86 mm particle size of the seed. With these values a fractional 2^{4-1} factorial experimental design was established to evaluate the effect of the CMC, lysis time, *M. oleifera* particle size, contact time, salinity and pH in the inhibition of *E. coli* growth. Finally, seeds will be applied to a water pretreated in a biofilter in the "Chinampera" Zone, to improve the quality water used in irrigation.

TH056

The principle of the adverse outcome Pathway in the context of testing the antidepressant venlafaxine

M. Gundlach, RWTH Aachen / Instituts für Umweltforschung; A. Schiwy, A. Haigis, Institute for Environmental Research, RWTH Aachen / Department of Ecosystem Analysis ESA; H. Hollert, RWTH Aachen University / Institute for Environmental Research

The worldwide production and use of pharmaceutical products has more than doubled over the last decade. A high interest could be found for the production of antidepressants whose neuroactive characteristics influence and change the functionality of different human transmitter systems. The discharge into the aquatic environment has also risen sharply due to the higher production rate of pharmaceuticals. An insufficient treatment of wastewater regarding the elimination of antidepressants and due to the higher production rate of neuroactive substances these drugs can get into the aquatic environment and cause neurotoxic effects like changes in the swimming behaviour of different fish species. One reason for comparable reactions in fish are the strong homologies of conserved genes which regulate basic functions of major systems like the serotonergic system. The analyses of pharmaceutical mixtures proves to be very difficult in practice because it is difficult to analyse synergistic and antagonistic effects especially if the environmental sample consists of many substances with different modes-of-action. A relatively new and auspicious model that can be used for the analysis of chemical mixtures with different modes-of-action is the principle of the adverse outcome pathway (AOP). The clarification of adverse effects such as changes in the swimming behaviour by analysing the underlying molecular initiating events represents a modular approach which has a great potential for the clarification of the primary key drivers. In order to validate the evaluation steps of pharmaceutical mixtures, the AOP evaluation was initially applied to zebrafish embryos exposed to the antidepressant venlafaxine. The results showed an increase in the swimming activity of 116 hpf old zebrafish embryos exposed with the antidepressant for 24 h. The analysis of the gene expression rate showed that especially genes of the serotonergic system had a log2 Fold-change rate, which was \n 2.5 times higher in comparison to the negative control. By including molecular pathway data, the ME could be traced back from the AO to the MIE and presented in the AOP concept. The results showed that the application of the AOP concept is possible for the analysis of pharmaceuticals and that it simplifies the analysis. An application to pharmaceutical mixtures is thus possible and will be performed in the future for a wide range of drugs within a network analysis.

TH057

The neuroactive cocktail: How to analyse the effects of the antidepressant clozapine in an AOP context

M. Gundlach, RWTH Aachen / Instituts für Umweltforschung; A. Haigis, Institute for Environmental Research, RWTH Aachen / Department of Ecosystem Analysis ESA; A. Schiwy, Institute of Environmental Research-RWTH Aachen / Institute for Environmental Research; H. Hollert, RWTH Aachen University / Institute for Environmental Research

Hospital wastewater is a mixture of different pharmaceuticals with diverse modes-of-action which show effects on different biological levels. Antidepressants are one sub-group of pharmaceuticals which are designed for the evoke of neuroactive changes in human and a worldwide used atypical antidepressant is clozapine. Strong similarities lead to comparable neuroactive effects in aquatic organisms which endangers the structure and stability of the ecosystem. One approach on how to structure and organize the effect analysis from an adverse outcome (e.g. behaviour) to the elucidation of molecular causes is the concept of the adverse outcome pathway (AOP). It works with a clear event chain between the molecular initiating event over different molecular events till the adverse outcome and it could also be used for the description and evaluation of complete adverse outcome networks. The swimming behaviour was tested with a DanioVision observation chamber in a light-dark rhythm with 10 min period length and a total testing time of 90 min. Zebrafish larvae treated for 116 h with clozapine showed an increase of the swimming activity of more than 40 % at a concentration of 12.5 μM in comparison to a negative control. Following the test protocol designed on the results of different pre-studies with pure substance investigations with clozapine and venlafaxine, the molecular modes-of-action were analysed with a real-time quantitative PCR (rt-qPCR) StepOnePlus system from ThermoFisher. Focussing on changes in the expression rate of genes related to the serotonergic system an increase of the Log2 Fold-Change ratio for *scl6a4a* and *htr5a* with more than 35 % for the highest exposure concentration of 12.5 μM in comparison to the negative control. The results show that the different components of the pharmaceutical mixture have a synergistic effect which provoke a hyperactivity reaction in zebrafish larvae. The behavioural reactions of zebrafish larvae against the exposure to different antidepressants show that the environmental risk assessment of this chemical is not sufficient to protect and to fulfil the aims of the Water Framework Directive 2000. That means that new approaches on how to test and analyse these substances is necessary and the AOP concept is an innovative way to solve the problems of future environmental risk assessment in the field of pharmaceutical testing.

TH058

Do scrubber water discharges from ships place additional stress on the marine environment?

W. Kathmann, Federal Institute of Hydrology / G3 Biochemistry Ecotoxicology; S. Buchinger, Federal Institute of Hydrology / Department G Biochemistry Ecotoxicology; T. Kirchgeorg, German Federal Maritime and Hydrographic Agency; G. Reifferscheid, German Federal Institute of Hydrology; A. Schaeffer, RWTH Aachen University / Institute for Environmental Research

With the objective of significantly reducing negative environmental impacts of air pollution from international shipping and improving air quality in coastal regions, the use of low sulphur fuel is being gradually established by the International Maritime Organization (IMO). As of January 2015, marine fuel with a maximum sulphur content of 0.1% only is allowed in Sulphur Emission Control Areas (SECAs). To meet the oncoming requirements for lower emissions, shipping companies can also install exhaust gas cleaning systems (scrubbers) in which exhausts are washed with seawater and subsequently discharged into the sea. As a consequence hazardous substances such as heavy metals, polycyclic aromatic hydrocarbons (PAH) and other organic combustion products are likely to be released into the surrounding water, possibly at elevated concentrations which could have adverse effects on the marine environment and infringe environmental quality standards. Modeling studies suggest a containment of harmful effects due to the quick dilution of discharge water. However, sufficient toxicity data are missing to confirm these assumptions especially if scrubbers will be used at a larger scale in regions where dilution and buffering capacity of the water body is limited. We addressed this knowledge deficit by comparing the ecotoxicological potential of scrubber discharge water from two different scrubber technologies at several stages along the cleaning process in terms of their (1) acute toxic effects on marine algae and luminescent bacteria, (2) endocrine activities using yeast-based bioassays, (3) mutagenic profiles by means of specific tester strains in the Ames fluctuation assay. The efficiency of alternative treatments of scrubber discharge water can be evaluated based on the detected ecotoxicological effects. Bioassay results obtained by this study are complementing a chemical characterization of scrubber discharge and thus make an important contribution to the environmental impact assessment of scrubber discharge against the background of environmental quality criteria defined by the European Water Framework Directive and Marine Strategy Framework Directive.

Risks of anticoagulants to fish in effluent-laden streams

J. Regnery, P. Parrhysius, R.S. Schulz, Federal Institute of Hydrology; C. Möhlenkamp, German Federal Institute of Hydrology / Biochemistry and Ecotoxicology; G. Reifferscheid, German Federal Institute of Hydrology; M. Brinke, Federal Institute of Hydrology / Biochemistry and Ecotoxicology

Anticoagulant rodenticides are used worldwide to control commensal rodents for hygienic and public health reasons. Despite considerable acute toxicity of several anticoagulants to fish, very little is known about their distribution, fate, and exposure routes in the aquatic environment. However, recent findings of anticoagulant rodenticides in raw and treated wastewater, sewage sludge, estuarine sediments, suspended particulate matter, and liver tissue of fish in the low ng/L and ng/g range, respectively demonstrate that the aquatic environment experiences a greater risk of anticoagulant rodenticide exposure than previously thought. To investigate whether anticoagulant rodenticides enter streams via treated wastewater effluents after bait application in municipal sewer systems, we analyzed tissue samples of fish from 25 wastewater treatment plant polishing ponds in Bavaria, Germany by liquid chromatography – tandem mass spectrometry following a QuEChERS approach for extraction and clean-up. These polishing ponds are exclusively fed by municipal effluents and annually stocked with carp (*Cyprinus carpio*) for six months to enable monitoring of potential adverse effects and bioaccumulation of contaminants. In addition, operators and administrators in charge of municipal pest control at specific sampling sites were surveyed to retrospectively obtain information about rodent control in associated sewer systems shortly before or during the 2015 bioaccumulation period of carp in respective polishing ponds. Anticoagulant rodenticide residues were detected in carp liver at 12 out of 25 sampling sites in the low ng/g range. Six sites revealed hepatic residues of one or more second-generation anticoagulant rodenticide (i.e. brodifacoum, difenacoum, bromadiolone). 82% of surveyed sampling sites confirmed sewer baiting with anticoagulant rodenticides in 2015. Products containing brodifacoum, difenacoum, bromadiolone, or warfarin were exclusively used. Notably, hepatic residues matched the reported active ingredients used for sewer baiting at six sites. Although effluent-dominated systems such as polishing ponds represent worst-case exposure scenarios for fish, our results clearly indicate incomplete removal of anticoagulants during conventional wastewater treatment and confirm high bioaccumulation potential of second-generation anticoagulants. Our findings also reveal potential causative associations between sewer baiting and hepatic anticoagulant residues in fish.

TH060

Implications of temperature stresses on the fate of micropollutants during wastewater treatment

P. Meynet, Newcastle University / CEGS; A. Joss, Eawag Swiss Federal Institute of Aquatic Science and Technology; R. Davenport, Newcastle University / Biological and Environmental Engineering; K. Fenner, Eawag Swiss federal Institute of Aquatic Science and Technology / Department of Environmental Chemistry

Biological treatment plants (WWTPs) show high variability in (micro)pollutants (MPs) removal, which complicates their exposure and hence also risk assessment. A lack of experimental data is limiting our understanding of how operational and environmental parameters, such as temperature, influence the potential and rates of MP biotransformation in WWTPs, and prevent the validation of exhisting modelling approaches. In particular, current environmental exposure assessment relies on Arrhenius-based models to estimate the biotransformation rates in biological systems at different temperatures, despite they neglect potential temperature-induced compositional and functional variation of the microbial community. This work investigates the predicting power of Arrhenius-based models of MP biotransformation rate in a biological system. Series of laboratory-scale batch studies simulated short (daily) and long-term (seasonal) temperature shifts (4-40°C range) in activated sludge, and investigated how these changes affect the biotransformation potential and rate to degrade a mixture of 93 environmentally relevant MPs. Experimental median biotransformation rate constants (k_{bio}) across all compounds showed a positive correlation of k_{bio} with temperature in the long-term studies, approaching an Arrhenius-like behaviour, while this correlation was lost above 20°C in temperature-shocked biological systems. However, assessment of individual MPs revealed unsystematic temperature responses that did not correspond in the short- and long-term studies. Under temperature shocks, similar temperature responses were found in MPs that undergo similar initial biotransformation reactions (substitution vs oxidative-type), while these reaction-specific temperature responses were mostly lost in the long-term studies, with the exception of a small group of compounds undergoing a conjugation-type reactions (i.e. mostly sulfonamides). 16S rRNA amplicon sequencing showed that temperature changes strongly affect not only the enzymatic activity (ribosomal RNA) of microbial systems, but also induce substantial alterations in community composition (DNA), even when the temperature fluctuations occur over short periods. These findings question the predictive power of the Arrhenius-like approaches in environmental modeling, and emphasise the need to more accurately evaluate the biotransformation potential of biological systems to ensure accuracy in chemical risk assessment.

TH061

EVALUATION OF THE ADEQUACY OF NUMERIC VALUES DEFINED IN THE TABLES OF BRAZILIAN QUALITY WATER LAW FROM THE TECHNICAL AND SCIENTIFIC POINT OF VIEW, TO ENSURE THE PRESERVATION OF ECOSYSTEMS

C.H. Soares, Universidade Federal de Santa Catarina / Biochemistry Department; M. Barbosa Xavier, Universidade Federal de Santa Catarina / Biochemestry; I. Baptista, Universidade Federal de Santa Catarina

For Lobo and Callegaro (2000), monitoring the quality of a water body includes physical, chemical and biological monitoring, it is important in two ways. According to Knie and Lopes (2004), in ecotoxicology the use of bioindicators allows the detection of substances at concentrations below the limits of detection by chemical analysis methods, since living beings respond in an integrated way to all disturbing agents, including produced effects by new substances in water, formed through water and effluent interactions. Thus, as an alternative complementation of the physical and chemical characterization of effluents, toxicological evaluation is recommended. In this study, acute effects (lethality and immobility) and chronic effects (change in growth, reproduction and survival) are evaluated in ecotoxicological tests using concentrations value provided for in Brazilian law. What helps in decision making for the formulation of public policies. In order to evaluate the behavior of organisms against chemical compounds of petrochemical, agricultural and pulp and paper industries, some compounds were chosen according to the abundance/frequency in their use to trace a comprehensive behavior of the organisms against such evictions resulting on main objective: "Evaluate the adequacy and pertinence of the numerical values defined in the tables of Resolution 357/05 of CONAMA from the technical and scientific point of view, to guarantee the preservation of the diverse ecosystems." Six substances were to chosen to be tested: Benzene, Toluene, Glyphosate, Atrazine, Aluminum and Phenols. The results obtained didn't show toxicity for the tested concentrations for some organisms and chemicals. When tested toluene and benzene there was no morphological changes or deaths in *Daphnia magna*, but with *Danio rerio* it is possible to see many morphological changes and unviable eggs. The tests with atrazine showed inhibition on the algal growth and morphological changes on the fishes, but no death on the acute test with Daphnia magna. For glyphosate, there was no changes in the algae growth nor mortality in the acute test with Daphnia magna, but there was signifies morphological changes in the Danio rerio fingerlings. First, those preliminary results show that we cannot only use one organism to test and create public policies on environmental protection. Second, in a general way, the Brazilian law for water quality seems to be adequate to protect aquatic ecosystem, whit some exceptions.

State of the Science on Emerging and Novel Poly- and Perfluoroalkyl Substances (PFASs) (P)

TH062

An outdoor aging study in Australia to investigate the release of per- and polyfluoroalkyl substances (PFASs) from functional rain jackets

S. Schellenberger, Stockholm University ACES / Department of Applied Environmental Science (ITM); R. Awad, Stockholm University / Department of Environmental Science and Analytical Chemistry; O. Levenstam, University of Borås; L. Schultes, Stockholm University / Department of Environmental Science and Analytical Chemistry; M.M. Plassmann, J.P. Benskin, Stockholm University / Department of Environmental Science and Analytical Chemistry ACES; I.T. Cousins, Stockholm University / Department of Environmental Science and Analytical Chemistry

Waterproof and breathable textiles provide protection against bad weather conditions. 88 million outdoor jackets are sold alone in Germany per year which comprises approximately 40 000 soccer fields of exposed surface area (presuming that an average jacket has $3m^2$ textile weave). A large proportion of these textiles are treated with durable water repellent (DWR) impregnations that are based on side-chain-fluorinated polymers (SFPs) and are subject to several material stressors during their service life, such as variable weather conditions, washing and abrasion. These stressors facilitate the release of per- and polyfluoroalkyl substances (PFASs) from the surface weaves of functional textiles. The loss processes of PFASs from polymeric SFPs are complex and various mechanisms lead to losses, namely; the loss of unbound residuals, polymer degradation (i.e. cleavage of side chains) or material loss in the form of particles or fibre fragments. The loss processes are likely to occur simultaneously during the textile's use. Different PFASs, especially perfluoroalkyl acids (PFAAs), have been identified in textiles in previous research, but a lot of precursors may remain unidentified. The complex chemistry makes the quantification of the total release potential for PFAAs from outdoor clothing a challenging problem. To determine the emission potential for PFASs, samples of outdoor fabrics treated with SFPs have been exposed in a real weathering test on the roof of a house in Australia for 6 months. In addition, we applied abrasion and washing to some of the fabrics after weathering to simulate their lifetime use. As well as testing the technical performance (e.g. liquid repellency) before and after ageing, we have measured the loss of total fluorine (using combustion ion chromatography, CIC) that occurred during aging of the textiles. We also used targeted analysis to measure residual PFAAs in the aged textiles using liquid chromatography tandem mass spectrometry (LC-MS/MS). These analytical measurements were complemented with microscopic investigation of the fibre surface defects after aging using scanning electron microscopy (SEM). The experiments allowed a better estimation of the extent to which outdoor garments contribute to the emissions of PFASs and provided new insights into the loss mechanisms.

TH063

Analysis of novel fluorinated compounds in wastewater, South Korea

H. Kim, K. Kim, J. Oh, Pusan National University / Department of Civil and Environmental Engineering

Perfluoroalkyl substances (PFASs) have been widely used for fire retardants, surfactants, circuit, and fabric etc. for a long time due to their stable physicochemical properties. However, due to their toxicity and persistence, perfluorooctane sulfonate (PFOS), perfluorooctanoic acid (PFOA), and its salts were regulated on production and use by Stockholm convention and EU REACH since 2009. Therefore, F53B, ADONA, and Gen-X (also known as HFPO-DA) have been introduced as several alternatives to current used PFASs and their occurrence in water was reported by several researchers (Pan et al., 2018; Strynar et al., 2015; Sun et al., 2016). However, only a few studies developed and validated the new PFASs analysis method. Moreover, lots of studies have been focused on investigating even-number carbon perfluorinated sulfonates (PFSAs) and perfluorinated carboxylic acids (PFCAs) in environmental media and limited studies are conducted on odd-numbered PFSAs such as PFPeS, PFHpS, and PFNS. Therefore, in this study, we validated the extraction method for analyzing 30 fluorinated compounds including legacy PFASs, novel fluorinated compounds, and some precursors of PFSAs in water samples. Furthermore, to investigate the usage and contamination of fluorinated compounds in industrial fields of South Korea, we analyzed these compounds in 16 industrial wastewater samples collected from industrial complex located in Gumi, South Korea. The water samples were pretreated using solid-phase extraction (SPE) with WAX cartridge (150mg, 6cm^3, Waters, Milford, MA, USA) and analyzed using high-performance liquid chromatography and tandem mass spectrometry (HPLC-MS/MS) in multiple reaction mode (MRM). The obtained accuracy of 30 PFASs ranged from 62.7 to 111.3% and the precision ranged from 1.60 to 9.51%, which were satisfactory on US EPA method 537 although one of compounds had below 70% accuracy. In addition, we investigated the instrument detection limits (IDLs) and method detection limits (MDLs) by using the optimizing method. The detailed results will be presented in the poster.

TH064

Changes in PFAS distribution from hot spots sources to the abiotic and biotic environment

H.A. Langberg, Norwegian University of Science & Technology (NTNU) / Biology; G. Slinde, H.M. Grønning, Norwegian Geotechnical Institute; M. Jartun, NIVA Norwegian Institute for Water Research; B. Jenssen, Norwegian University of Science and Technology / Biology; G. Breedveld, Norwegian Geotechnical Institute / Environmental Engineering; S. Hale, Norwegian Geotechnical Institute

The environmental PFAS distribution in proximity to hot spots is not well investigated. Most studies have focused on concentrations of perfluorooctanesulfonic acid (PFOS), perfluorooctanoic acid (PFOA) and related compounds. The distribution of other PFAS present in the technical mixtures, their distribution in the abiotic environment and selective accumulation in organisms at several trophic levels, needs to be investigated further. The PFAS mixture used at a hot spot source zone varies depending on desired properties for the intended application. As an example, the PFOS precursor N-EtFOSE (n-ethylperfluorooctanesulphonamidoethanol) is associated with production of water repellent paper. Thus, the environmental mixture near a factory producing water repellent paper, or downstream a wastewater treatment plant (WWTP), is expected to be different from the mixture near a fire fighting training area. We are carrying out investigations of PFAS distribution in the abiotic environment and the food chain near different point sources in Norway: 1) Bodø Airport in the north of Norway, and 2) Longyearbyen Airport on Svalbard in the high arctic – two airports were AFFF related PFAS are released to marine fjords. Site 3), Tyrifjorden, is a large freshwater lake in the southern part of Norway were high levels of PFAS have been observed in fish (perch livers). The major active sources of PFAS-contamination in the lake are considered to be residues of historical use, and the largest sources identified are the sediments outside a closed-down industrial area for disposable paper products (plates, bowls, cups, etc.), and a fire station. We will present a comparison of changes in distribution and concentrations of PFAS mixtures in water, sediments and aquatic biota at these locations. Our work has special focus on source specific profiles and the changes that occur in the environment resulting in species-specific profile differences. Uptake from water and sediments will be compared by investigating PFAS profiles in benthic versus pelagic species. We will discuss our approaches to environmental monitoring of PFAS in different environmental compartments, especially with respect to sampling of biota (choice of species and tissues). Results from our work will be a significant contribution to risk assessment and management, and for regulation and policy making for contamination from point sources with complex PFAS mixtures.

TH065

Decision analysis of risk management options in dossiers to restrict dangerous substances in REACH legislation

I. Hilber, Agroscope ART / Environmental Analytics; S. Gabbert, Wageningen University / Social Sciences

Under the European Chemicals legislation REACH, 24 restriction dossiers have been adopted for reducing or eliminating the production, manufacture and use of harmful substances to protect human health and the environment from unacceptable risks posed by chemicals. In a restriction proposal, the dossier submitter (DS) proposes a risk management option (RMO), which is evaluated according to defined criteria (risk reduction capacity (rrc), proportionality, implementability, enforceability, manageability, monitorability) and compared to a baseline (business-as-usual situation). In addition, possible alternative RMOs can be compared to the baseline. Limiting, substituting or phasing out the production, manufacture and use of dangerous chemicals has substantial and potentially long-term implications for producers, consumers, and the environment. To better understand how decisions of restrictions are adopted, this paper analyses the determinants for selecting the RMO that was ultimately proposed. Specifically, we investigate whether or not the selection of the preferred RMO is objective, transparent, and comprehensible given the results of the criteria-based evaluation. We analysed all parts of the 24 dossiers addressing the evalution and selection of RMOs. Tools are for instance an explanatory evaluation, a criteria matrix, and/or a socio economic analysis (SEA). The latter two are proposed by the Eurpean chemicals agency. Eleven DS used the criteria matrix with the above mentioned criteria and 13 motivated their decision of the RMO in an explanatory discussion. However, the expected rrc was most decisive in all 24 dossiers for the final selection of the RMO. Eight DS used an SEA to compare the rrc and costs/benefits with the business as usual situation to find the best out of several RMOs. The trend is that the lower the costs and the higher rrc the higher the probability that an RMO is chosen. Hence, the majority of the dossiers did neither include a criteria based matrix nor an SEA, but based the selection of the RMO on qualitative reasoning only. To facilitate coherent and more objective decision-making on restrictions a harmonisation of the selection process of RMOs would be desirable. Furthermore, we suggest reducing the number of criteria, which would avoid obvious definition overlaps. Finally, our results imply that SEA does not (yet) contribute to a systematic and comprehensive comparison of costs (and benefits) and, hence, to the choice of an RMO.

TH066

Determination of plant uptake of modified polyfluorinated substances and their biodegradation products in soil and in plants

L. Wiedemann-Krantz, Fraunhofer Institute for Molecular Biology and Applied Ecology IME / Environmental & Food Analysis; R. Laemmer, Fraunhofer IME Institute for Molecular Biology and Applied Ecology / Environmental & Food Analysis; L. wiedemann, Fraunhofe IME / Fachgebiet IV.3 Spezielle landwirtschaftliche Analytik; M. Buecking, Fraunhofer IME - Institute for Molecular Biology and Applied Ecology

After the EU-wide statutory restriction of the production and use of perfluorinated substances (e.g. Perfluorooctanoic acid [PFOA] or Perfluorooctanoic sulfonic acid [PFOS]) due to their proven tendency to be bioaccumulative and persistent organic pollutants in 2006, polyfluorinated alkyl substances (PFAS), which are not covered by the legal guidelines, replaced many of these compounds. One replacement strategy is the use of polyfluorinated substances based on a fluorotelomeric structure modified with functional groups as phosphates, sulfates, alcohols and acrylates or methacrylates. This investigation deals with different PFAS, namely 6:2 fluorotelomer alcohol (FTOH), 8:2 FTOH, 10:2 FTOH, 6:2 fluorotelomer sulfonate (FTS), 6:2 polyfluoroalkyl phosphate (PAP), 8:2 PAP, 6:2 fluorotelomer acrylate (FTAC), 8:2 FTAC, 6:2 fluorotelomer methacrylate (FTMAC) and 8:2 FTMAC. The substances were applied on different types of soil (approx. 0.2 - 1 mg/kg soil) which was planted with radishes (*Raphanus sativus).* The grown period of radishes was 60 days. In first experiments investigating the content of PFAS in soil samples by using a methanol extraction and LC-MS/MS analysis method, several polyfluorinated carbon acids [perfluoropentanoic acid (C5) to perfluorodecanoic acid (C10)] were found in concentrations of approximately 1 – 30 μg/kg soil. As none of these acids was applied on the testing soils, it can be postulated that biodegradation processes formed them during the growth period of the radishes. In addition to that, in the soil samples the applied substances (PAPs, FTOHs and 6:2 FTS) were not found. For the determination of the FTOHs, FTACs and FTMACs as well as possible biodegradation intermediates, a GC-MS/MS method will be designed in the following experimental steps. Furthermore, the grown radishes will be analyzed to ascertain the amount of PFAS and their degradation products as well as the resorption capacity from soil to the radishes.

TH067

Direct uptake and translocation of Perfluoroalkyl Acids (PFAAs) in hydroponically grown red chicory (radicchio)

A. Gredelj, University of Padua / Department of Industrial Engineering; C. Nicoletto, University of Padua; S. Valsecchi, Water Research Institute - Italian National Research Council, IRSA-CNR; C. Ferrario, Water Research Institute - National Research Council; S. Polesello, Water Research Institute - Italian National Research Council, IRSA-CNR / Water Research Institute; R. Lava, F. Zanon, ARPA Veneto; F. Corrà, University of Padua; A. Barausse, L. Palmeri, University of Padua / Department of Industrial Engineering; L. Guidolin, M. Bonato, University of Padua

In the past decade, high concentrations of Perfluoroalkyl substances (PFASs) in the Veneto Region (northern Italy) have been detected, primarily in the groundwater. Due to the scarcity of research regarding the human health risks posed by PFASs, especially in this region, and the high importance of agriculture in Veneto, with food (particularly vegetables) intake being a major route of the human exposure to PFASs, a study with the final goal of assessing health risk for the Veneto population is needed. A perfluoroalkyl acids (PFAAs) uptake study was carried out with red chicory (*Cichorium intybus L., rubifolium* group) as the model crop, given its significance for the Veneto agriculture. *C. intybus* was grown in the hydroponic system in a greenhouse, where nutrient solutions were spiked with nine PFAAs, 7 perfluoroalkyl carboxylic acids (PFCAs), C4-C10, and

2 perfluoroalkyl sulfonic acids (PFSAs), C3 and C8, in three treatments with the nominal concentrations of each PFAAs respectively being 62,5 µg/L, 125 µg/L and 250 µg/L. Actual PFAAs concentrations in the nutrient solution were monitored weekly and the concentrations in the roots and leaves were separately measured at the end of growing cycle. Mass balances, root concentration factors (RCFs), leaves-to-root concentration factors (LRCF), leaves concentration factors (LCF) and transpiration stream concentration factors (TSCFs) were calculated to evaluate the bioaccumulation of various PFAAs and their transfer from the nutrient solution to the radicchio roots and leaves. Analyses of the PFAAs concentrations confirmed that the short-chained PFAAs (C3-C6) accumulate mostly in the vegetative plant compartments, the edible part of radicchio, while the long-chained ones (C8-C10) adsorb to or are taken up more by the roots, resulting in a concentration of PFBA (C4) higher than 2000 $ng/g_{w.w.}$ in the leaves and concentrations of PFDA (C10) and PFOS (C8) up to 20000 $ng/g_{w.w.}$ in the roots (250 ug/L nominal treatment). Plants from the two treatments with the highest PFAAs' concentrations manifested physiological changes (discoloration, inhibited roots and leaves growth), with the smaller improvements with the concentration decrease in the nutrient solutions over time. Trends of increasing root concentrations and RCFs with chain-length increase of the PFCAs were noticed, while the LCFs, even though showing a trend of the linear decrease with the chain-length increase, were higher than expected for the PFHpA (C7).

TH068

Emissions and Fate of Fluorotelomer Alcohols in Municipal Sewage Treatment Plants

C. Chen, Peking University / College of Environmental Sciences and Engineering; L. Li, University of Toronto, Scarborough / Department of Environmental Sciences; J. Liu, Peking University

Volatilization of fluorotelomer alcohols (FTOHs) from municipal sewage treatment plants (STPs) and subsequent atmospheric transformation contribute to the occurrence of perfluorocarboxylic acids (PFCAs) in the urban atmosphere and even in remote background regions. To date, a detailed, mechanistic description of how, and to what extent, the volatized FTOHs influences the ambient environment is inadequate. To this end, we determined FTOH concentrations in wastewater (influents and effluents) and the overlying air in a representative STP in Beijing, calculated FTOH emission flux from water to air based on concentration gradient, and estimated the magnitude of atmospheric emissions. Our results indicate that, among all investigated FTOHs, only 6:2 and 8:2 FTOHs are detectable in air and wastewater, with the former dominant in the air (55-69%) and the latter in wastewater (64%-73%). Seasonal (temperature) difference is absent in FTOH concentrations in wastewater but in those in the air. Emission fluxes from aeration and sedimentation tanks to the air above are estimated to be 122-375 $ng \cdot m^{-2} \cdot d^{-1}$ and 5.2-78 $ng \cdot m^{-2} \cdot d^{-1}$, respectively, depending on the ambient temperature. Each year, STPs across Beijing are estimated to receive 15 kg FTOHs along with domestic sewage, and to release nearly half (7 kg) to the environment, 30% of which enter the atmosphere. This implies that each resident in Beijing releases 2.6 mg FTOHs to the atmosphere per day. This presentation illustrates the environmental fate of FTOHs in STPs and provides a reference of emission level for other megacities similar to Beijing.

TH069

Investigation of PFAS concentrations in US food products.

S. Genualdi, FDA; L. deJager, U.S. Food and Drug Administration / Division of Analytical Chemistry; P. South, J. Sheehan, T. Begley, US FDA

Perfluoroalkyl and polyfluoroalkyl substances (PFASs), in particular perfluorooctanoic acid (PFOA) and perfluorooctane sulfonate (PFOS), have been widely studied due to their persistence, distribution, toxicity and bioaccumulation in humans and the environment. These compounds can enter the environment through landfills (products containing stain repellents, food packaging), wastewater treatment plants (industry waste), and from the use of firefighting foams (aqueous film-forming foams [AFFF]. The heavy use of PFAS compounds has led to their wide-spread presence in the environment.\n The PFASs have been found at relatively high concentrations in surface water, groundwater, and soil surrounding airports and military bases where AFFFs have a history of use. Recently several contamination events in the United States caused concerns of possible contamination of food commodities produced using contaminated waters. An QuECHERS LC-MS/MS method has been developed for PFASs in a number of commodities, including fruits, vegetables, milk, cheese, cattle silage and other foods. In this presentation, method development and validation and results of the analysis of these food products and non-implicated samples purchased on the US market will be discussed.

TH070

Investigation of the Feed to Egg Transfer of PFAS Including the Transformation of PFAA Precursors in Laying Hens

M. Buecking, Fraunhofer IME - Institute for Molecular Biology and Applied Ecology; M. Eichhorn, Fraunhofer Institute for Molecular Biology and Applied Ecology IME; M. Kotthoff, Hochschule Hamm-Lippstadt; B. Goeckener, Fraunhofer Institute for Molecular Biology and Applied Ecology IME; J. Kowalczyk, German Federal Institute for Risk Assessment

Per- and polyfluorinated alkyl substances (PFAS) are widely used in industry and in a wide range of consumer products due to their outstanding properties. Among the PFAS, the group of perfluoroalkyl acids (PFAA), which can be divided into perfluorocarboxylic (PFCA) and perfluorosulfonic acids (PFSA) depending on the functional group, is best characterized. Several PFAS are known precursors for PFAA which, due to their chemical stability, are persistent, bioaccumulative and toxic. The distribution of PFAS is ubiquitous. They were detected in animal, water, plant and soil samples. Due to their detection in human samples and drinking water, investigations of PFAS and especially PFAA precursors also come into focus in terms of consumer protection. In a feeding study conducted by the German Federal Institute for Risk Assessment (BfR), chickens were fed PFAS-contaminated feed. The distribution of PFAA in the animals was investigated. The results of the transfer study showed that the animals excreted higher amounts of PFAA through the egg than was ingested with the feed. In investigations of the feed different precursor compounds could be identified. In addition, the eggs were investigated for their content of precursors. Chicken eggs play an important role in the human diet, therefore a valid analysis for this matrix is necessary. At the same time, the transfer of precursors from contaminated feed into eggs can be traced. For this purpose, a multimethod for the detection of more than 40 PFAS is adapted to the matrix chicken egg. Using the Total Oxidizable Precursor (TOP) approach, precursors are degraded to their corresponding PFCA. By comparing the PFCA concentrations before and after the oxidation, it is possible to draw conclusions about the amount of precursors, and thus non-detected PFAS. This will provide an overview of the overall PFAS burden of egg samples obtained in the chickens transfer study.

TH071

Multimedia modelling of the fate of per- and poly-fluoroalkyl substances in Fuxin, China

A.M. Lampic, Trent University / Chemistry; J. Parnis, Trent University / Cemistry; D. Mackay, Trent University / Chemistry

We will report the current status and progress in the creation of a fugacity-based multimedia model for river ecosystems in urban and agricultural environments that surround two PFAS (perfluoroalkyl substance) point sources in Fuxin, China. The modelling work is being done using the experimental data from the work of Chen et al. (2018). The objective is to accurately describe the fate and transport of 25 PFASs in this environment. We will report and critically review predictions of physicochemical properties of many previously ill-characterized PFAS made by application of COSMO-RS solvation theory. Fugacity-based multimedia models will be created in the manner of Mackay (2001). Three models with increasing complexity will be created (Mackay Level I, Level II, and Level III). The quality of the model will be assessed by the degree of agreement between the predicted and experimentally measured PFAS levels in the various environmental compartments of the system. This research will shed light on the important processes that control the fate and distribution of these compounds and will provide a supportive framework for regulatory control and environmental remediation. Sensitivity analysis and uncertainty analysis will be performed on the estimates from each model, toward generating a model that can accurately predict concentration values of several PFASs in the urban and agricultural environments. The resulting models will also provide insight and understanding into the processes and important factors that govern PFAS fate in the environment. The primary sinks for PFASs will also be highlighted under the defined environmental conditions.

TH072

Perfluoroalkyl acids (PFAAs) in soil and groundwater: transport modeling

D. Mussabek, LTH, Lund University / Water Resources Engineering; K.M. Persson, LTH, Lund University / Department of Water Resources Engineering; L. Ahrens, Swedish University of Agricultural Sciences SLU / Dept. of Aquatic Sciences and Assessment; R. Berndtsson, Lund University / Department of Water Resources Engineering; K. Nakagawa, Nagasaki University / Graduate school of fisheries science and environmental studies

PFAS have been reported in series of studies as a hazard to environment and human health. Mobility in aqueous (dissolved) phase and spread in aquatic systems are the main drivers for transport and distribution. Physicochemical properties of PFAS define a particular behavior for transition between different domains as from infiltration from surface water to advective transport in saturated media. Transport mechanisms, however, are subject to retention (retardation) factors that require better understanding. Transport and behavior of PFAS in saturated flow were studied for a site with contaminated groundwater in Ronneby Municipality, Sweden. The main objective was to reconstruct the contamination pattern and reproduce the temporal variation of PFAS in groundwater. Fieldwork was organized with support of local waterworks and municipality. The project was conducted as a part of epidemiological study on PFAS exposure and health effects. Environmental investigation included analysis of the media properties (soil/sediment), PFAS analysis and monitoring (surface and groundwater), and different sampling strategies. The transport/retention model was built on a detailed cross-section profile of the aquifer properties. The solute transport model was calibrated to estimate the pulse duration and retention time in soil media.

TH073

PFAS Terminology - Clear, Specific and Descriptive. How have we done?

R.C. Buck, The Chemours Company / Fluoroproducts

In 2011, a landmark publication, "*Perfluoroalkyl and Polyfluoroalkyl Substance in the Environment: Terminology, Classification and Origin*" (doi: 10.1002/ieam.258) set forth terminology and classification for per- and poly-fluoroalkyl substances (PFAS). PFAS are a diverse class of substances with vastly different physical, chemical and biological properties. In the paper, the authors strongly encouraged the global scientific community to adopt the terminology and classification presented and use clear, specific and descriptive terminology in writing. The authors specifically discouraged the use of broad, poorly defined terms and acronyms, like PFAS alone. How have we done? This paper will present an assessment of the published scientific literature for 2017 and 2018. A large number of the published papers have missed the mark by using the acronym PFAS to describe the work presented in the title and abstract when the work was really done on a subset of PFAS substances. Greater clarity, specificity and description would have been desirable. For example, many papers describe studies on perfluoroalkyl acids (PFAAs) not PFAS as an entire class. For a representative group of these papers, the use of terms that would be clear, specific and descriptive and thereby strengthen the work will be offered. In addition, papers which do hit the mark and provide clear, specific and descriptive titles and abstracts will be highlighted. The intent is to further engage the community to strengthen the commitment to more clearly communicate about PFAS and specific substances within it the broad class.

TH074

PFASs in a Tropical Estuarine Food Web: Trophic Magnification and Wildlife Exposure

D.d. Miranda, Instituto de Biologia da UFBA / Biology; R. Awad, Stockholm University / Department of Environmental Science and Analytical Chemistry ACES; J. Leonel, Universidade Federal do Rio Grande / Instituto Oceanográfico; J. Benskin, Stockholm University ACES / ACES; V. Hatje, Universidade Federal da Bahia / Centro Interdisciplinar de Energia e Meio Ambiente

Biomagnification of per- and polyfluoroalkyl substances (PFASs) was investigated in biota from a tropical estuary in Bahia, Brazil. This area is one of the few regions in the world where a PFOS-precursor (the commercial pesticide Sulfluramid; N-ethyl perfluorooctane sulfonamide, EtFOSA) continues to be used under manufacture and use exemptions of the United Nations Stockholm Convention on Persistent Organic Pollutants. Samples of liver or muscle were obtained from bivalves (n=5), crustaceans (n=4), annelids (n=1) and fishes (n=12) covering 3 trophic levels (based on analysis of stable-nitrogen ($\delta^{15}N$) and carbon ($\delta^{13}C$) isotopes). ∑PFAS concentrations were dominated by PFOS, followed by perfluoroheptanoate (PFHpA) and perfluorotridecanoate (PFTrDA). Perfluorooctane sulfonamide (FOSA) and EtFOSA were also detected. Liver PFOS concentrations were highest in *Aspistor luniscutis* (45.1 ng g^{-1}) and lowest in *Genyatremus luteus* (0.23 ng g^{-1}). Evaluation of PFAS trophic magnification was achieved by converting liver or muscle-based concentrations to whole-body concentrations, which were then plotted against trophic level. To our knowledge, this is the first time PFAS trophic magnification has been investigated in Brazilian wildlife.

TH075

Poly- and perfluoroalkyl substances (PFASs) in global surface waters. A review of spatial and temporal trends

D.C. Muir, Environment and Climate Change Canada / Aquatic Contaminants Research Division; A.O. De Silva, Environment and Climate Change Canada; L. Miaz, Stockholm University

Poly- and perfluoroalkyl substances (PFASs) are aliphatic organofluorine molecules with highly fluorinated carbon chain "tails," and a hydrophilic "head" groups of carboxylates, sulfonate, or phosphonates/phosphinates. Many are degradation products of more complex precursors. It has been well established that they are transported in wastewater and rivers to the oceans which serve as a terminal sink. This study builds on a review of data for PFOS in surface waters published up to early 2015 that was included in the Stockholm Convention 2nd Global Monitoring Report http://chm.pops.int/Implementation/GlobalMonitoringPlan/Overview/tabid/83/Default.aspx). Our goal was to provide an updated overview of spatial trends, and where possible, temporal trends of PFASs in oceans and freshwater globally, in order to assess effectiveness of national and global bans and provide a baseline for future work. In order to provide an estimate of the range of concentrations without including wastewater effluents we used results from the lakes, rivers and estuaries that included two or more sampling sites per river reach and identified by the study authors as being upstream or remote from urban waste water effluents. On large rivers, only data from mainstream river sampling sites were selected rather than tributaries. For marine environments we used results from open ocean cruises. We found that the spatial coverage of PFAS measurements in water was dominated by information for rivers in western Europe, Eastern China, Japan, and the Great Lakes in North America. For marine waters most data was from the North Sea, the Baltic, and the South China Sea while for open oceans measurements in the North Atlantic and the Arctic Ocean predominated. Results showed that ice and snow melt inputs of PFAS are likely to be important during spring melt events and need to be considered in timing of monitoring programs in polar areas. The presence of PFOS in remote sectors of the southern Ocean, the Arctic Ocean and the mid-North Atlantic, including in deep waters (>1000 m), illustrated the long range ocean transport of PFOS and other PFASs and their value as tracers of ocean circulation. Temporal trend information has improved over the past 5 years due to repeat sampling of some locations (eg in the Canadian arctic archipelago), as well as separate cruises especially for the Eastern North Atlantic, and the first evidence is emerging of declining PFOS concentrations.

TH076

Research Needs to Inform the Substitution of Polyfluorinated Substances New to Canada: Assessment of New Substances Subject to Regulation

G. White, Health Canada / Health Canada; D. Ashby, Health Canada; G. Hammond, J. Tigner, Environment and Climate Change Canada

Substances new to Canada are subject to the New Substances Notification Regulations (NSNR) where prescribed information submitted by notifiers is assessed by the New Substances Program (NSP) of Health and Environment Canada. Per/polyfluorinated substances (PFAS) containing long-chain perfluoroalkyl groups were assessed by the NSP and found to be "CEPA toxic". These assessments were instrumental in banning long-chain perfluorocarboxylic acids (PFCAs) and their precursors in Canada (http://www.chemicalsubstanceschimiques.gc.ca/plan/approach-approche/pfca-apfc-eng.php). Further regulatory efforts to minimise exposures to these substances have led companies to propose "alternative substances" that are merely structural variants of those found to be of concern. "Informed Substitution" challenges researchers developing alternatives to proactively generate relevant information to delineate their potential health effects and environmental effects. Chronic hazard, metabolite data, multi-generational studies and monitoring of environmental media would facilitate comprehensive assessments but go beyond what is required under the NSNR. Such critical information would contribute to discerning substances which are viable PFAS alternatives from a health and ecological perspective. Assessment methodologies for new substances in general will be presented and those pertaining to polyfluorinated substances will be highlighted.

TH077

Short-chained PFAS in Finnish aquatic environment

E.S. Vähä, Finnish Environment Institute / Centre for Sustainable Consumption and Production; V.A. Junttila, Finnish Environment Institute SYKE / Centre for Sustainable Consumption and Production; K.S. Siimes, Finnish Environment Institute SYKE / KTK / Contaminants; N. Perkola, Finnish Environment Institute / Laboratory Centre; A. Räike, Finnish Environment Institute; J. Mannio, Finnish Environment Institute SYKE / Centre for Sustainable Consumption and Production

This study presents the results of PFAS-survey in Finland. Surface water and fish were sampled in locations with high to very low anthropogenic pressure including rivers, lakes and the Baltic Sea. Short-chained PFASs were detected in more than 60% of the river water samples. PFHpA was detected in 95% and PFHxA in 84% of the samples, and they were the most commonly detected substances after PFOA, which was detected in 96% of the samples. The concentrations were rather low, maximum concentrations being < 6 ng/L. PFBS and PFBA were not detected in the background sites. The concentrations were higher in rivers receiving effluents from municipal waste waters and there was a visible peak in concentrations during snowmelt period in spring. The riverine load of PFBA to the Baltic Sea was 17 kg, which even exceeds the loads of PFOS (10 kg) or PFOA (11 kg) of the same rivers in 2017. Short-chained PFAS have been measured from perch (*Perca fluviatilis*) and herring (*Clupea harengus membras*) tissue starting year 2014, and PFHxA has been detected once and 6:2 FTS in 3 samples. The other measured short-chained PFASs have not been detected in fish. As comparison, long-chained PFAS are commonly detected in the fish samples. The results show that short-chained PFASs are widely spread in the surface waters but do not accumulate in the fish tissue. They enter the waters via atmospheric deposition but also from point sources. Short chained PFASs contribute up to 54% of the total PFAS concentrations of the 23 studied PFAS in the rivers and their loading to the Baltic Sea even exceeds the load of PFOS and PFOA. These first results still leave us with many open questions regarding short-chained PFASs. The sources of these substances are not well known: we have little knowledge on PFAS-polluted soils and no data of atmospheric deposition of PFASs in Finland. The huge number of PFASs is a challenge and requires further development in the analytical methods, screening and monitoring activities as well as modelling the environmental fate of these substances.

TH078

Size-specific distribution of perfluoroalkyl substances (PFASs) in aerosols close to one of the major fluoropolymer manufacturing facilities in China

B. Sha, Stockholm University; J. Johansson, Stockholm University / The Department of Environmental Science and Analytical Chemistry (ACES); M. Salter, Stockholm University / Department of Environmental Science & Analytical Chemistry (ACES); I. Cousins, Stockholm University / Department of

Environmental Science and Analytical Chemistry (ACES)
The ubiquitous presence of per- and polyfluoroalkyl substances (PFASs) in the environment has attracted increasing public attention. The manufacture of fluoropolymers such as polytetrafluoroethylene (PTFE) is a major source of low-molecular-weight PFASs like perfluorooctanoic acid (PFOA). However, limited information is available in terms of direct emissions of PFASs into the atmosphere as well as the role of direct sources in the atmospheric transport of PFASs. In order to investigate the long-range atmospheric transport potential of directly emitted PFASs via airborne particles, size-segregated aerosol samples were collected in a residential area close to a fluoropolymer (FP) manufacturing plant in China. Ambient aerosol was sampled everyday over the course of 30 days using a 5-stage impactor (cutoff sizes were 12.2 µm, 4.05 µm, 1.35 µm, 0.45 µm and 0.15 µm) connected with a quartz fiber filter (for particles < 0.15 µm). The preliminary results of a pilot study demonstrated that a large portion (~40%) of perfluoroalkyl acids (PFAAs) was found in the < 1 µm size range. A sharp elevation in the concentrations of C6-C8 perfluorocarboxylic acids (PFCAs) was observed when there was wind coming from the direction of the FP plant, and the concentrations of individual PFCAs were significantly correlated with each other, indicating a common source. Among the PFAAs investigated, PFOA was the dominant one, and was about three orders of magnitude higher in concentration than the other PFAAs.

Trier, European Environment Agency / Green Economy Group, Integrated Environmental Assessments; S. Valsecchi, Water Research Institute - National Research Council; K. van der Jagt, European Commission / DG CLIMA; L. Vierke, German Environment Agency / Chemicals
Per- and polyfluoroalkyl substances (PFASs) are man-made chemicals that contain at least one perfluoroalkyl moiety, $–C_nF_{2n}–$. To date, over 4,000 unique PFASs have been used in technical applications and consumer products, and some of them have been detected globally in human and wildlife biomonitoring studies. Because of their extraordinary persistence, human and environmental exposure to PFASs will be a long-term source of concern. Some PFASs such as perfluorooctanoic acid (PFOA) and perfluorooctanesulfonic acid (PFOS) have been investigated extensively and thus regulated, but for many other PFASs, knowledge about their current uses and hazards is still very limited or missing entirely. To address this problem and prepare an action plan for the assessment and management of PFASs in the coming years, a group of more than 50 international scientists and regulators held a two-day workshop in November, 2017. The group identified both the respective needs of and common goals shared by the scientific and the policy communities, made recommendations for cooperative actions, and outlined how the science–policy interface regarding PFASs can be strengthened using new approaches for assessing and managing highly persistent chemicals such as PFASs. The Statement has been published in the open-access journal Environmental Health Perspectives, and this poster intends to present the Statement to a wider audience from academia, civil society, governmental agencies and industry.

Chemical Exposure via Plastics and Synthetic Rubbers: Quo Vadimus? (P)

TH080

Marine debris as a source of hazardous chemicals in the marine environment: Transfer of hexabromocyclododecane from expanded polystyrene debris to marine organisms inhabiting the pristine environment

M. Jang, Korea Institute of Ocean Science and Technology / oil and POPs reserch group OPRG; S. Hong, W. Shim, G. Han, Y. Cho, Korea Institutue of Ocean Science and Technology KIOST
The role of plastic marine debris as a carrier of hazardous chemicals in the marine environment is an emerging issue. This study focused on expanded polystyrene (EPS, commonly known as Styrofoam) debris, which is a common marine debris item worldwide, and its additive chemical, hexabromocyclododecane (HBCD). To identifythe potential of EPS debris for the transfer and dispersion of chemicals to the pristine marine environment, two islands located in the southern part of Korea with very different EPS debris pollution levels (one contaminated islands and one non-contaminated island) were selected as study sites, and the exposure levels of HBCDs in marine organisms inhabiting each island were assessed and compared. Along with HBCDs, a typical sorbed chemical, polychlorinated biphenyl (PCB) were analyzed for comparison. No difference was observed in PCB levels in organisms such as oyster, limpet, and gastropods from two islands, while the HBCD concentration was significantly higher in organisms inhabiting contaminated islands than those inhabiting non-contaminated island (Mann-Whitney, $p< 0.05$). The result of this study indicates that EPS marine debris has a strong potential for source and carrier of plastic additives, HBCDs, in the marine environment.

TH081

Plasticizers in German rivers: DEHP and its emerging substitutes

R. Nagorka, Federal Environment Agency UBA / Water and Soil; J. Koschorreck, Umweltbundesamt
Plasticizers are among the most commonly used functional additives in PVC. Their proportion by weight in products can be up to 50 % w/w. The phthalate plasticizer Di(2-ethylhexyl) phthalate (DEHP) is a well-documented ubiquitous contaminant and frequently regarded as the predominant plasticizer in the environment. In the EU, the use of DEHP and other phthalates was banned because of their endocrine-disrupting activity. As a result, the production of these phthalates decreased significantly. Market data show that high-molecular-weight phthalates are now extensively substituting DEHP together with various types of non-phthalate plasticizers. However, the global plasticizers demand is continuously growing. The objective of this study was to obtain spatio-temporal trends for DEHP and its substitutes in freshwater systems. We analyzed suspended particulate matter samples (SPM) for the presence of 23 plasticizers, i.e. 17 phthalates and 6 non-phthalates. Samples from recent years were retrieved from the German environmental specimen bank (ESB), which covered 16 sampling sites from major rivers including Rhine, Elbe and Danube. In samples from today, we observed a higher diversity of softeners than in samples from the past together with a shift to less volatile substances. The high-molecular-weight plasticizer Diisononyl phthalate (DINP) is the most abundant plasticizer detected in the SPM-samples. Our results indicate a fast appearance of new plasticizers like Diisononyl cyclohexane-1,2-dicarboxylate (DINCH) in freshwater environments and we identified several compounds, for instance Di(2-propylheptyl) phthalate (DPHP), as potential chemicals of emerging concern with increasing levels. In addition to the substitutes, we continued to demonstrate DEHP in the major German rivers: this results in an increasing total exposure to plasticizers at some of the sites we investigated. Despite the strict EU regulations, DEHP levels have not been declining for some years, but are stagnating at relatively high concentration levels in some cases. This is in contrast to the decreasing levels of DEHP in human samples from the German ESB over the last decade.

TH082

Assessment of microplastics occurrence and composition in Swedish road waste water through a thermal degradation method

a. gomiero, International Research Institute of Stavanger / Enviromnent; A. Vianello, Aalborg University / Civil Engineering Department - Section of Water and Environment; J. Vollertsen, Aalborg University / Department of Civil Engineering, Section of Water and Environment; K. Øysæd, NORCE Norwegian Research Centre / Environment; I. Järlskog, Y. Andersson-Sköld, Swedish National Road and Transport Research Institute
The global production of thermoplastics has grown rapidly since the start of its large-scale production around the 50s. The different varieties of polymers produced have unique characteristics in terms of durability, production costs, weight, strength, flexibility and limited electric conductivity. Nowadays, the market of thermoplastics is dominated by four main classes of plastics, being polyethylene, polyethylene terephthalate; polypropylene, polyvinyl chloride, polymethacrylate, nylon, polycarbonate and polystyrene. Besides thermoplastics, rubber is also considered a class of plastic. Plastics are also used in road materials. To improve the properties of asphalt, polymers are added to some bitumen. The materials used are Styrene Butadiene and Styrene Ethylene Butylene Styrene copolymer. In brief, the polymers make the asphalt stiffer on warm summer days and more flexible on cold winter days. Another abrasion surface made of plastics on the roads is the road marking paint. This is made by mixing variable amounts of Styren-Isopren-Styren, Etylen-vinylacetat, Polyamide and acryl-monomer. City

dust in urban runoff is known as a significant contributor to the pollution of receiving waters. A preliminary study of microplastic abundance in Skagerrak, the coastal waters among Norway and Sweden, pointed out that a large fraction of particles found in the sea seems to be associated to city dust e.g. asphalt and car tires. To support this hypothesis four samples of road runoff close to the kerb on a road ending up into a stream located in a nature conservation area in Gothenburg were collected. Samples were characterized for plastic polymers and rubber abundance. The whole sample preparation, combining a sequential step of enzymatic and strong oxidizing treatments followed by density separation, was designed to avoid intermediate filtration steps, preserving the whole particle size range. Plastics and rubber content were estimated thorough a thermal degradation method based on a GCMS-pyrolysis technique adopting specific indicator ions for the detection of PP, PVC, PS, PMMA, PET, PC, NY, PE and rubber. The analysis of pyrograms showed that the sample preparation process was successful and resulted in optimal analytical conditions, leaving very limited matrix or background interference. PVC, PP, PVC PS PMMA, PET and rubber where quantified in the range of μg/L, with PVC and PP being the most abundant polymers. Rubber contents spanned from 1.7 to 7.7 μg/L.

Car tyre wear in freshwaters - a probabilistic mass balance modelling approach

M. Kooi, Wageningen University & Research / Aquatic Ecology and Water Quality Management Group; A. van Wezel, KWR Watercycle Research Institute / Chemical Water Quality and Health; A. Koelmans, Wageningen University / Aquatic Ecology and Water Quality Management

Microplastics have been detected in rivers and streams around the world. Car tyre wear is a major source of microplastics in the freshwater environment. Measurements of car tyre wear are scare, and when available they are fragmentary in both space and time. Moreover, the measurements cannot reveal all sources or transport characteristics, and therefore hamper the development of exposure assessments. Models can help to integrate these fragmentary data into more comprehensive exposure overviews needed for risk assessments. The models currently available are however focussing on small (sub) catchments or are on a very coarse scale. In this study we modelled the transport and fate of car tyre wear in the Netherlands. Based on the WFD Explorer 2.2., a national-scale, steady state mass balance model, the Dutch water network was divided into almost 19000 surface water units. We identified and quantified different point sources including over 300 waste water treatment plants and 9 cross-boundary flows, but also took into account diffuse surface runoff of tire wear particles. Emission input data were based on existing literature. We focussed on the variability and uncertainty of the particle properties and emission scenarios, using a probabilistic approach. Also, we calculated the export of car tyre wear to the North Sea. We found that car tyre wear concentrations vary several orders of magnitude between surface water units, both in the water and in the sediment. Large variations in car tyre wear concentrations were also found for specific locations and for the export to sea when varying the particle properties with the Monte Carlo approach. Our model provides the first comprehensive exposure assessment for car tyre wear on a national scale, and will form the basis for a prospective risk assessment, since modelled concentrations can be compared with effect thresholds for different aquatic organisms. Also, management measures can be included in the model, to illustrate how these measures would affect car tyre wear concentrations in freshwater systems.

Chemical additives in plastics: overview and possible prioritization strategies

H. Wiesinger, ETH Zurich / Civil, Environmental and Geomatic Engineering - Ecological Systems Design; Z. Wang, S. Hellweg, J. Houska, ETH Zurich / Institute of Environmental Engineering

Plastics pervade every aspect of our modern life due to their cheap price and versatility associated with different chemical additives therein. These chemical additives may provide not only desired functionalities such as flame retardancy and plasticity, but also features such as color and smell that make the products more attractive to consumers. However, many additives are not chemically bound to plastics, and may be released during the production, use, disposal and recycling of plastics, leading to undesired human and environmental exposure to these chemicals and causing adverse effects in some cases. In contrast to the broad range of chemical additives that are currently used in plastics (e.g., it is recently estimated that over 900 chemicals additives have been used in different polypropylene (PP) products), the current research and risk assessment has focused on a limited number of chemicals such as heavy metals, phthalates and brominated flame retardants. One major cause of such phenomenon is that the identities of many chemical additives are yet unknown/unfamiliar within the wide scientific and regulatory community. This ongoing shortcoming has motivated us to develop a comprehensive database of chemical additives in plastics and to develop an adaptable prioritization strategy that would help to systematically focus resources on those most problematic substances, subject to protection goals. In the first step of this study, information on intentionally added additives in plastics was collected from publicly accessible databases, scientific literature, books, patents, and technical reports, including CAS numbers, chemical names, molecular structures, and different hazardous properties. The collected information was harmonized and compiled into one single database. In addition, predictive quantitative structure-activity relationship (QSAR) tools were used to fill in data gaps in physicochemical and toxicological properties. In the second step, a framework of adaptable prioritization strategies was developed based on hazard and exposure assessment and multi-criteria-decision-analysis. In particular, various selection criteria such as persistence, bioaccumulation, toxicity and release potential can be integrated and weighted to fit different purposes. To validate the framework, a case study on prioritization of substances that are critical to plastic recycling was conducted.

TH085

Evaluation of impacts of expanded polystyrene leachate on four marine microalgae

Y. Chae, Konkuk University; Y. An, Konkuk University / Department of Environmental Heath Science

Due to enormous amounts of plastic wastes in marine environment, the concerns about marine pollution and ecological impacts on marine organisms also have increased. Especially, plastic pollution which originated from expanded polystyrene (EPS) is serious in Korea. In this study, we used EPS leachate and four marine microalgae species to evaluate the impact of EPS on marine microfauna. Various EPS fragments and spheres with different size, shape, and concentrations were incubated with F/2 media for 28 days and four marine microalgae (*Dunaliella salina, Scenedesmus rubescens, Chlorella saccharophila,* and *Stichococcus bacillaris*) were exposed to these leachates for 10 days. After exposure, photosynthetic activities and cell morphologies were analyzed in each microalga. In results, cell growths of four microalgae were stimulated when they were exposed to high concentration of EPS leachate and the photosynthetic activities also increased. This result is assumed to be the effects of additive chemicals included in EPS and more future studies are needed. *Acknowledgement - This research was also supported by a research project titled, "Environmental Risk Assessment of Microplastics in the Marine Environment" from the Ministry of Ocean and Fisheries, Korea (PM60690).*

TH086

Microplastics as vectors of emerging contaminants in the terrestrial ecosystem: ecotoxicological impact

C. Martin, Universidad Politecnica de Madrid / Biotechnology-Plant Biology; S. Sanchez-Fortun, UCM; C. Fajardo, Universidad de Alcala; E. Carrio, Universidad Politecnica de Madrid; M. Nande, UCM; G. Mengs, Natural Biotec; G. Costa, Universidad Complutense de Madrid; M. Martin, Universidad Complutense Madrid

We live in a world in which plastic wastes are accumulating in different ecosystems. For this reason, the study of the impact of plastics on the environment has become an **emerging area** of research. Recently, research on the environmental impact of plastics has acquired a new dimension through the discovery and study of **microplastics (MPs)**(plastic particles MPs have become an environmental problem because: (i) they are small enough to be **ingested by biota**, which affects their integrity and can accumulate in the food chain; and (ii) they can **adsorb contaminants** on their surfaces, serving as **contamination vectors**, especially organic compounds. MPs have been located in different systems (surface waters, oceans, sediments) and organisms, although their environmental impact has been studied almost exclusively in marine environments and coasts. However, there is an evident **lack** of MPs' distribution and impact data on the **terrestrial system.** The main sources of MPs in the terrestrial ecosystem are sludge from wastewater treatment plants (WWTP), urban runoff, agricultural mulching, as well as landfills and industrial areas. The MPs found in wastewater come mainly from the fragmentation of plastic waste, but also from personal care products and synthetic textile fibers. The presence of MPs in the terrestrial system can have harmful effects on different processes, not only their presence but their capacity to carry other contaminants, affecting indigenous organisms of the soil / water system. The MPs adsorb hydrophobic organic contaminants, since they have a high relation surface / volume. This makes them **vectors of contamination** with the consequent risk of dispersion of **emerging pollutants** that may exceed the WWTP. Therefore, a better understanding of ecotoxicological responses in vivo of MPs and their interaction with emerging pollutants should be considered a necessary and integral part of investigations into their impacts on the environment In this study, we have conducted a set of ecotoxicological bioassays: Microtox® Test, *Caenorhabditis elegans* Test, emergence and growth inhibition of two plant species (*Lactuca sativa* and *Zea* mays) to evaluate the potential ecotoxicological risks associated with three polietylene microspheres (blue, white and phosphoren blue) ranging 212-300 μm. In addition, we have tested the interaction of these MPs with the pharmaceutical ibuprofen, and the herbicide simazine. Keywords: emerging pollutans, bioassays, microplastics

Preliminary results of the urinary bisphenol A in adolescents

M. Milanović, J. Sudy, N. Milošević, University of Novi Sad, Faculty of Medicine / Department of Pharmacy; A. Stojadinović, V. Pavlović, University of Novi Sad, Faculty of Medicine / Institute for Health Care of Children and Adolecents of

Vojvodina; B. Vuković, University of Novi Sad, Faculty of Medicine / Clinic for Endocrinology, Diabetes and Metabolic Diseases Clinical Centre of Vojvodina; N. Milić, University of Novi Sad, Faculty of Medicine / Department of Pharmacy; M. Medić-Stojanoska, University of Novi Sad, Faculty of Medicine / Clinic for Endocrinology, Diabetes and Metabolic Diseases Clinical Centre of Vojvodina
Humans are exposed to bisphenol A (BPA) through wide range of everyday products such as metal cans, food and drink plastic containers, medical devices, toys, thermal papers etc. The widespread exposure to the estrogen-like compound, BPA is related to variety of health disorders including weight gain and insulin resistance, disrupted thyroidal function, cardiovascular adverse health effects and increased carcinogenic risk. However, the findings related to the BPA levels in adolescence and possible health effects are very scarce and limited. The aim of the study was to determine the prevalence of BPA in urine among adolescents as part of the survey about the association between human disorders and exposure to endocrine disruptors in Vojvodina, the north province of Serbia. The cross-sectional study was conducted on 30 healthy adolescents from Novi Sad, Serbia, aged from 10-21 years. After the enzymatic treatment the morning spot urine samples were preconcentrated using methyl tert-butyl ether as solvent for liquid-liquid extraction. BPA was analysed in samples by gas chromatography coupled with mass spectrometry using the deuterated bisphenol A as an internal standard. The urine samples from 17 adolescents (out of 30) were positive on BPA. The higher frequency of the detection was obtained in boys (75%) in comparison with girls (50%). The obtained results suggest that adolescents are ubiquitously exposed to BPA in this region. Therefore, the special attention should be paid on urinary BPA levels in adolescents, in order to evaluate the health risks that may be associated with the obtained high prevalence of BPA contamination (57%).

Presence of different chemicals of concern in rubber crumb used in synthetic football fields
M. Rocha, A. Alves, Faculty of Engineering - University of Porto; N. Ratola, Faculty of Engineering - University of Porto / Laboratory for Process Engineering, Environment, Biotechnology and Energy
A large volume of end-of-life tires (ELT) enters the waste stream in the world each year and recycled rubber from ELT is used as infill material in synthetic turf fields and playgrounds. After research published in the past 10 years, concerns exist regarding the safety of synthetic turf fields and the governmental agencies US-EPA, in April 2016 and European Chemicals Agency (ECHA) in February 2017 conducted independent studies, which have not provided consistent evidences and found the need to obtain further information, proving that this issue is not yet closed. Although ECHA has found no reason to advise people against playing sports on synthetic turf, it made specific recommendations as: inclusion in future possible changes in REACH legislation to decrease the maximum limit of 0,001% w/w of PAHs concentrations in the rubber granules, mandatory periodic measurement of PAHs levels in rubber granules by owners and operators, guidance of producers of rubber granules towards helping manufacturers and importers to test their infill material, adequate ventilation of indoor fields and users awareness of appropriated basic hygiene measures. While exposure assessment, toxicological studies and chemical characterization of toxic substances are still under study, technological measures to eradicate the substances of concern from the rubber granules and support the use of this material have not yet been considered. This work intends to shed light on the presence of different chemicals of concern (such as polycyclic aromatic hydrocarbons (PAHs), metals and other volatile and semi-volatile organic compounds (VOCs and SVOCs, respectively) in rubber crumb used in synthetic football fields, reviewing the scientific literature available so far in this subject.

Proteomic and biochemical alterations in mussel gills after exposure to the organophosphate flame retardant TDCPP
L. Fernández González, University of Vigo / Ecology and Animal Biology; P. Sánchez Marín, Instituto Español de Oceanografia / Ecology and Animal Biology; L. Vidal Liñán, Instituto Español de Oceanografia; R. Montes, R. Rodil, J. Quintana, University of Santiago de Compostela; M. Carrera, J. Mateos, CSIC Spanish National Research Council; A. P Diz, University of Vigo / Biochemistry Genetics and Immunology; R. Beiras, University of Vigo
The organophosphate flame retardants (OPFRs) are a diverse group of substances used as flame retardants, plasticizer and anti-foaming agents in several consumer and industrial products including plastics. Like other additives, they are not chemically bound to the substrate material, and therefore they are released into the medium throughout the useful life of the products. This has resulted in the detection of the presence of OPFRs in air, soil, sediments and surface waters. Harmful effects of OPFRs have been detected in animals and humans. In the aquatic environment, the effects of the OPFRs reported are mainly in freshwater species. The aim of this study is to evaluate the effects of the OPFR tris (1, 3-dichloro-2-propyl) phosphate (TDCPP) on the gill proteome of the mussel *Mytilus galloprovincialis,* a sentinel species in marine pollution monitoring, as well as to assess the effects on molecular biomarkers, including a neurotoxic response as acetylcholinesterase (AChE) and a Phase II detoxification enzyme: glutathione S-transferase (GST). For that, mussels from a pristine area were exposed to the flame retardant TDCPP during 28 days, at a concentration of 10 μg/L. Gills proteomic analysis was performed by LC-MS/MS using "tandem mass tags" (TMTs) isobaric labelling. Stability of TDCPP in water and its bioaccumulation in *M. galloprovincialis* in tissues was also studied. Water analysis showed that TDCPP was stable in water during the course of the experiment and mussels bioaccumulated TDCPP rapidly, the bioconcentration factor being 150 L/Kg. Differentially expressed proteins upon exposure to TDCPP at both 7 and 28 days of exposure will be presented and discussed with the aim of gaining insight on the toxicological action of TDCPP and the cellular detoxification processes activated in mussels. Also, differential expression of AChE and GST proteins will be compared with the results of biochemical analysis of their activities.

TH090
Quantification of the amounts and PAH levels in different PM fractions deposited on roadside vegetation
E. Germann, RWTH Aachen; H. Fuchte, RWTH Aachen / Institute for Environmental Research (BioV); K. Smith, RWTH Aachen University / Institute for Environmental Research; N. Beck, RWTH Aachen / Institute for Environmental Research BioV; A. Schaeffer, RWTH Aachen University / Institute for Environmental Research
Particulate matter (PM) is a ubiquitous air pollutant formed by natural processes such as soil erosion or volcanic eruptions, but also anthropogenically by industrial plants and combustion processes. Major sources in densely populated conurbations include traffic exhaust (gases and soot particles) as well as tyre and brake abrasion. As the fine particles can penetrate deep into the lungs, they can cause health problems ranging from inflammation of the mucous membranes to cardiovascular diseases. Particles below 10 μm can penetrate into the bronchi, particles below 2.5 μm can penetrate into the bronchioles and alveoli and particles below 0.1 μm can even penetrate into the lung tissue and circulatory system. These health problems might be further exacerbated since the particles are loaded with various pollutants such as heavy metals or polycyclic aromatic hydrocarbons (PAH) depending on their source. Therefore, it is important to reduce these PM levels as much as possible. Here, the large surface area of urban vegetation can play a role due to its filtering effect. In this study, we investigated the amount of PM and associated PAHs retained by roadside vegetation (*Hedera helix*, ivy) next to a main thoroughfare in Aachen, Germany. Samples were collected from 5 sampling sites situated at different distances from the road. To investigate seasonal variation, samples were also taken at different time points. PM deposited on the leaf surface was collected by first washing with water, and in a second step with chloroform (to release PM bound in the cuticle wax layer). The PM was fractionated using three filter stages (10 μm, 2.5 μm and 0.2 μm) and gravimetrically quantified. Finally, the different fractions were extracted with Soxhlet and analysed for PAHs using GC-MS. SEM images of individual filters and leaves were taken to check the PM fractionation procedure as well as the particle composition.

TH091
RNA-Seq analysis of estuarine amphipods exposed to highway road dust
K. Hiki, National Institute for Environ. Studies / Center for Environmental Risk Research; F. Nakajima, The University of Tokyo / Environmental Science Center; T. Tobino, The University of Tokyo / Department of Urban Engineering; H. Watanabe, H. Yamamoto, National Institute for Environmental Studies / Center for Health and Environmental Risk Research
Road dust is a very complicated mixture of chemical contaminants, originating from many types of sources such as motor vehicle exhaust, road pavement, tire wear particles, pesticides, and atmospheric deposition. Chemicals accumulated in the dust are potentially transferred into receiving waters by rainfall and sometimes cause adverse effects on water environments. Despite the extensive previous research efforts on road runoff toxicity, little is known about the mode of action of road dust toxicity in aquatic organisms. With an aim to reveal the biological effects of road dust on the estuarine amphipod *Grandidierella japonica*, we performed de novo transcriptome analysis of the amphipod exposed to road dust collected from highways around Tokyo. The transcriptome analysis by Illumina HiSeq 2500 identified a total of 97 transcripts differentially expressed by road dust exposure. These transcripts included the transcripts related to oxidative damage (e.g., peroxiredoxin), gamma-aminobutyric acid (GABA) signalling pathway, cuticle biosynthesis and metabolism, and transferase activity of

phosphorus containing chemicals (e.g., pyruvate kinase). Among these, the expression of $GABA_B$ receptor subunit was down-regulated in the road dust treatment but remained at the control level in the treatment of road dust with a carbonaceous resin XAD-4 which can reduce the acute toxicity of road dust to *G. japonica*. This indicates that the $GABA_B$ receptor expression was the biological response associated with acute lethality by road dust exposure. The expression changes of $GABA_B$ receptor and the related transcripts (e.g., glutamic acid decarboxylase, sodium- and chloride-dependent GABA transporter, GABA transaminase) were confirmed by additional quantitative PCR experiments. Although the linkage between the molecular initiating events by road dust exposure and acute lethality was still unclear, our findings in this study provide lines of evidence to understand the mode of action of road dust toxicity and to identify the causative toxicants in urban road dust.

TH092
Transfer of chemical compounds through ingestion of micronized tire wear particles in Mysida spp.
L.L. Halle, Roskilde University / Science and Environment; A. Palmqvist, Roskilde University / Department of Science and Environment; K. Kampmann, Danish Environmental Analysis; M.H. Sandgaard, Roskilde University / Department of Science and Environment; A. Jensen, T. Hansen, Danish Environmental Analysis; F. Khan, Roskilde University / Science and Environment
Tire wear particles (TWP) constitute a significant contribution to particulate contamination of the aquatic environment. TWP are produced from driving, and may eventually be released to the surface waters, possibly together with leached granulated rubber particles used in artificial turf. Although rubber particles have been detected in wastewater treatment plants and in the aquatic environment, potential environmental impacts of this contamination and its effect on water-living organisms are largely unknown. In this present study we exposed field collected *Mysida spp.*, to varying dietary concentrations of TWP (0, 10 or 30% TWP) for 28 days. Initially, ingestion and depuration times of laboratory made micronized TWP (d< 250μm) were established. Hourly photos were obtained to track TWP in the stomach and gut, which was filled within 4 hours and emptied after 72 hours. The 28-day experiment was conducted with a daily 4-hour feeding window of 0, 10 or 30% dry weight TWP on top of regular diet (spirulina powder), after which all remaining particles were collected from the aquarium, to minimize leaching. Organisms were sampled for analysis on day 0, 14 and 28 to investigate possible chemical transfer of EPAs 16 priority PAHs, 10 tire-associated organic compounds of interest and a suite of metals, from gut lumen to tissue upon TWP ingestion. Results of the study will be discussed in this context and feed into the current debate on micro particle pollution.

Reclaiming an old fuel oil storage cave for producing sustainable energy utilizing the microbiological remediation process
A. Nousiainen, Pöyry Finland Oy / Environmental Consultancy; A. Reunamo, Finnish Enviornment Institute / Marine Research Centre
In order to ensure fuel safety, oil storage in caves has been a common practice in the Nordic countries for several decades. Due to the changes in fuel distribution and transportation, many of these caves have been emptied. The possibility to reuse these caves is challenging because residual oil is difficult to remove from the cave walls. However, if the oil can be eliminated, the caves can be reclaimed to produce sustainable, renewal energy as heat storages or by storing the energy of the sun heated seawater to be used in the cold winter months. This case study demonstrates the reclamation of an oil storage cave in Helsinki, Finland by utilizing the oil degrading bacteria naturally present in the sea water. The oil degrading bacterial communities of the Baltic Sea are known to be efficient oil degraders in optimal conditions, and could be utilized as the sole bioremediation agent. Sea water was collected in the late summer from Haakoninlahti bay in Helsinki, as well as water from a nearby decommissioned diesel oil storage cave in Kruunuvuori. The Kruunuvuori cave has a volume of 300 000 m^3, and is currently approximately one third full of oil contaminated groundwater. Oil degradation was tested in aquarium scale experiments corresponding to three scenarios: 1) oil degradation in the cave, 2) oil degradation in the cave if it is filled with seawater, and 3) oil degradation in the cave if it is filled with seawater and aerated. The C_{10}-C_{40} oil concentrations in the aquariums were measured at 0h, 1 week, 2 weeks, and 6 weeks. DNA samples were taken from each sampling to measureoil degradation genes PAH-RHDα GN, PAH-RHDαGP and AlkB by quantitative PCR. Bacterial V3-V4 and archaeal V4 regions of 16srDNA gene and fungal ITS1 regions from selected time points were sequenced by Ion Torrent for microbial community structure analysis. Our results show, that in six weeks 72% of the oil was degraded in the cave water in laboratory conditions. Mixing the cave water with 2/3 volume of sea water increased degradation to 96%, and mixing seawater and aeration to 96%. The copy numbers of PAH degradation genes were orders of magnitude lower than alkane degradation genes, indicating that alkanes are degraded rapidly. Our results show, that the residual oil is degraded naturally in the storage cave, but the addition of seawater enhances and accelerates the process.

TH094
Depth distribution of phototrophic bacteria, redox potential and hydrogen sulfide in highly stratified meromictic lakes of the White Sea region
A. Zhiltsova, M.V. Lomonosov Moscow State University / Faculty of Physics; A. Kharcheva, M.V. Lomonosov Moscow State University / Faculty of Physic; P. Emelyantsev, M.V. Lomonosov Moscow State University; E. Krasnova, Lomonosov Moscow State University, Faculty of Biology; D.A. Voronov, A. Kharkevich Institute for Information Transmission Problems of Russian Academy of Science; N.M. Kokryatskaya, G. Losyuk, N. Laverov Federal Center for Integrated Arctic Research Russian Academy of Science; S. Patsaeva, Lomonosov Moscow State University / Depament of General Physics
Ecological monitoring of sub-Arctic water bodies is essential for studying their evolution under the action of global climate change and other natural processes; it becomes extremely important when solving such practical problems as construction of tidal power plants, seawalls, bridges, and other hydraulic structures leading to the separation of water areas from the sea. As a result of isolation, the ecosystem of a saline water body undergoes irreversible changes: the surface water layer gradually becomes fresh and the near-bottom water stagnates with the formation of oxygen deficiency and hydrogen sulfide accumulaction. This leads not only to changes in the physicochemical characteristics of the water mass but also implies sharp changes in the microbial community which distribution can be monitored using optical spectroscopy. Along the coastline of the Kandalaksha Bay of the White Sea several lakes are known to be at different stage of separating from the Sea. We summarize the results of complex inspection of 5 meromictic lakes and lagoons performed in different seasons in 2014-2018. We sampled water from various depths and measured water temperature, salinity, pH, Eh, dissolved oxygen content, and illumination in the field. In laboratory conditions spectroscopic investigations of natural water samples and measurements of dissolved oxygen and sulfide anions (S2–) were carried out. The total Chl *d* and *e* concentrations were calculated from absorption spectra of pigment extractions in acetone:methanol mixture or directly from absorption spectra of intact bacterial cells in natural water using the recently developed technique. Spectroscopic methods allowed us not only to determine the presence of green sulfur bacteria (*Chlorobiaceae*), anoxygenic phototrophic bacteria, at different horizons but also to draw conclusions about relative concentrations of two forms of green sulfur bacteria (green-colored and brown colored) in each lake. Comparing the photosynthetic pigment concentrations with physicochemical parameters of water in the lakes made it possible to reveal favorable conditions for green sulfur bacteria: a layer with a sharp gradient of hydrogen sulfide concentration, salinity, and change of the redox potential from positive to negative. This study was supported by the Russian Foundation for Basic Research, project No 16-05-00548, and by the grant from the “Bazis” Foundation for Development of Theoretical Physics and Mathematics.

How was the Sour-Sweet Lake (Kandalkshsky Bay of the White Sea) born?
T. Repkina, Lomonosov MSU / Faculty of Geography (Geomorphology and Paleogeography); E. Krasnova, Lomonosov Moscow State University, Faculty of Biology; A. Entin, M.V. Lomonosov Moscow State University / Faculty of Geography
During course-work practicums at the White Sea based on Nikolai Pertsov White Sea Biological Station, the second year students of Geomorphology and Paleogeography, Cartography and Geoinformatics departments of faculty of geography, Moscow State University, developed a method of integrated geomorphological mapping of the seabed, coastal zone and seaside land. The purpose of the work is to identify the mechanisms of transformation of the seabed in the coastal zone. On the northern coast of the Kindo Peninsula, a tacheometric and geomorphological survey and aerial photography of the coastal strip from an unmanned aerial vehicle (UAV) were carried out. A bathymetric survey was performed in the Rugozerskaya Bay, the Velikaya Salma Strait and the Kislo-Sladkoe Lake. The granulometric analysis of bottom sediments , tidal zone, beaches and coastal terraces was carried out. A combined digital elevation model (DTM) of the coast and the bottom, the geomorphological maps and orthophotoplans of key sections were compiled. The seabed relief of the glaciated shelves consists of structural-tectonic and glacial forms, partially modified by the processes of underwater morpholithogenesis. As a result of theglacioisostatic uplift of the coast the highest forms gradually fall within the wave impact zone. In the coastal zone, they undergo significant processing under the action of waves, tides, fast ice and biogenic processes manifesting in dramatic changes in the morphological characteristics and composition of sediments. Sea bays and straits turn to meromictic lakes and lagoons, and later to freshwater lakes and swamps. Mosaic-like morpholithodynamic situation control the time for specific sections of the coast to emerge from under sea level. At the semi-isolated lake Kislo-Sladkoe (Rugozerskaya bay, Kanadalaksha Bay, White Sea) northern strait formerly connected the lake with the sea was closed by sand spit created by the waves. The study allows to determine that the creation of the spit made the process of lake separation almost 150-250 years faster.

TH096
Spectroscopic characterization of CDOM in contrasting lakes Svetloe and Tyomnoe (Arkhangelsk region), extremely pure and extremely reach in humic substances
N.M. Kokryatskaya, G. Losyuk, N. Laverov Federal Center for Integrated Arctic Research Russian Academy of Science; S. Patsaeva, Lomonosov Moscow State University / Depament of General Physics
The Arkhangelsk region is distinguished by a large number of lakes; according to estimates there are about 74000 water bodies. The majority of the lakes in the region were formed after disappearance of the last glacier, and some lakes have tectonic origin. Small lakes, abundant in the region, are especially significant from the viewpoint of a carbon biogeochemistry. The chromophoric dissolved organic matter (CDOM) is a complex mixture of organic biochemicals that undergo various pathways of diagenetic alteration. The CDOM absorbs UV and visible light and is a major determinant of optical properties for both fresh and marine waters, directly affecting the spectral quality of the underwater light field. The CDOM optical properties are currently used for monitoring of aquatic ecosystems. Fluorescence spectra of different CDOM types may vary in wavelength of emission maximum, fluorescence quantum yield values and their dependence upon excitation wavelength. We describe depth profiles of optical characteristics (absorbance, wavelength-derivated absorbance spectra, fluorescence emission and excitation spectra) for two contrasting freshwater lakes located in Arkhangelsk region: extremely pure (Svetloe Lake) and extremely reach (Tyomnoe Lake) in humic substances. Both studied lakes are located in boreal taiga within 100 km from Arkhangelsk. The Lake Svetloe is the first in a system of 5 lakes giving rise to the Svetlaya River, which belongs to the White Sea catchment area. Its maximum depth is 39 m; the area of the mirror is 0.125 km^2. The Lake Tyomnoe has maximum depth 37 m, the area of the mirror is 0.094 km^2. Both lakes are meromictic and belong to a specific type of water bodies intriguing researchers in many countries of the world. The chemocline is located at 20 m in Svetloe and at 25 m in Tyomnoe dividing water column in two zones with differing optical characteristics. The presence of chemical stratification, redox processes within the chemocline zone, contrasting optical properties lets us to consider those lakes as unique research objects for understanding both modern and ancient aquatic ecosystems. Those lakes, remote from major industrial centers, are especially interesting for the assessment of climate change effects as they are minimally influenced by acid rains and local anthropogenic impacts.

Linking Models, Experiments and Measurements to Reliably Investigate the Environmental Fate and Effects of Hydrophobic Organic Contaminants and Mixtures (P)

Determining the influence of street vegetation on PAH loads in the surface run-off from urban streets.
N. Beck, RWTH Aachen University; H. Fuchte, Institute for Environmental Research, RWTH / Institute for Environmental Research (BioV); E. Germann, A. Schaeffer, K. Smith, RWTH Aachen University / Institute for Environmental Research
Organic pollution in the environment is mainly caused by development and urbanisation. Especially in the city, many sources of pollution occur including power stations, factories or traffic. Polycyclic aromatic hydrocarbons (PAH) are a group of relevant and potentially carcinogenic organic pollutants with traffic being one important source. Here, the main PAH sources are exhaust gases, road and tyre wear, and leakage of motor oil. Gaseous as well as particle-bound PAHs get into the air, leading to exposure of the inhabitants. Further to the pollution of air by PAHs, they deposit to urban surfaces and are then washed off by rain into the sewer system. This leads to a potential contamination of surface waters and their sediments. Several studies have shown that vegetation can reduce pollutant loads via a filtering effect. Therefore, urban vegetation can potentially have a positive impact on health and quality of life. The aim of this work was to determine a possible impact of urban greening on PAHs in street run-off. In September 2018, run-off was collected at five locations with different amounts of vegetation along a main thoroughfare in Aachen, Germany using specially constructed sediment traps placed in the road drains. PAH concentrations in the water-phase were determined by both grab and passive sampling, and the particle-associated PAHs in the collected sediment. Total water flows were determined by coating the outer trap walls with plaster and measuring the weight loss. Additionally, the sediment was analysed with a CHN analyser to determine the natural organic matter and soot amounts. PAH concentrations and profiles were compared for the different street sections and related to the different amounts of vegetation.

TH098
Liposome mediated delivery of challenging organic chemicals to Daphnia magna
M. Castro, D. Lindqvist, Stockholm University / ACES
Liposomes are phospholipid vesicles widely used in drug delivery, shown to be beneficial for stabilizing the delivery of therapeutic compounds.[1] It has been observed that giant liposomes (6-7 µm) can be efficiently taken up as food particles by filter feeders when they share the same size range as their food.[2,3] Giant liposomes can be used as a delivery system of a wide range of organic chemicals: hydrophobic chemicals can be trapped within the lipid bilayer, whereas hydrophilic and ionic compounds can be encapsulated in the aqueous pocket.[1,4] This offers the advantage to study challenging chemicals for aquatic toxicity testing, when the use of a solvent carrier does not allow a controlled exposure to the toxicant. Moreover, their natural buoyancy and composition (non-toxic, digestible components), adds to the advantages of using such approach in this context. In this study, we prepared large phospholipid vesicles in synthetic freshwater (M7 medium). Liposomes were prepared with a mixture of phosphatidylcholine and cholesterol, and a final average size of 6.1 ± 0.44 µm. Staining of the liposomes with the fluorescent dye Nile Red allowed us to confirm the ingestion of liposomes by *D. magna*,viewed under the microscope. Uptake rate of liposome particles was also measured and compared with the uptake rate of algae cells. Thereafter, liposomes were prepared with 1% (w/w) ^{14}C-labelled chemicals, to evaluate the encapsulation yield. The chemicals tested were tetrabromobisphenol A (TBBPA, log K_{ow} 5.9, pK_a 7.5), medium-chain chlorinated paraffin CP-52 (log K_{ow} 8-12) and the amphiphile perfluorooctanoic acid (PFOA, pK_a 2.8). When the chemical-specific encapsulation yield was known, animal experiments were conducted to evaluate the survival of *D. magna* after aqueous or liposome-mediated chemical exposure. Survival of the neonates (2 mL water/ animal) was followed for 48 hours, as according to the OECD guideline 202. Several concentrations were used by manipulating the ratio of dosed and chemical free liposomes. The major aims of this work was to i) establish differences in internal dose of the different chemicals via aqueous or liposome-mediated exposure, ii) compare the dose-response curves, and iii) ultimately, validate the use of liposomes for as a controlled delivery method for challenging chemicals.

TH099
Predicting mobility of hydrophobic organic chemicals in soil: exploring limits and reliability of multimedia fate models
C. Vitale, University of Insubria; E. Terzaghi, University of Insubria (Como) / Department of Science and High Technology, Como; A. Di Guardo, University of Insubria / Department of Science and High Technology
A soil column leaching experiment was performed to investigate the effect of many influential variables on vertical transport of polychlorinated biphenyls (PCBs) in an aged contaminated soil. The factors investigated were: 1) contact time between soil and leaching solution (2, 5, 7, 48 days), 2) dissolved organic carbon (DOC) content in leaching solution (tap water *vs.* Aldrich humic acid), 3) temperature (25 °C *vs.* 15 °C) and 4) soil saturation conditions (saturated *vs.* field capacity conditions). Additionally, the transport mediated by mobile organic carbon (OC) coated fine particles/colloids was accounted for. Measured bulk water concentrations were compared to data predicted using a multimedia environmental fate model (SoilPlusVeg) to explore model performance, limits and predictive capability. The factors instigated had a relevant influence on DOC and particle production and movement, with significant variations in PCB leachate concentrations (up to 1 order of magnitude), generally not captured by model simulations. Environmental fate models substantially mismatched predicted and observed concentrations, especially for the high chlorinated congeners because some key features are missing: 1) the transport of chemicals associated to small particles/colloids; 2) the modulation of the production of DOC/particles varying with temperature, soil/water contact time and environmental conditions; 3) the chemical sorption/desorption kinetics.

TH100
Experimental measurements and modeling assessment of snow scavenging of octamethylcyclotetrasiloxane (D4) and decamethylcyclopentasiloxane (D5)
S. Xu, Dow Chemical Company / Toxicology and Environmental Research and Consulting; J. Miller, Impact Analytical; A. Vogel, The Dow Chemical Company; J.A. Durham, Dow Corning Corporation / Toxicology and Environmental Research Consulting
Snow scavenging of two volatile methylsiloxanes, octamethylcyclotetrasiloxane (D4) and decamethylcyclopentasiloxane (D5), was examined by a combination of laboratory measurements and modeling assessment. In the experimental study, snow sorption coefficients of ^{14}C-labeled D4 and D5 on snowflakes (K_{iA}) were measured against a benchmark compound, cyclopentanone, at different temperatures varying from -2 to -20 °C using a custom-made snow chamber. In addition, the transfer of D4 and D5 in snow to surface media was measured in simulated snow melting experiments using ^{14}C-D4 and -D5 spiked snowpacks (30 cm thick) placed on top of a frozen soil layer (10 cm thick) under controlled air flow rates (representing wind speeds). In the modeling assessments, the snow scavenging effects in Polar Regions with yearly snow-melting processes were evaluated with the measured K_{iA} values and other physicochemical properties such as air/water (K_{AW}) and octanol/air (K_{OA}) partition coefficients and their temperature dependences, and the transfer efficiency of D4 and D5 in snow melting processes. It was found that the gas scavenging of D4 and D5 was small because of their small K_{iA} values, while the particle scavenging is negligible due

to D4 and D5's small K_{OA} values (thus small K_P values) together with low aerosol concentrations in the Polar atmosphere. Most importantly, almost 99% of all D4 and D5 in a snowpack was lost during the snow melting process and D4 and D5 became non-detectable in snowmelt water and surrounding soil. In short, snow scavenging is not an effective deposition mechanism for these volatile hydrophobic compounds.

TH101

Mass Balance of Atmospheric PAH at Alpine Lysimeter

T. Schiedek, Applied Geosciences / Hydrogeology; L. Nersissian, Technische Universitaet Darmstadt / Applied Geosciences; S. Birk, University of Graz / Department of Geosciences; M. Herndl, Bundeslehr- und Forschungsanstalt Raumberg-Gumpenstein

Polycyclic aromatic hydrocarbons (PAH) are well known ubiquitous organic contaminants, which are emitted to a huge extent into the atmosphere (emissions of EPA-PAH benzo(a)pyrene in 2016 in Germany ca. 30 t/a). Little is known about atmospheric deposition and mass balances in alpine regions. Meyer et al. (2006) showed a PAH flush release in snow lab experiments simulating cold environments. The ecological impact, particularly at e.g. eco-sensitive alpine regions is unknown. This study is aiming the quantification and mass balance of atmospheric PAH in alpine soil lysimeter from precipitation, soil and seepage samples. The 2 lysimeter are located at Mount Stoderzinken (1800 m amsl) and Gumpenstein village (696 m amsl) in the Northern Limestone Alps in Austria. All investigated PAH could be quantified in the soil samples, but at different concentrations. At Gumpenstein in the same order of magnitude at all sampling sites, but not at Stoderzinken (remarkable differences from site to site). Usually heavy PAH (molecular weight MW > 202) were enriched. During summer, PAH concentrationsin water samples (precipitation, seepage) with MW < 202 were in the same order of magnitude. PAH with MW > 202 were detected in precipitation samples, but not in snow samples. PAH mass balances were calculated for May/June and autumn 2016 at both lysimeter showing higher input rates at Stoderzinken. At Stoderzinken for 6 detected PAH (naphthalene Nap, fluorene Fln, benzo(b)fluoranthene BbF, benzo(e)pyrene BeP, phenanthrene Phe, pyrene Pyr) the mass balance indicated an accumulation in soil for May/June for Nap, Fln, BbF und BeP. A release was found for Phe, Pyr und Fln. We assumea particle and or colloid transport due to the low water solubility and high sorption coefficient of those compounds. Lysimeter Gumpenstein showed for May/June an input into soil for Fln and Pyr and output of Nap, Fln and Pyr. In September 2016 Nap, Fln, Phe and Pyr were deposited at Stoderzinken as well (no BeP and BbF), in addition benzo(a)pyrene was accumulated. Nap showed higher abundance compared to June/May and was detected in the output as well. At Gumpenstein it was possible to balance from Oktober to December 2016, with similar results like at Stoderzinken in September: High Nap in- and output, input only for PAH with MW > 202. We assume the heating season for the different results in summer and autumn/winter.

TH102

Bisphenol A study in rainbow trout (Oncorhynchus mykiss) at elevated environmental concentrations

V. Cerkvenik Flajs, University of Ljubljana, Veterinary Faculty / Veterinary Faculty; S. Šturm, V. Jenčič, B. Cerk, T. Švara, University of Ljubljana, Veterinary Faculty; M. Gombač, University of Ljubljana, Veterinary Faculty / Veterinary Faculty; M. Pogačnik, University of Ljubljana, Veterinary Faculty

A study on rainbow trout (*Oncorhynchus mykiss*) fingerling weighted from 10–20 g was conducted in the laboratory. For 20 days fish were exposed to nominal water concentration of bisphenol A (BPA) of 1 µg/l, 20 µg/l and 0 µg/l for the first, second and third group, respectively. To ensure adequate water quality while maintaining tested concentrations of BPA in a closed water system fish were moved between two aquariums in one and two-day intervals. In the study every second day, seven fish per group were sacrificed, dissected and muscle and skin tissue samples were collected and pooled. In addition, water samples were taken before and after fish were settled in the aquaria. Aquaria water and muscle tissue samples were analysed for the presence of BPA by either isocratic or gradient reversed-phase HPLC using water and acetonitrile as a mobile phase, Hypersil Gold C18 (3 µm) analytical column, and fluorescence detection. Aquaria water samples were measured either directly, after proper dilution, or with a pre-concentration using solid phase extraction (SPE) phase Chromabond HR-X. Homogenised muscle tissue samples were extracted with acetonitrile and purified with the two SPE phases, at first with Chromabond HR-X and secondly with (MIP) AFFINIMIP® SPE Bisphenol A. Limit of detection values of BPA determination were 0.1–0.5 µg/l for aquaria water and 1 µg/kg for fish muscle and skin in natural proportions. The results showed that the deviation values of the measured exposure concentrations from the nominal concentrations were low, on average by –14.8 and 1.7% for the group exposed to 1 and 20 µg BPA/l, respectively. Breakdown of BPA in water with fish was in correlation with the number of fish in aquaria and duration of inhabitation period. After one-day settlement with fish it was 41 and 54% on average, and after two-day settlement, concentrations of BPA dissipated on average for additional 28 and 9% for the group exposed to 1 and 20 µg BPA/l, respectively. On the wet weight basis, concentrations of BPA in the fish muscle and skin tissue, ranged from 3.3 µg/kg (days 14 and 16) to 7.6 µg/kg (day 2) for the group exposed to 1 µg BPA/l, and from 18.3 µg/kg (day 4) to 75.5 µg/kg (day 20) for the group exposed to 20 µg BPA/l. The presented study aimed to contribute to understanding the BPA exposure concentrations and its bioaccumulation in the environment.

TH103

Passive sampling of traffic-derived dissolved pollutants in street run-off from urban areas with different amounts of vegetation

H. Fuchte, Institute for Environmental Research, RWTH / Institute for Environmental Research (BioV); N. Beck, RWTH Aachen University; E. Germann, K. Smith, A. Schaeffer, RWTH Aachen University / Institute for Environmental Research

The constantly rising demand for mobility is accompanied by increasing emissions of traffic-derived pollutants. This causes problems, especially in urban areas where traffic is high, air exchange low and the surfaces predominantly sealed. Considerable amounts of the emitted contaminants deposit to urban surfaces, where they can be re-dispersed or get flushed into street drains during rain events. Particularly during heavy rain, untreated run-off can therefore directly enter surface waters. An important role in managing rising pollutant emissions can be played by urban green, with the huge surface of the foliage and the soil underneath offering the potential for filtering and binding the pollutants, leading to a lower bioavailability.\n \n To further investigate the influence of urban vegetation, a field study was conducted along a busy ring road in Aachen city (Germany) with greened and non-greened sections. Over one month, surface run-off was sampled in five street drains equipped with passive samplers for the determination of time weighted average (TWA) concentrations of the traffic-derived dissolved pollutants. The samplers were used in kinetic mode with the hydrodynamic conditions varying strongly between dry and rainy periods. Therefore, a robust sampler calibration was necessary and two methods were compared (i) a new approach using the concentration ratios of samplers with different thicknesses and (ii) an established approach based on the release rates of performance reference compounds. Polycyclic aromatic hydrocarbons were chosen as marker substances, since they show a wide range of physical-chemical properties, thus allowing for extrapolation to other traffic pollutants.

TH104

Impact of soil conditions and simultaneous application of 6 pharmaceuticals on their sorption and degradation in 7 soils

R. Kodesova, Z. Schmidtova, M. Kocarek, Czech University of Life Sciences Prague / Dept of Soil Science and Soil Protection; K. Grabicova, University of South Bohemia in Ceske Budejovice / Faculty of Fisheries and Protection of Waters; A. Klement, M. Fer, A. Nikodem, Czech University of Life Sciences Prague / Dept of Soil Science and Soil Protection; R. Grabic, University of South Bohemia in Ceske Budejovice / South Bohemian Research Center of Aquaculture and Biodiversity of Hydrocenoses

The leakage of pharmaceuticals present in soils towards groundwater and their uptake by plants are largely controlled by sorption and degradation of those compounds in soils. Standard laboratory batch sorption and degradation experiments were performed using soil samples taken from top horizons of seven different soil types (Stagnic Chernozem Siltic, Haplic Chernozem, Greyic Phaeozem, Haplic Luvisol, Arenosol Epieutric, Haplic Cambisol, Dystric Cambisol) and 6 pharmaceuticals (carbamazepine, citalopram, clindamycin, fexofenadine, irbesartan and sulfamethoxazole), which were applied either in single-solute solutions or their mixture. The sorption affinity of different compounds depended on their form and particular soil properties. The sorption of positively charged compounds (citalopram and clindamycin) increased with the increasing base cation saturation of soils. The sorption neutral and negatively charged (sulfamethoxazole and irbesartan) and zwitter-ionic (fexofenadine) molecules decreased with the increasing base cation saturation of soils. Sorption of carbamazepine depended on the organic carbon content. In soils of the high pH and high base cation saturation, the largest sorption was obtained for citalopram, followed by fexofenadine, clindamycin, carbamazepine, irbesartan and sulfamethoxazole. In soils of the low pH and low base cation saturation, the irbesartan sorption affinity was between fexofenadine and clindamycin sorption affinities. The simultaneous applications of all pharmaceuticals slightly decreased sorption of carbamazepine, and clindamycin, and increased sorption of fexofenadine, irbesartan and sulfamethoxazole. This documented completion of some compounds for the same sorption sites but also compound synergy. The compound degradations depended overall soil conditions that affected microbial activities in soils. The highest half-lives were observed for citalopram followed by carbamazepine, fexofenadine, irbesartan, clindamycin and sulfamethoxazole. The simultaneous application of all compounds increased the half-lives of carbamazepine citalopram, fexofenadine and irbesartan, which can be likely explained by the negative impact of antibiotics (sulfamethoxazole and clindamycin) on soil microbial activity.

TH105

Why and what scientists should know about intercomparison studies?

K. Björklöf, R. Koivikko, M. Leivuori, Finnish Environment Institute SYKE / Reference Laboratory

Analytical test results are used to test, monitor, assess, and model the state of environment. The reliability of any result used depends on the quality of the whole chain of its production. The end user of any numerical or qualitative result must rely on the proficiency of that chain. For environmental data the chain covers the field observations and sampling as well as data production in environmental laboratories. One way for the data producer to demonstrate its competence is to take part in intercomparison studies. Intercomparison studies are comparisons performed in accordance with predetermined conditions by two or more participants. The competence of individual participants is evaluated by the objective scheme, including measurements of the same or comparable tasks. Intercomparison studies provide an effective external way to assess participant's proficiency to produce certain information and whether the participant's procedures are fit for purpose. Participants can use the results to confirm the quality of their measurements and to compare their results to those of other participants, also they may promote their quality to their customers. Proftest SYKE provides a wide range of intercomparison studies for analysis of environmental samples and recycled materials. The open access reports of Proftest SYKE intercomparison studies are published at the Digital Repository of the University of Helsinki. The results are presented anonymously, but the participants are listed in each report. The publicly available reports are found to be important not only for the participants but also for a much wider audience. Different authorities responsible of e.g. monitoring data on the area of environmental health, accreditation bodies and various researchers exploit the open access of the reports. End user of the analytical test results should understand the basics of the quality assurance procedures. Scientists and other end users of the test results could request and obtain the quality information related to the provided data from the data producer, and utilize the information when employing the data. Participation in the intercomparison studies and documented good performance in them is evidence of satisfactory quality of the results. Reference: www.syke.fi/proftest/en

TH106

Can long-range atmospheric transport events of "new" POPs to a remote site in Norway be predicted using FLEXPART?

C.C. Moeckel, NILU - Norwegian Institute for Air Research / Environmental Chemistry; S. Eckhardt, NILU - Norwegian Institute for Air Research / Atmosphere and Climate Change Department; I.S. Krogseth, Norwegian Institute for Air Research / Environmental Chemistry; K. Breivik, NILU - Norwegian Institute for Air Research

Air monitoring of organic contaminants with suspected POP properties at background sites helps to assess their long-range atmospheric transport (LRAT) potential. The most accurate approach is active sampling but this is often limited to intermittent collection, e.g. one day per week. Regarding LRAT, such sampling strategies may be incomplete if the sampling schedule misses episodes of heavy influence by LRAT. Despite their low occurrence, these episodes can have a significant effect on the overall pollutant amounts transported to remote sites. The Lagrangian particle dispersion model FLEXPART was applied earlier to successfully forecast LRAT-dominated episodes for polychlorinated biphenyls (PCBs). Using emission data for PCB-28 as model input, it predicted the relative temporal variation of concentrations equally well for other PCB congeners too. Unfortunately, for many other compounds emission estimates are not available, e.g. for some industrial organic contaminants of emerging interest. Our aim is to assess whether possible spikes in concentrations of such chemicals can be predicted, detected and potentially explained by LRAT, assuming similarities in source regions as for the PCBs. Targeted air sampling was carried out at the Birkenes observatory (southern Norway) over 24 h each, using a high volume active sampler at a sampling rate of ca. 50 m^3/h. Samples were collected during periods when the model-based forecasted air mass transport path, and the resulting predicted concentration of PCB-28, indicated potentially interesting events. The samples will be analysed for compounds suspected to behave similar to PCBs and/or which have only very recently been added to Annex A of the Stockholm Convention, such as chlorinated paraffins, dechlorane plus and selected brominated flame retardants. To help with the interpretation of the data we will also analyse compounds with already identified LRAT potential, such as PCBs and PBDEs. The results will help to evaluate whether the selected contaminants of emerging interest undergo LRAT and where their source areas are. If FLEXPART can predict concentration variations sufficiently well, then a model-based sampling strategy may complement intermittent monitoring strategies and provide valuable information about atmospheric source-receptor relationships.

TH107

Environmental fate and behaviour of thifensulfuron methyl metabolites

W.K. Winiarska, Institute of Industrial Organic Chemistry / Department of Ecotoxicological Studies; A. Godziek-Botor, A. Żmijowska, M. Wójcik, Institute of Industrial Organic Chemistry Branch Pszczyna / Department of Ecotoxicological Studies

Nowadays, herbicides are widely used for the purposes of weed control in households and arable field spraying in agricultural production. Therefore, there is a risk that active substance residues and metabolites may leak into the soil. The presence of pesticide residues in the soil can cause damage to sensitive follow-up plants. Residues of pesticides can also get into groundwater. Hence, it is extremely important to determine the dynamics of pesticide degradation in the soil. For this study thifensulfuron methyl metabolites were selected. The reason for it was their common occurrence in various herbicides commercially available in Poland. This herbicide is used as a post-emergence herbicide for the control of grass and broad-leaved weeds. Thifensulfuron methyl is commonly used in wheat, barley, triticale, rye and maize crops. This study was aimed at determining the rate of degradation of thifensulfuron methyl metabolites in three types of soils commonly found in Europe. The DT_{50}, DT_{75} and DT_{90} values represent the time within which the concentration of thifensulfuron methyl metabolites is reduced by 50%, 75%, and 90 %, respectively. Other aims of the study were to assess the adsorption and desorption behaviour of thifensulfuron methyl metabolites on five different soil types and to determine the K_d, K_{oc}, K_{Fads}, and K_{des}. Based on the obtained results, it was shown that the dynamics of degradation of the investigated metabolites of thifensulfuron methyl depended on the soil (i.e. the amount of organic carbon, microorganisms biomass, or the pH level). It was also shown that these metabolites had different affinities for soils.

TH108

First results from the AQUA-GAPS program for global monitoring of POP

F. Smedes, Masaryk University, Faculty of Science, RECETOX / Environmental chemistry and modelling; J. Sobotka, Masaryk University, Faculty of Science, RECETOX / Research centre for toxic compounds in the environment; R. Lohmann, Graduate School of Oceanography, University of Rhode Island, Narragansett, Rhode Island 02882 / Chemical Oceanography; D.C. Muir, Environment and Climate Change Canada / Aquatic Contaminants Research Division; E.Y. Zeng, Jinan University / School of Environment; P.A. Helm, Ministry of the Environment, Conservation and Parks / Environmental Monitoring and Reporting Branch; L. Bao, Jinan University / School of Environment

Under the Stockholm Convention on persistent organic pollutants (POP), the Global Monitoring Plan (GMP) collects data on POP levels in human milk and air, but not in the aqueous environment. Inspired by GAPS (Global Air Passive Sampling), an international group of scientists meeting at Jinan University (2016, Guangzhou, China), started a passive sampling program in the aqueous environment, each using their network to expose passive samplers all over the globe, giving birth to "the AQUA-GAPS initiative". Indeed, monitoring POP in water on global scale is a (logistical) challenge, but has become feasible with the further maturation of aqueous passive sampling procedures. The resulting freely dissolved concentration have little confounding factors allowing comparison on a global scale. Instead of merely reporting freely dissolved concentrations, passive sampler data can also be converted to lipid basis, which represents a relevant indicator for the exposure conditions for aquatic organisms. Besides providing data for assessing spatial and temporal trends of POP, AQUA-GAPS will also act as a platform for expertise exchange and assisting participants that want to extend the local spatial coverage. Hardware for sampler deployments was manufactured and passive samplers, both silicone and LDPE, were prepared and send to participants in the network. Presently AQUA-GAPS covers approximately 30 sampling sites distributed over North and South America, Europe, Africa, Australia and Asia. Samplers were analyzed at RECETOX, Masaryk University, Czech Republic and from the uptake aqueous and lipid based concentrations of various compounds were derived. These are polycyclic aromatic hydrocarbons, polychlorinated biphenyls, various chlorinated pesticides, organo-phosphate and brominated flame retardants. Other pollutants of global concern will be included over the course of time when samplers and analytical methods become available. In this poster the first results will be presented showing spatial occurrence of the listed compound groups.

Recommendations for the monitoring of priority substances in freshwater fish based on practical experiences

N. Bandow, German Environment Agency / Contaminant Transfer and Environmental Technologies; A. Duffek, German Environment Agency-Umweltbundesamt; G. Radermacher, Fraunhofer IME - Institute for Molecular Biology and Applied Ecology / Environmental Specimen Bank and Elemental Analysis; A. Fliedner, Fraunhofer IME Institute for Molecular Biology and Applied Ecology; H. Ruedel, Fraunhofer IME - Institute for Molecular Biology and Applied Ecology / Department of Environmental Monitoring

The Water Framework Directive (WFD) and in particular Directive 2013/39/EU set requirements for monitoring of environmental quality standards (EQS). For compounds, which tend to bioaccumulate in biota and show a risk of secondary poisoning or for human health by fish consumption, EQS were derived for biota (fish, mollusc and shellfish). To support the implementation of biota monitoring in Germany a research project was initiated with the aim to integrate all legal requirements into an appropriate monitoring concept. A comprehensive sampling campaign including six sampling locations (rivers, lake and a lagoon at the Baltic Sea) and three fish species with twenty individuals per species was conducted. Beside biometric data, concentrations of total mercury and organic substances such as perfluorooctanesulfonate (PFOS), brominated diphenyl ethers (BDE) or hexachlorobenzene were determined in pooled fillet and carcass samples. This data set allows the evaluation according to fish species, age, size, weight, sex and trophic level. Furthermore, the concentrations in fish fillet and whole fish were compared as the use of fillet samples better reflects protection of human health via fish consumption, which is the protection goal for five of the nine biota EQS for fish. Based on the results of this study, recommendations for future monitoring are given. Special focus is laid on a good compromise between scientific justification and aspects of practical implementation.

TH110
Studying desorption of additives from polymers using quartz crystal microbalance
L. Xiao, Department of Chemistry, Umeå University / Department of Chemistry; Z. Zheng, Umea University / Department of Chemistry; P. Andersson, Umea University / Chemistry Department
Various additives, including plasticizers, flame retardants, and UV filters, are incorporated into virgin polymers to improve their properties and enhance their processabilities. These additives are not bound to polymers and can be released from the matrix to the surroundings during their production, use, recycling or disposal phase. These chemicals could pose a hazard and cause adverse effects on human health and the environment. It is of great importance to study desorption mechanisms to increase our understanding of chemicals fate in products and the environment. Quartz crystal microbalance (QCM) is a fast and highly sensitive tool for environmental research at solid/liquid interface with the advantage of high accuracy (*i.e.*, ng cm^{-2}) in real time, which is rarely used for studying desorption processes of additives. The aim of this research was to study desorption characteristics of additives from various polymers using QCM and to predict their emission rates. The specific aims were: (1) to develop a fast and highly sensitive system to measure desorption kinetics of additives in real time; (2) to study effects on desorption of factors, such as polymer properties, temperature, pH, and salinity; and (3) to establish desorption kinetic models for predicting emission rates of various additives. Commonly used polymers, including polyvinyl chloride (PVC), polystyrene (PS), polyethylene terephthalate (PET), and poly(methyl methacrylate) (PMMA), were selected in our study. They differ in e.g. hydrophobicity, crystallinity, glass transition temperature, and hydrogen bonding properties, which affect desorption of additives. Virgin polymeric materials were blended with selected additives, which octanol-water partition coefficient (log K_{ow}) values ranged from 1.6 to 7.0. The composites including PVC, PS, PMMA, or PET were coated on QCM electrodes to measure desorption in real time. We found that desorption of additives can reach steady-state in less than 12 hours, which differed depending on studied polymers, log K_{ow} value of additives, and loading content. Additives with high log K_{ow} value or blended with hydrophobic polymers showed lower desorption rates. In a next step, contact angles and crystallinity of polymer films will be measured to increase our understanding on desorption behaviors of additives from a molecular interaction perspective. Furthermore, desorption data will be used to establish kinetic models to predict emission rates of ranges of additives.

TH111
Development of Multimedia Fate Model for Human Risk Assessment of EDCs in the South Korea
Y. Kim, Greenecos Inc. / CEO; J. Kim, M. Choi, Greenecos Inc.
Multimedia fate model, HURAME (multimedia fate model for HUman Risk Assessment in Multimedia Environment) has been developed considering topographic features and environmental and been meteorological data of watershed region of South Korea. Human risk assessment system using this multimedia fate model was established and integrated to assess spatial exposure and risk about human living in this area. For this purpose, first, GIS database system consisting of environmental and meteorological data and measured data of hazardous chemicals was developed. Second, Environmental concentrations of various EDCs (Endocrine Disrupting Chemicals) were predicted, applying different fate processes according to different chemical properties. Third, advection and dispersion by wind in air grids, runoff in watershed, flows of water in water segments are considered in the watershed-based multimedia fate model, which was linked to a risk assessment system that predicts environmental multimedia concentrations of EDCs and assesses human risk in this area. HURAME is valuable tools for predicting the fate of chemicals in evaluative and real environments with areas consisting of many watersheds. These models are an integral component of exposure assessment and risk assessment strategies, and are used in detailed assessments of contaminant fate. The aim of these models is to describe quantitatively contaminant fate and migration in a defined watershed region, with water segments and air grids inside of the region of interest treated more complicatedly. As a result, regional levels of environmental contamination are controlled by environmental parameters and processes and meaningful evaluation requires assessment of contaminant fate in neighboring regions. A linked set of regional models thus has the potential to describe quantitatively the impact of chemical emissions over a wider geographic scale with significant spatial differences in environmental characteristics and chemical use patterns.

TH112
Occurrences, sources, and transport of organophosphorus flame retardants (PFRs) and persistent bioaccumulative toxic (PBT) contaminants in polar seas
Y. XU, Research Center for Eco-Environmental Sciences, Chinese Academy of Sciences / Key Laboratory of Drinking Water Science and Technology; X. GAO, Research Center for Eco-Environmental Sciences, Chinese Academy of Sciences; Q. Huang, Dept. of Environmental Science, Tongji University / Department of Environmental Science
Organic pollutants in the polar seas have given rise to ongoing public concern, which also provide a good opportunity to study the spatial transport and temporal accumulation of environmental contaminants and the impacts of anthropogenic activities. However, the vast dynamic marine water poses challenges to their comprehensive monitoring within appropriate spatial and temporal scales. In this study, an combined approach of time integrated and on-board passive sampling of organic pollutants using triolein-embedded cellulose acetate membranes (TECAMs) was performed in waters of Fildes Peninsula, Antarctica and an Arctic cruise. The TECAM extracts were used for target analysis of organophosphorus flame retardants (PFRs), and non-target screening of persistent, bioaccumulative, and toxic (PBT) contaminants using two-dimensional gas chromatography with time-of-flight mass spectrometry (GC×GC-TOFMS). In the non-target analysis, 16 PBT contaminants were screened out from 1500 suspected compounds and performed with further confirmation. Multiple local sources (wastewater, air traffic, research stations, and animal feces) for different PFRs in waters of Fildes Peninsula were proposed, whereas both West Spitsbergen Current (WSC) and local sources (settlements, oil exploitation, and petroleum fuel emissions) were found to contribute to the PBT pollution in Arctic sea. Furthermore, a comparison among water sampling cases revealed that passive sampling can be a tool for aquatic time-integrated investigations in polar seas. Finally, annual transport fluxes of the contaminants from the North Atlantic to Arctic Ocean by WSC were estimated and their hazard to Arctic should be concerned.

TH113
Partitioning based determinations of water solubility for highly hydrophobic liquid chemicals
H. Birch, DTU Environment / Department of Environmental Engineering; P. Mayer, Technical University of Denmark / Department of Environmental Engineering
Water solubility is a fundamental parameter for the environmental risk assessment of organic chemicals. It is experimentally and analytically challenging to determine the aqueous solubility for highly hydrophobic liquid chemicals, because they are prone to the formation of micro-droplets and emulsions in the saturated water. Two partitioning based methods were therefore recently developed for saturating water while avoiding direct contact with the hydrophobic liquid test substances. The first method is based on first saturating a silicone rod with the test substance and then using the silicone rod for saturating the water. The second method is based on saturating water from the liquid phase chemical via the headspace. Equilibrium kinetics of the headspace dosing method was determined in order to explore its applicability domain. Headspace passive dosing of 5 chemicals with log K_{ow} of 4-6 and K_{aw} of 0.8-200 reached 95% of equilibrium within a few hours. Headspace passive dosing was very precise and well-behaving for several of the test compounds, but challenges remained for chemicals with a log $K_{ow} > 6$ that are most prone to the formation of micro-droplets, emulsions and also other potential artefacts. A third passive dosing format has thus been developed and will be tested aiming for increased robustness of solubility determinations for highly hydrophobic liquid chemicals of log$K_{ow} > 6$. Finally, the solubility of several model compounds will be determined in pure water and five other media such as algae toxicity test medium, lake water and seawater.

TH114
Investigating PCB mobility in soil water after a rhizoremediation experiment: role of different plant species and soil conditions
E. Terzaghi, University of Insubria (Como) / Department of Science and High Technology, Como; G. Salina, University of Insubria / Department of Science and High Technology; C. Vitale, University of Insubria; A. Di Guardo, University of Insubria / Department of Science and High Technology
The study of organic contaminant mobility through soil profile is important to understand their environmental fate. This can be achieved by both field and laboratory experiments. Among laboratory tests, column leaching experiments could allow to investigate organic contaminant movement due to a water flux that simulate an irrigation or a rain event under more realistic conditions. The aim of the present work was to investigate the mobility of PCB in soil performing a laboratory experiment with glass column filled with an aged highly contaminated soil (mg/kg level). The soil was collected in a National Relevance Site for remediation located in Northern Italy (SIN Brescia-Caffaro) and has undergone a rhizoremediation treatments (P) for 18 months with different plant species (*Festuca arundinacea* and *Cucurbita pepo ssp pep*o in consociation (P4) and *Medicago sativa* withmycorrhizal fungi (P7)). The same but unplanted soil was also considered as control (C) for comparison. Three replicates were considered for each type of soil. The columns were leached with tap water and PCB concentrations were measured in the leachate after 7 days of contact. The samples were also characterized for pH, conductivity, temperature and dissolved organic carbon (DOC) content. Total PCB concentrations (sum of 84 congeners) ranged

from 15 to 42 ng/L in the dissolved phase and from 5 to 135 ng/L in the particle phase, representing a small fraction of the total amount in soil. Leachate samples were enriched in tetra to hepta PCBs, while deca PCB showed a lower contribution to the fingerprint considering bulk concentration; mono, di, octa and nona PCB concentrations were below the detection limit due to their low concentrations in soil. Both treatments (P4 and P7) showed similar PCB dissolved concentration with respect to the control, while water leached from soil treated with *Medicago sativa* (P7) showed PCB particle phase concentrations a factor of about 2 higher than those of the control and the other treatment (P4). This indicated that the selected plant species, during the rhizoremediation treatment, acted differently on one of the most important fluxes influencing chemical movement in soil (POC, particle organic carbon).

TH115

Bioaccumulation of brominated flame retardants (BFRs) by two freshwater invertebrates exposed through different routes.

A. Ratier, Irstea Lyon; C. Lopes, Université Lyon 1, UMR CNRS 5558 / Laboratory of Biometry and Evolutionnary Biology; H. Budzinski, University of Bordeaux / EPOC LPTC UMR5805 CNRS; P. Labadie, UMR CNRS EPOC Universite Bordeaux / UMR 5805 EPOC; O. Geffard, Irstea / UR RIVERLY Laboratoire Ecotoxicologie; M. Babut, Irstea Lyon / UR RIVERLY Laboratoire Ecotoxicologie

Brominated flame retardants (BFRs) have been a major concern for several decades due to their intensive use in commercial, consumer and household products. The contamination of various environmental samples has been recognized worldwide. As a result, regulations were adopted, in order to restrict or ban their production and use. Nevertheless, some BFRs are still detected in various invertebrates and fish species, such as hexabromocyclododecane (HBCD) and penta and octa-BDEs, mainly represented by BDE-47 and BDE-99. Debromination mechanism leading from BDE-99 to BDE-47 have been demonstrated in some fish species. Additionally, previous studies suggested an isomerization of HBCD from sediment (mainly γ-HBCD) to fish (α-HBCD). To a better understanding of the fate of BFRs in aquatic organisms, the evaluation of the transfer of these compounds from sediment to invertebrates is required, since sediment serves as a sink for these pollutants. Toxicokinetic (TK) models have been developed to describe the accumulation of contaminants in aquatic food webs. TK model parameters could be easily determined by short-term exposures of organisms under controlled laboratory conditions. To date, few data are available on the bioaccumulation kinetics of BFRs in freshwater invertebrates. Chironomids and gammarids are ubiquitous in European freshwaters, easily sampled in the field and they play important ecological roles as a link between the base of food webs and higher-order consumers such as fish or birds. Besides, these two organisms have been reported to accumulate metals and various organic pollutants. The aims of this study were (i) to investigate the potential biotransformation of BDE-99 in to BDE-47 and the potential isomerization of γ-HBCD to α- or β-HBCD in invertebrates and (ii) to describe the related bioaccumulation kinetics. *Gammarus fossarum* were exposed in aquatic microcosms to BDE-99 spiked leaves and clean sediment, while *Chironomus riparius* and *G. fossarum* were exposed to HBCD spiked sediment. Thus, internal levels of chemicals were regularly measured to estimate uptake and elimination rates.

TH116

Influence of co-dosed lipids from biota extracts on the availability of chemicals in in vitro cell-based bioassays

E.B. Reiter, Helmholtz-Zentrum für Umweltforschung GmbH - UFZ / ZELLTOX; A. Jahnke, B.I. Escher, Helmholtz Centre for Environmental Research - UFZ GmbH / Cell Toxicology

Bioanalytical tools are widely used for assessing the burden of chemical mixtures in the environment including biota. However, interpretation of bioanalytical data from biota samples can be challenging because of matrix effects caused by co-extracted lipids or proteins. In cell-based reporter gene assays, these matrix residues are expected to have a substantial effect on the read-out quality. We consider co-extracted lipids to act as an additional phase in the bioassay system because lipids do not dissolve and are not likely to be taken up by cells. This additional lipid phase is expected to reduce the bioavailability of dosed chemicals, thereby reducing the apparent sensitivity of the assay. We can describe partitioning of diverse chemicals between co-extracted lipids, medium components and cells by a simple equilibrium-partitioning mass-balance model that is parameterized with (a) the partition constants between lipid and water, medium and water as well as cells and water, (b) the constituents of medium and cells in terms of volume fractions of lipids, proteins and water and (c) the volume fraction of co-extracted lipids. We used triolein, a synthetic triglyceride often used as a standard lipid, to mimic the co-dosed lipid matrix. We measured the dependence of the effects on triolein in the well-characterized cell lines AhR-CALUX for activation of the aryl hydrocarbon receptor and AREc32 that responds to Nrf2-dependent oxidative stress. Triolein was spiked with two bioactive reference compounds for each assay with different log K_{OW} and dosed directly to the cell assays to cover triolein volumes between 0.5 and 4%. For a proof of principle the applied triolein volumes were much higher than realistic co-extracted lipids (in the extract typically

Novel methods for assessing the environmental risk caused by the reuse of sewage sludge

H. Ahkola, Finnish Environment Institute, SYKE; P. Lindholm-Lehto, Natural Resources Institute Finland; P. Välitalo, Aalto University; K. Maenpaa, University of Eastern Finland / Department of Biology; N. Perkola, I. Heiskanen, J. Alegre Stelzer, Finnish Environment Institute SYKE; P. Meriläinen, National Institute for Health and Welfare / Department of Health Security; J. Järvistö, Finnish Environment Institute; J. Nuutinen, Finnish Environment Institute / Laboratory Centre; J. Knuutinen, University of Jyvaskyla; M.T. Leppänen, Finnish Environment Institute SYKE

Sewage sludge is an inevitable byproduct produced in waste water treatment process. Sludge is rich in nutrients, and bringing them back to natural circulation would diminish the amount of waste ending to soil dumping areas and promote the circular economy. However, during the sewage treatment process several harmful organic chemicals are retained in the sludge which raises concerns towards its use in agriculture and landscaping. Proving the safety of processed reused sludge would encourage its more extensive use. Sewage sludge is a complex matrix including a number of organic and inorganic compounds. Due to complexity of the matrix, the analyses of chemicals in municipal sewage sludge are not straightforward. Total concentrations of harmful chemicals include both dissolved and particle-bound fraction which may overestimate the actual toxic effects. The most harmful chemical fraction is the dissolved one which is able to transport in the environment and accumulate to organisms. This fraction can be studied with passive sampling. In this study passive sampling was combined with chemical and ecotoxicological examinations to indicate the readily bioavailable part of the chemical and assess the toxicity after digestion and composting. The polydimethyl siloxane (PDMS) passive samplers were deployed in untreated, digested and composted sludge. The toxicity of the extract was studied with chronic toxicity test with *Daphnia magna*, neutral red retention assay and umuC assay. The concentrations of selected chemicals such as polyaromatic hydrocarbons (PAHs), triclosan (TCS), and methyl triclosan (mTCS) were determined in sludge as well as in PDMS passive samplers. Digestion decreased both cytotoxicity and genotoxicity. This indicates that some of the compounds causing cytotoxicity are more efficiently removed in digested sludge compared to untreated sludge. The PDMS passive sampling method can be applied to estimate the bioavailable chemical fraction in waste water treatment plant (WWTP) sludge. Assessing the toxicity of sludge based on different bio assays can provide a more comprehensive picture of its true harmfulness to organisms. The treatment stages of municipal sewage sludge, especially composting, reduce toxicity and amount of studied chemicals. Nevertheless, based on the chemical analysis a rather large part remains in the sludge.

TH118

Fluorescent probes for measuring toxic effects in Daphnia magna

P. Roslev, Aalborg University / Biology and Environmental Science

The toxicity of chemicals to aquatic organisms such as *Daphnia magna* is often evaluated using dichotomous endpoints such as immobility and/or mortality. However, changes occurring at the biochemical level can indicate early responses to toxicant stress. This study investigated sublethal effects of common toxicants to *D. magna* using a novel fluorescence based assay for measuring in vivo enzyme activity. The study examined the hydrolysis of fluorescein diacetate (3,6-diacetoxyfluoran) as a measure of hydrolase activity in *D. magna* after exposure to toxicant stress. Live *D. magna* rapidly hydrolyze fluorescein diacetate (FDA) to fluorescein in aqueous solution resulting in distinct changes in absorbance (color) and fluorescence in the surrounding medium. The hydrolase activity in *D. magna* was proportional to animal biomass, incubation time and viability of the animals. Dose-dependent changes in hydrolase activity was observed after exposure to a range of potential toxicants including glyphosate, bisphenol A, fluoxetine, propranolol, β-estradiol, copper, chromium and UV A radiation. Changes in hydrolase enzyme activity in *D. magna* compared favorably to changes in mobility resulting in comparable or lower EC values. The FDA assay is simple and cost effective compared to other staining techniques. The fluorescein product provides a visual cue (green color) and green fluorescence that can be visualized and quantified using standard instrumentation (microscopes and plate readers). Hydrolase activity may be quantified as a combination of whole animal fluorescence and fluorescence in the surrounding water. The results suggest that the FDA assay can be used as an index of toxicant stress in *D. magna* and may be used as a quantitative supplement for toxicity testing. The FDA assay can be supplemented with use of 2',7'-dichlorodihydrofluorescein diacetate (H_2DCFDA) as a probe for detection of reactive oxygen species (ROS) after toxicant exposure.

TH119

Suitability of silicon passive sampler for monitoring TBT concentrations in surface water

H. Ahkola, Finnish Environment Institute, SYKE; K.S. Siimes, Finnish Environment Institute SYKE / KTK / Contaminants; P. Rantakokko, National Institute for Health and Welfare

Polymer based passive samplers are increasingly used in studying harmful substances in different environmental matrices. The samplers measure freely dissolved chemical concentration which is the most harmful to organisms. The samplers are deployed until the equilibrium between the sampler and the surrounding media has been reached. This enables the determination of low concentrations which in convenient grab water samples remain below the detection limit. The average concentration of studied chemical in the surrounding media can be calculated as the sampler-water partition coefficient is known. The environmental quality standard concentration (EQS) of tributyltin (TBT) in surface water is very low (0.2 ng/L) and in many cases near the laboratory detection limit. However, if TBT is not detected it doesn't mean it is not present in the environment. With passive sampling the TBT content can be enriched to the measurable level. The partition coefficient of TBT between water and a silicon passive sampler was determined in a laboratory trial by analyzing the TBT concentrations by GC/MS. As the coefficient is determined it can be used to estimate dissolved TBT concentrations in marine, surface and effluent waters. The determined partition coefficients were rather high likely due to adsorption of organotins to the sample bottle walls which decreases the freely dissolved chemical fraction C_w. The adsorbed chemical fraction is not included in our calculation since it is not available for passive samplers. The silicone passive samplers measure only freely dissolved chemical fraction so the concentrations determined with field deployed passive sampler are lower than the total ones. With silicon passive sampler the presence of TBT in aquatic environment can be revealed which further enables more reliable risk assessment.

TH120

Assessing the atmosphere-surface exchange of gaseous elemental mercury using passive air samplers

M. Feigis, S. Mistry, M. Snow, University of Toronto Scarborough / Physical and Environmental Sciences; Y. Lei, University of Toronto / Physical and Environmental Sciences; C. Mitchell, University of Toronto, Scarborough / Physical & Environmental Sciences; F. Wania, University of Toronto, Scarborough / Physical and Environmental Sciences

The specific properties of gaseous elemental mercury (GEM) allow it to undergo bidirectional exchange between the atmosphere and the Earth's surface. Determining the direction and the magnitude of GEM's atmosphere-surface flux is possible and has been accomplished using micrometeorological and chamber techniques, but is (i) complex and labor intensive, and (ii) often only yields fluxes over relatively short time scales. A recently developed passive air sampler for GEM may have the precision required for identifying and quantifying vertical concentration gradients above the Earth's surface and therefore the direction and size of exchange fluxes at much longer time scales of weeks to a year and with much less effort and lower cost than existing approaches. We tested the feasibility and performance of this approach by measuring concentration gradients for one year with a monthly resolution above both natural soil in a forest and a nearby clearing, as well as above soil artificially contaminated with inorganic mercury. Significant gradients of GEM air concentrations, both increasing and decreasing with height above ground, were observed and found to be dependent on soil contamination, temperature, snow cover and solar irradiation. Because the sampler's uptake kinetics has a known, small dependence on wind speed, sampled amounts of Hg that decrease with increasing proximity to the soil surface could be an artifact caused by wind speed gradients. Measurements, however, reveal that wind differences above the soil are insufficient to explain the differences in the sampled amounts with height, implying that deposition of GEM can be recorded with this method. The method holds promise to also find use for the measurement of GEM fluxes between atmosphere and vegetation, e.g. in forest and tundra ecosystems.

New Frontiers in Life Cycle Inventory Data Collection and Modelling (P)

TH121

GeoFootprint: A publicly available web-platform with regionalised LCI data for agricultural modelling

A. Ernstoff, Quantis / Quantitative Sustainability Assessment; L. Iten, S. Humbert, X. Bengoa, M. Faist-Emmenegger, J. Reinhard, Quantis

Life Cycle Inventory (LCI) of agricultural products (i.e. crops) tend to use the average or "archetypal" meteorological and ecological conditions for an entire country limiting the accuracy and representativeness across subregions. Specifically, the process inputs (e.g. chemical and organic fertilizers) and the accompanying release of emissions into soil, air and water (e.g. nitrate, dinitrogen monoxide, or phosphate) are sensitive to environmental parameters (precipitation, soil properties, slope, etc.) which vary spatially. Furthermore, land use change (LUC) and soil organic carbon are increasingly being recognized as major drivers of agricultural carbon footprints that are highly spatialised. Initiatives to produce regionalized LCI have not yet succeeded in developing a publicly available interface, covering multiple regions globally, available for practioner use. **GeoFootprint represents a new frontier in regionalised LCI data collection and modelling.** The initiative is led by Quantis through a grant by EIT Climate-KIC, the EU's largest public-private partnership addressing climate change through innovation. GeoFootprint aims to address the data gaps regarding spatially sensitive LCI, with focus on LUC and soil characteristics. Spatial data from Geographic Information Systems (GIS) will be merged with agronomical data (e.g. yield) in order to generate LCI that is spatially sensitive. The LCI will be democratized through a **publicly available, web-based platform by the end of 2020**. Quantis will work together with arxIT, World Resources Institute (WRI), Cool Farm Alliance and a network of leading organizations to further explore these issues and provide solutions that better support sustainable crop management practices. The network, which will be expanded over the course of the project, will provide guidance and feedback throughout the development of the platform. Initial partners include General Mills, Mars, Nespresso, Nestlé, Swiss Federal Office for Agriculture, Unilever, UPM Raflatac and Yara. This poster will **present the latest update on the GeoFootprint project** and its implications for improving regionalised LCA of agricultural products.

TH122

Challenges Associated with Life Cycle Inventory/Life Cycle Impact Assessment for Metal Mine Tailings

K.J. Rader, Mutch Associates, LLC; L. Assim, International Copper Association / Health, Environment and Sustainable Development; M. Spielmann, Quantis International; E. Nordheim, European Aluminum; C. Albersammer, International Council on Mining and Metals; C. Bayliss, International Aluminium Institute; A. Vaccari, International Copper Association / Health, Environment and Sustainable Development

The addition of human health and ecotoxicity metrics into Life Cycle Impact Assessment (LCIA) tools has increased the focus on trace amounts of metal impurities in metal mine tailings and their potential release to the environment. Recent research efforts have focused on the development of updated life cycle inventory (LCI) datasets for sulfidic tailings disposal from metal ore beneficiation. An empirical tailings model forms the basis for these LCI datasets. In this work, the development of the LCI datasets from the model was reviewed. The review identified three challenges associated with LCI/LCIA for metals released from tailings: (1) model reliability (e.g., lack of data to ground truth the LCI model, lack of a groundwater compartment in LCI/LCIA models, and limited consideration tailing management practices); (2) data representativeness (e.g., potential for inconsistent extraction protocols, lack of paired composition/leachate data, nature of operation/facility) and (3) uncertainty (e.g, definition of acceptable levels of uncertainty). The following actions/recommendations address some of these challenges: (1) Available geochemical models for tailings are being evaluated for use as a resource to validate/refine the LCI tailings model formulation. (2) A guidance document discussing data representativeness guidelines for tailing composition/leachate chemistry dataset inclusion in the model database should be developed to ensure data quality. (3) Efforts are being undertaken to bolster the tailings composition and leachate chemistry database. (4) The effect of applying the Best Available Techniques (BATs) for tailings management should be assessed as an additional scenario at a minimum. The long-term performance of the BATs is worth considering in more detail. (5) Attenuation of leachate metals in groundwater is expected but must be quantified. In the long-term, a groundwater compartment—specifically its impact on leachate metal fate--should be included in the USEtox LCIA model.

TH123

Metal emission quantification, relevant aspects from an LCA perspective

N.A. Peña, IRTA / GIRO; A. Kahru, National Institute of Chemical Physics and Biophysics / Laboratory of Environmental Toxicology; A. Assumpcio, IRTA / GIRO-Integral Organic Waste Management Program

Agricultural production contributes significantly to several impact categories such as eutrophication, acidification or toxicity. Direct farm emissions strongly depend on farm management practices and are influenced by location characteristics. In the last decade, life cycle assessment (LCA) has been increasingly improved and used for the quantification of these category indicators. However, an aspect that still needs a deep understanding is the quantification of metal emissions from agricultural systems. Currently, simplistic approaches to model metal emission fractions into the different environmental compartments are implemented, from which the most widely used is the SALCA methodology. Several shortcomings in this approach have been identified. Therefore, the aim of this study is to advance and agree on the methodology to improve the current quantification of metal emissions from agriculture and its harmonization with characterization models. As a first step, a literature review was performed to give an overview of the relevant metal sources of emission from different agricultural activities. Inventory is built following the methodological guidelines for agricultural products, in a balance of metal inputs and outputs. We have considered seven metals from agricultural sources: cadmium, chromium, copper, lead, nickel, and zinc. The different sources of emission were classified into four categories: synthetic fertilizers, organic-related fertilizers (e.g., bio-solids, manure, compost, etc.), pesticides (as dissolved metal forms such as copper-based fungicides) and wastewater irrigation. Regarding the mass balance between inputs and outputs, we suggest improvements by adjusting the inputs on the balance for different application inventories, re-calibrating the model by using experimental data for specific soil characteristics; and by updating the metal releases from the different emission sources. Furthermore, a better discrimination for the bioavailable fraction of metal by taking advantage of the knowledge of biological tests and biological sensors is accounted. These findings and recommendations also demonstrate the need and relevance of spatially differentiated inventory of metal emissions that are harmonized and can be used with characterization models for life cycle impact assessment to support effective decision-making and finally a consensus agreement similar to that for pesticides assessment would be advisable.

New Developments in the Science of vPvB and PBT Assessment (P)

TH124

Initiative towards improving our understanding of persistence in the 21st century

G. Whale, Shell Health / Risk Science Team; P. Van Elsacker, FPS Health Food Chain Safety and Environment; K. van Ginkel, AkzoNobel; R. Davenport, Newcastle University / School of Engineering; J. Parsons, University of Amsterdam / Institute for Biodiversity and Ecosystem Dynamics; E. Vaiopoulou, CONCAWE; K. Fenner, Eawag Swiss federal Institute of Aquatic Science and Technology / Department of Environmental Chemistry; A. Schaeffer, RWTH Aachen University / Institute for Environmental Research

There is increasing awareness that progress in the scientific understanding of factors which influence the outcome of persistence (P) assessments of chemicals (particularly biodegradation) are not fully recognised in existing regulations and environmental risk assessments. As all biodegradation tests have their limitations, which are accentuated for 'difficult to test' substances, failure to recognise these can potentially lead to chemicals being incorrectly labelled as 'P', 'vP' or not P. Many of the shortcomings of existing biodegradation studies have been previously recognised and discussed in a series of ECETOC reports and workshops which were subsequently used to help develop and formulate a series of research projects to try and address key issues and propose methods to mitigate the existing limitations of persistence assessments. However, many of the recent developments recommended in the multi stakeholder workshops and related research projects have not been incorporated into existing regulatory frameworks for environmental hazard and risk assessment. Due to growing awareness that this situation needs to be rectified a Persistence Workshop was held in Helsinki on the 27th September 2018. The objective of the workshop was to disseminate key findings from recent projects and develop proposals regarding how the current situation can be improved to ensure appropriate classification of the hazards posed by a wide range of chemicals. The challenge being to develop consensus regarding how recent knowledge can be incorporated into existing regulatory frameworks to improve the environmental hazard and risk assessment of chemicals. From the outset it was recognised that any proposal to modify guidance needs to be based on sound science, transparent and relevant to all stakeholders. The workshop provided a unique opportunity to initiate a process to re-examine the fundamentals of biodegradation and what existing test methods can achieve by 1) providing an overview of some of the key elements and messages coming from recent research initiatives and 2) stimulating discussion regarding how these interrelate and can be used to redress some of the previously identified persistence assessment needs. This presentation will provide a summary of the key messages from the workshop and subsequent progress on the next steps required to start a journey to take the persistence assessment of chemicals into the 21st Century.

TH125

Relationship between biodegradation and bioaccumulation. Practical outcomes.

O. Mekenyan, Prof. Asen Zlatarov University / Laboratory of Mathematical Chemistry; I. Dermen, Laboratory of Mathematical Chemistry OASIS LMC / Laboratory of Mathematical Chemistry; N. Dimitrova, Prof. Dr. Assen Zlatarov University / Laboratory of Mathematical Chemistry; K. Vassilev, Prof. Asen Zlatarov University / Laboratory of Mathematical Chemistry

According to the REACH Regulation, for all substances manufactured or imported in amounts of 10 or more tons per year, that are not exempted from the registration requirement, a Chemical Safety Assessment (CSA) must be conducted. According to CSA criteria, for these substances a PBT/vPvB assessment is requested. PBT/vPvB properties are defined by the criteria described in Annex XIII to the REACH Regulation. If based on the available information the substance is potentially B/vB and fulfils the P/vP criteria, experimental data according to the OECD TG 305 protocol should be generated. In order to reduce the number of applications of the expensive bioaccumulation test it seems useful to search thresholds for other related parameters below which no bioaccumulation is observed. Taking into account the known relationship between ready biodegradability and bioaccumulation such parameter is biodegradation. Given the stringent regulatory criteria for avoiding *BCF* tests based on *BOD* it is interesting to investigate in more details this relationship in searching for *BOD* threshold below which practically no vB/B chemicals could be observed. It is especially interesting to relate the *BOD* criteria for not vB/B chemicals with regulatory criteria for persistency which are in the range of 10% - 30% *BOD* depending on local regulations determined in terms of half-life. This analysis is the first aim of the present work. The second aim is the analysis of the relationship between the rates of *in vivo* metabolic transformations and bioaccumulation thresholds. Metabolic transformation rates were defined ensuring low bioaccumulation of chemicals, in terms of vB and B thresholds.

TH126

Membrane partitioning of organic cations, anions and ion pairs - estimating the bioconcentration potential of charged compounds

J. Dołżonek, University of Gdansk / Department of Environmental Analysis; M. Markiewicz, Technical University of Dresden / Institute of Water Chemistry; P. Stepnowski, University of Gdansk; S. Beil, S. Stolte, Technical University of Dresden / Institute of Water Chemistry

Experimental measurements of bioconcentration factors (BCFs) are not feasible for large sets of chemicals. In the absence of experimental data BCFs are often predicted using quantitative structure activity relationships (QSARs) employing octanol-water partition coefficient (log Kow) as a descriptor. This approach often underestimates BCFs of charged speciesbecause it neither sufficiently considers the interactions of charged compounds with the heterogeneous membrane system that contains, e.g., polar and charged phospholipids nor interactions of cations and anions in solution – both strongly influencing the transport, uptake and bioavailability of ions. The aim of this study was to use log K_{MW} to obtain a more realistic estimation of the bioconcentration potential of organic cations and anions because lipid membrane-water partitioning coefficients (log K_{MW}) generally correlate better with BCF than the log Kow. The interactions of organic ions and ion pairs with biological membrane lipids and their consequences in terms of bioconcentration were investigated in order to develop QSAR that can be used in estimation of bioconcentration potential of permanently charged species. The log K_{MW} values showed that tested cations and anions can have a strong affinity for phosphatidylcholine bilayers. The results need to be verified *in vivo* but they indicate considerable bioaccumulation potential. The log K_{MW} values for the organic cations were orders of magnitude higher than log K_{OW} values reported in the literature, suggesting that log K_{OW} might not be a valid descriptor for this group of compounds. Moreover, the partitioning of organic ions is expected to be more dependent on environmental parameters than what is known for neutral compounds. Our study indicates that interactions with other ions in particular need to be considered when assessing the bioconcentration potential of hydrophobic cations and anions, including the type of counter ion, the concentration and type of the other hydrophobic ions in the medium (other pollutants) and the ionic strength of the medium (e.g., fresh vs. marine water)

TH127

Assessing Persistence, Bioaccumulation and Toxicity (PBT) properties of Unknown or Variable Composition, Complex Reaction Products and Biological Material (UVCB) hydrocarbon solvents

C. Prosser, ExxonMobil Biomedical Sciences, Inc.; M. Lampi, ExxonMobil Biomedical Sciences, Inc. / Toxicology & Environmental Sciences; T. Parkerton, ExxonMobil Biomedical Sciences Inc. / Toxicology & Environmental Science; D. Letinski, ExxonMobil Biomedical Sciences Inc; G.E. Bragin, ExxonMobil Biomedical Sciences, Inc. / Toxicology and Environmental Sciences; S. Arey, ExxonMobil Biomedical Sciences, Inc. / Toxicology & Environmental Sciences

Under European Union's Registration, Evaluation and Authorization of Chemicals (REACH) Regulation, assessing PBT properties is required for all chemicals for which a chemical safety assessment is required. Many petrochemicals, including hydrocarbon solvents, are UVCBs and thus the assessment can be challenging as the current capabilities of analytical chemistry precludes the resolution of every chemical present in a substance. This is of particular concern to regulators as the ECHA REACH Guidance Chapter R.11 PBT/vPvB assessment (2017) states that any constituent > 0.1% should be evaluated for PBT properties. However, when the carbon range is sufficiently narrow, whole substance testing should be employed as a method to evaluate PBT properties. Here we demonstrate a weight of evidence approach to evaluating PBT properties of hydrocarbon solvents. This involves comparisons of laboratory whole substance biodegradation tests (e.g. OECD 301F manometric respirometry) along with biodegradation data on individual constituents that demonstrate that the whole substance will not persist in the environment. Water accommodated fraction testing demonstrates the biologically available fraction does not induce toxicity, and thus are not T. Finally, we present new biomagnification (BMF) on two solvents demonstrating a method for evaluating bioaccumulation potential and demonstrating the substances do not biomagnify. The evaluation of hydrocarbon solvent UVCBs is challenged by technical limitations in resolving every individual constituent. As such, a weight of evidence approach towards PBT assessments should be adopted, using whole substance laboratory data when available. In this work, we show that when a weight of evidence approach is applied, the hydrocarbon solvents do not meet the criteria for PBT.

TH128

Solving complexity of biodegradation assessments for UVCB chemicals using an automated system: EVABIO

M. Cregut, University of Nantes CAPACITES / GB; C. Sweetlove, lOREAL SA /

RECHERCHE ENVIRONNEMENTALE; V. Le Cunff, Tronico Alcen; E. Grangé, S. Jouanneau, University of Nantes / GEPEA CNRS UMR CBAC Laboratory; M. Durand, University of Nantes / UMR CNRS GEPEA CEBAC Laboratory; A. Lahmar, University of Nantes / GEPEA CNRS UMR CBAC Laboratory; Y. Pichot, Tronico Alcen; H. Martin, TRONICO; J. Lharidon, LOréal Research & Innovation / Life Sciences Direction; G. Thouand, University of Nantes / Microbiology

According to the United Nations (UN), a substance is the "chemical elements and their compounds in the natural state or obtained by any production process". This definition has evolved according to different acts of regulation. Now days, thousands of new chemicals require a biodegradability assessment annually. For this task, the development of new metrological solutions needs to be investigated to achieve our assessments needs, especially for complex chemicals, such as UVCB*, for which measurement systems are lacking. For UVCB, assessing biodegradability can be limited by technical issues and/or difficulties to rule on ready or inherent biodegradability. To increase reliability of this assessment, our objective was to develop a multiparametric platform disposing of a global measuring methodology based on both O_2 consumption and CO_2 releasing. Different technologies of sensors have been validated in operating conditions to establish a carbon balance measurement, using several modeling steps involving the use of different parameters such as O_2, CO_2, pH, T°C, Pressure and Biomass. Finalization of these investigations enabled the development of an automated device dedicated to biodegradation assessment of chemicals, whatever their complexity (pure chemicals to UVCB). The multiparametric platform will discriminate inorganic carbon released and organic carbon allocated in biomass. According to the UTOC methodology developed to highlight UVCB fate (Ultimately Transformed Organic Carbon), final conclusion onto UVCB biodegradability will be done in a weight of evidence analysis including both results of biodegradation and ecotoxicological potential of biodegradation by-products (Brillet et al., 2018). **Keywords:** Biodegradation assessment, biodegradation platform, UVCB, complex chemicals, biodegradability * UVCB stands for Unknown or Variable composition, Complex reaction products or of Biological materials.

Investigating the effect of test concentration on biodegradation kinetics of two hydrophobic UVCBs

R. Hammershøj, Technical University of Denmark / Department of Environmental Engineering; K. Knudsmark Sjøholm, Technical University of Denmark (DTU) / DTU Environment; H. Birch, DTU Environment / Department of Environmental Engineering; K.K. Brandt, University of Copenhagen / Department of Plant and Environmental Sciences; P. Mayer, Technical University of Denmark / Department of Environmental Engineering

While risk assessment of mono-constituent substances has for many years been in focus, regulatory and scientific attention has currently shifted towards investigating the exposure, fate and effects of chemical mixtures. This includes multi-constituent substances and substances of Unknown or Variable Composition, Complex Reaction Products and Biological Materials (UVCBs). Petroleum and essential oils are UVCBs, and difficult to test as they cannot be described by a simple chemical structure and contain unknown constituents. In addition, they contain highly hydrophobic organic chemicals. In this study we combined a recently established platform for biodegradation testing of hydrophobic and volatile chemicals with new advancements in passive dosing to determine biodegradation kinetics of two complex and hydrophobic mixtures, diesel oil and lavender oil. The aims were to 1) investigate the effect of changing the initial mixture concentration on the biodegradation kinetics and 2) to couple delayed biodegradation to toxicity, measured as inhibition of ^{3}H-leucine incorporation. Passive dosing from a silicone rod was used to set mixture composition and mixture concentration level in the tests and facilitated stable and reproducible initial test concentrations in many replicate test systems. All tests were carried out in gas-tight autosampler vials with a headspace. Automated head-space Solid Phase Microextraction (HS-SPME) was carried out directly on the test systems and coupled to gas chromatography mass spectrometry (GC-MS) for chemical analysis. The first results show a correlation between test concentration, biodegradation kinetics and toxicity and provide a basis for further studies on biodegradation of complex mixtures.

TH130

Changes in sediment bacterial community diversity and structure throughout an OECD308 test with ten micropollutants

C. Coll Mora, Stockholm University / Environmental Sciences and Analytical Chemistry; A. Sobek, Stockholm University / Department of Environmental Science and Analytical Chemistry ACES; Z. Li, Stockholm University / ACES; R. Bier, S. Langenheder, Uppsala University / Department of Ecology and Genetics/Limnology; E. Gorokhova, Stockholm University / Department of Environmental Science and Analytical Chemistry (ACES)

The OECD308 standard test is widely used to assess the degradability of pollutants in water-sediment systems, however, the recommended settings for the test often do not reflect the original conditions in the natural environment. In this study, we hypothesized that bacterial communities present in the sediment, which are responsible for biotransformation of pollutants, might shift due to differences between environmental and test conditions. We performed OECD308 bottle incubations using sediment from two rivers (F and G), before (1) and after (2) the discharge of a local waste water treatment plant, after 10 day acclimation period, triplicate-sets were spiked with a mix of ten micropollutants at two concentration levels (20ug/l and 2000ug/l) and incubated for 40 days. An extra triplicate control was not spiked with micropollutants. Bacterial community composition was analysed using Illumina sequencing of bacterial 16S rRNA in sediment samples collected directly from the rivers, samples after the acclimation period, and after the incubation period. The bacterial community structure was generally found to be significantly different between rivers and sites ($p\text{-value} \leq 0.001$). Bacterial diversity did not show consistent behavior along the test, and generally remained stable. However, the specific composition of the bacteria community was variable throughout the study. The most significant changes in the bacterial communities appeared between the river sediment collection and the end of the acclimation period, where i.e. bacteria of the Burkholderiales and Rhodospirillales orders had a significant decrease in abundance. Interestingly, in our study we associated several bacteria genera belonging to these orders to fast degradation of micropollutants. Significant changes were also observed between the acclimation period and the end of the test for bacteria in four orders. No significant differences were found in the bacteria community composition between the two concentration levels and the non-spiked control, showing bacteria communities can be robust against high concentrations of micropollutants. Our results show that conditions used for the OECD308 test can affect the bacterial community structure, thus the degradation observed in OECD308 may not necessarily represent degradation observed in the environment and that the implications for risk assessment should be evaluated.

TH131

Comparing chemical persistence assessed using unspiked OECD 309 test to field measurement

Z. Li, Stockholm University / ACES; M. McLachlan, Stockholm University / Environmental Science and Analytical Chemistry (ACES)

Biodegradation is a primary removal pathway thus a major persistence determinant for many organic contaminants in natural systems. The OECD 309 guideline is important for providing biodegradation kinetic data in surface waters for use in persistence and risk assessments. According to the OECD 309 protocol, biodegradation is measured in aerobic natural waters spiked with test chemicals and incubated in the laboratory. However, results from our prior study with an unspiked OECD 309 test combining non-target analytical approaches confirmed that spiking natural aquatic systems with test chemicals can strongly influence biodegradation measurements, most likely due to the adaption of microbial organisms. This study was designed to further evaluate the environmental relevance of the unspiked OECD 309 test by comparing chemical biodegradation half-lives assessed in the laboratory against their persistence directly measured in the field by a benchmarking approach. To this end, Lake Norra Bergundasjön in southern Sweden was selected, a recipient for wastewater treatment plant (WWTP) effluent with a freshwater dilution factor of ~4. For measuring chemical persistence in the field, the WWTP effluent discharged to the lake as well as surface water of the lake inlet and outlet were collected over a period of 3 months in 2017. The samples were analyzed with a weekly temporal resolution to verify that chemicals in the lake were in steady state. The conservative chemical bicalutamide, which was detected constantly throughout the whole sampling period, was used as the benchmark chemical. For assessing chemical biodegradation in the laboratory, an unspiked OECD 309 test was carried out in duplicate using fresh lake water collected at the end of the field sampling period. The test was under conditions recommended by the standard OECD 309 protocol and lasted for a period of 60 days at 20 °C in the dark. Triplicated water samples were collected at 11 time points. All samples were filtered and analyzed with UHPLC-Orbitrap-MS/MS using a direct injection method. Data was processed using a non-target approach. Biodegradation half-lives of organic contaminants detected both in the laboratory test and in the field will be calculated and contrasted.

TH132

Compartment-Specific Screening Tools for Persistence - Potential Role and Application under REACH

T. Junker, ECT Oekotoxikologie GmbH; A. Coors, ECT Oekotoxicologie GmbH; G. Schuurmann, Helmholtz centre for environmental research - UFZ / Department of Ecological Chemistry

The persistence assessment under REACH relies on compartment-specific degradation half-lives derived from laboratory simulation studies with surface water, aquatic sediment or soil. Although these data are given priority, they are not available for most of the compounds. Thus, in a first step according to the current Integrated Assessment and Testing Strategy (ITS) for persistence assessment in REACH guidance R.11, a substance is generally considered to be not persistent, if it is readily biodegradable in water and there is no need to perform further biodegradation tests for the PBT assessment. Ready biodegradability tests (RBTs) must be designed so that positive results are unequivocal, i.e. rapid and ultimate biodegradation in the environment can be assumed. However, the fate of a substance may differ substantially between aquatic systems and soils or sediment, which are very complex and heterogeneous matrices with a large amount and variety of binding sites. This might result in sorption and a reduced biodegradability. Nevertheless, soil and sediment compartments are still not considered in existing RBTs and simulation studies covering all relevant environmental compartments (i.e. water, aquatic sediment, soil) are only required if the substance cannot be rated as non-persistent based on all available information in step 4 of the ITS. Consequently, there is a lack of experimental methods suitable to derive biodegradation data in soil and sediment at the screening test level, which can be used to identify potential persistence in sediment or soil. In previous studies, compartment-specific screening tools for water-sediment (Water-Sediment Screening Tool; WSST) and soil (Soil Screening Tool; SST) have been developed and were successfully applied to determine sound and reliable biodegradation data for a set of test compounds. The results were used within a new alternative persistence screening approach, the Compartment-Specific Persistence Screening (CSPS). In this poster, the CSPS is presented and the results are compared with the outcome of the REACH standard persistence screening. The differences between the two approaches are discussed and potential scopes of application for the WSST and the SST in the context of the REACH ITS for persistence assessment are proposed.

TH133

Persistence assessment of Plant Protection Products (PPPs) in the light of a changing EU regulatory environment

P. Dalkmann, Bayer AG Crop Science Division / Environmental Safety; D. Schaefer, Bayer Crop Science / Environmental Safety

Persistence (P) assessment is hazard based and performed in the framework of a Persistence Organic Pollutants (POP; UN level) and PBT (Persistent, Bioaccumulative, Toxic) / vPvB (very Persistent, very Bioaccumulative) (EU level) classification. To assess potential PBT / vPvB properties, the criteria were introduced into different, substance-specific EU legislations for industrial chemicals (EC No. 1907/2006), Plant Protection Products (PPPs; EC No. 1107/2009) and biocidal products (EC No. 528/2012). PBT guidances implemented in these different regulations specify the same trigger values for assessing P and vP, but different criteria on how to derive trigger endpoints are applied; this is in particular true since the latest REACH PBT guidance update in 2017. In addition, also the consequences of a PBT / vPvB classification are differing. While a PBT / vPvB classification is a direct cut-off for PPPs, mitigation, restrictions or further registration requirements are applicable for industrial chemicals. These differences are particularly critical due to the observed tendency towards a harmonization of the PBT / vPvB assessment for the different chemical classes. Although the DG SANCO PBT guidance from 2012 is applicable for PPPs (noted by the Standing Committee on Plants, Animals, Food and Feed [SCoPAFF]), applicants for PPP authorizations experienced of late that the REACH PBT guidance is more and more used by the European Food Safety Authority (EFSA) and Member States (MS) authorities. For example, applicants received requests for soil and water half-life (DT_{50}) values normalized to 12°C, although the SANCO PBT guidance specifies a reference temperature of 20°C for assessing P. As a consequence, a 12°C normalization would lead to significant increase in the number of PPPs classified as "P" when applying the currently valid trigger values which, in turn, would lead to a disablement of this hazard tool. Logically, when normalizing DT_{50} values to a specific reference temperature, the currently applicable trigger values, which were orginally derived at room temperature, should be normalized to the identical temperature. Overall, these developments result in a high degree of uncertainty, especially for the applicants of PPPs (but also for MS). There is no clarity for the applicant on how a P assessment should be performed presently and in the future. Therefore, EFSA is requested to provide guidance on that topic, involving all stakeholders in this field.

TH134

Temperature dependency of biodegradation kinetics in environmental surface waters

K. Knudsmark Sjøholm, Technical University of Denmark (DTU) / DTU Environment; H. Birch, DTU Environment / Department of Environmental Engineering; P. Mayer, Technical University of Denmark / Department of Environmental Engineering

Biodegradation kinetic data are keystone in persistency assessments and risk assessments of chemicals. Biodegradation is temperature dependent, and biodegradation tests used for persistency assessments should be conducted at standard test temperatures, which were recently lowered from 20°C to 12°C in the Guidance on Information Requirements and Chemical Safety Assessment from ECHA (2017). Current practice in compensating for the difference in standard test and environmental temperature is to assume that microbial communities have the same temperature response and uniform biodegradation capacity at a given temperature[1]. These assumptions have led to the use of a "rule of thumbs" correction factor based on the Arrhenius equation for extrapolation of biodegradation rates from one temperature to another. This practice is however discussed as it is based on abiotic, not biotic degradation rates. It was recently reported that the temperature effect differed, for example, amongst compounds depending on their chemical structure[2]. Comparative biodegradation kinetic data at different test temperatures are needed for a large number of chemicals in order to improve extrapolation between temperatures in risk assessment and predictive modelling. Here we present an experimental setup that will provide biodegradation kinetics for approximately 40 petroleum hydrocarbons (HCs) at origin of inoculum temperature and two standard test temperatures for three different surface waters. Natural inoculum is sampled from Northern, Middle and Southern European Rivers to cover a broad temperature range. The HCs are tested in composed mixtures at environmental realistic low concentrations generated by passive dosing, and the tests performed in air-tight vials are incubated at two different temperatures. After incubations of 0-28 days, triplicate test systems are analyzed by Headspace Solid Phase Microextraction (HS-SPME) Gas Chromatography Mass Spectrometry (GC/MS), and the concentration relative to abiotic controls are used to model biodegradation kinetics[3]. The obtained dataset can also be compared with literature. From the Northern European site, the biodegradation will additionally be determined using three different samples to cover seasonal variance. [1]Bagi, A. *et al.* (2013) *Mar Environ Res*, pp. 83–90. [2]Birch, H., Hammershøj, R. and Mayer, P. (2018) *Environ Sci Technol*, pp. 2143–2151. [3]Vergeynst, L. *et al.* (2018) *JHazard Mater*. Elsevier, pp. 127–134.

TH135

Challenges and Experimental Issue for Kinetic Simulation Studies conducted at 12°C (OECD TG 309)

S. Fiebig, S. Goller, H. Maischak, Noack Laboratorien GmbH

Historically most kinetic simulation studies were conducted at a standard laboratory temperature of 20 +/- 2°C. With the update of ECHA IR and CSA Guidance r.7b and R.11 new kinetic simulation studies as required for persistency assessment of industrial chemicals must be conducted at environmentally relevant temperatures. For the European Union 12°C are regarded as a reasonable average temperature for fresh water systems. The OECD TG 309 as a prelagic test at 12°C is the preferred study to be carried out independing of the physical-chemical properties and the exposure pathway of the substance. Most data for physical-chemical properties (e.g. water solubility) are generated at a temperature of 20°C in pure water and so far only very limited data for solubility at 12°C in natural surface water are available. Especially for substances with low water solubility testing is a challenge and the set-up of a reliable experimental test design becomes an issue. Another aspect is that due to the slower decline the uncertainties in deriving half-lives by kinetic fitting are increasing. Acc. to FOCUS guidance the data must be of sufficient quality to clearly establish the dissipation pattern. At 12°C the degradation is slower and a decline to 50% of the initial concentration might not be reached within the standard study duration of 60 days. Experiences with studies conducted at 12°C will be presented.

TH136

Aerobic Transformation of a Biocide in an Aquatic Marine Sediment System at 9°C

R. Commander, E. Pratt, Scymaris Ltd / Environmental Fate

A modified OECD 308 study was performed at 9°C to determine the amount and rate of degradation of a biocide at the more environmentally relevant temperature of 9°C than the OECD 308 guideline temperature of 20°C. This study had the following adaptations and enhancements from a standard OECD 308 to establish if degradation was improved: The temperature assessed was lowered to 9 ± 2°C Test substance was radiolabelled in two positions to enable tracking of different metabolites The seawater had mineral media added (following the OECD TG 306) Vessels were dosed either into the water phase or the sediment phase to monitor any differences in degradation Sediment was not sieved to ensure optimal viability at study initiation Lower water:sediment ratio (1:1.6) to minimise movement of test substance between water and sediment Non-extractable residue (NER) analysis was performed on all sediment samples to determine if the residues were Type I NER (sequestered, entrapped NER), Type II NER (covalently bound NER) or Type III NER (biogenic NER). **Keywords**: Biocide; marine sediment degradation; Non-extractable residue (NER); OECD 308

TH137

How to characterise non-extractable residues (NER) in PBT assessment - development of a harmonised procedure to be used in routine testing

D. Hennecke, Fraunhofer IME - Institute for Molecular Biology and Applied Ecology / Ecological chemistry; U. Jöhncke, German Environment Agency Umweltbundesamt / Chemicals; A. Wiemann, UBA Umweltbundesamt; J. Schmidt, German Environment Agency; D. Claßen, German Federal Environment Agency UBA; A. Schaeffer, RWTH Aachen University / Institute for Environmental Research; M. Kästner, Helmholtz centre for environmental research - UFZ / Department of Environmental Biotechnology; B. Meisterjahn, Fraunhofer IME - Institute for Molecular Biology and Applied Ecology / University of Vienna, Department Environmental Geosciences; S. Trapp, Technical University of Denmark DTU / Department of Environmental Engineering

In degradation testing in soils and water/sediment systems for regulatory purposes according to OECD standard guidelines, very often a fraction of the test substance is observed, that cannot be released from the solid matrix with non-destructive extraction methods. These so called Non-Extractable Residues (NER) can be detected only, if isotope labelled test substance is used, which is mandatory in regulatory framework if technically feasible. The importance of NER in the persistency assessment has been more or less neglected in the past. But according to new developments e.g. in REACH guideline revisions (ECHA R.11, 2017) the NER has to be considered as they may potentially be remobilised as parent or transformation product. One approach is to consider NER as 100% potentially available parent substance if not proven otherwise. This worst case assumption might be misleading because NER can also represent residues or products of degradation without any environmental relevance as they are irreversibly bound or transformed into biomass. Therefore, the ECHA published in June 2018 the discussion paper "*Consultancy services to support ECHA in improving the interpretation of Non-Extractable Residues (NER) in degradation assessment*" where guidance is given on how to characterise NER and the different NER types in practical testing. However, the discussion paper clearly states that discussions on NER assessment are still ongoing and the current paper represents a state of the art report only. In parallel and on behalf of the German Environment Agency (UBA) a project was conducted in order to develop a straightforward extraction procedure for NER characterisation for use in practical testing (FKZ 3713 63 413 1). The project results differ to some extent from the procedures described in the discussion paper and the question came up, how an acceptable method for use in regulatory routine testing can be derived. Thus, in September 2018 the German Environment Agency (UBA) initiated a project (FKZ 3718 65 407 0) in order to develop a harmonised procedure for practical testing taking into account both current approaches and proving the applicability of the harmonised approach experimentally using a set of reference substances. The project results will be discussed with regulators, scientists and stakeholders in an international workshop at the end of the project and it is intended to set the standard for future consideration of NER in chemicals persistency assessment.

TH138

Part II: Non-extractable residues (NER) in soil - A regulatory view.

T. Junge, knoell Germany GmbH

In order to assess the environmental fate of chemicals knowledge on their biotic and abiotic degradation is essential and is a key factor in risk assessment and their registration. While for industrial chemicals the main focus lies on screening tests to assess biodegradation, extensive degradation tests are needed to investigate the route and rate of degradation of plant protection products (PPP). This poster part II is complemented by poster part I outlined in a separate abstract (*F. Schnitzler et al., Part I: Non-extractable residues in soil – Review and definitions*). In general, degradation of chemicals in soil results in the formation of degradation products (i.e. metabolites), non-extractable residues (NER), microbial biomass and finally in their mineralization. Whereas on the one hand degradation products and as a final step mineralization (i.e. formation of CO_2) are rather easy to identify, assess and evaluate in laboratory tests on the other hand composition, nature and identity of NER are often unknown. As a consequence of these uncertainties, the question arises when NER should be considered as a safe sink and when as a potential risk. Beside the potential bioavailability and bioaccessibility of NER a major concern is a possible slow release from soil over the long term. Therefore, NER are an important parameter not only in risk assessment (i.e. PEC/PNEC) but also in hazard/persistence assessment (PBT) of chemicals. Regarding EU regulatory aspects of NER there are generally two essentially different views for authorisation of industrial chemicals and PPP. Within the regulation of industrial chemicals a precautionary approach is followed considering NER as non-degraded parent which generally overestimates the exposure concentration. For PPP a less conservative approach underlies their regulation considering NER as degraded residues of the active substance which are of no further concern representing a safe sink. However, a general cut-off criterion is laid down for PPP regarding the maximum amount of NER formed in combination with a low mineralization rate. On the basis of current regulations regarding NER in soil their evaluation in environmental risk assessment and PBT assessment within the regulatory context will be presented and discussed.

TH139

Part I: Non-extractable residues (NER) in soil - Review and definitions

F. Schnitzler, T. Junge, S. Dorn, knoell Germany GmbH

This poster aims to provide an introduction to the topic and goes back to the roots of the non-extractable residues (NER) concept in presenting an overview of the history, the evolvement of definitions and naming conventions over time and the current scientific state of the art. This poster part I is complemented by poster part II outlined in a separate abstract (*T. Junge, Part II: Non-extractable residues in soil - A regulatory view*). Based on different types of binding several types of NER are defined which correlate with the binding strength of (agro-)chemical compounds to soil. To characterise these bindings a wide range of extraction methods is commonly used. Advantages and disadvantages of these applied methods from gentle (i.e. shaking at ambient temperature) to harsh (i.e. supercritical fluid extraction) are presented and discussed. The formation of NER in soil is closely linked to the (bio)availability of (agro-)chemical compounds and their degradation kinetics. Implications from the formation of different types of NER on persistence and/or toxicity are briefly highlighted in a regulatory context before being discussed in more depth on poster part II. A scientific state of the art overview is provided regarding the characterisation and/or identification of xenobiotic NER and biogenic NER as well as the determination of (bio)availability. In parallel, also areas where sufficient insights are still missing today are presented: e.g. the lack of knowledge about the chemical nature of NER and how to detect NER with reliable methods and tools (experimental or modelling) to evaluate NER toxicity. Although NER represent a topic that has been discussed for decades it is still far from completion and leaves the door wide open for new scientific findings and regulatory developments.

TH140

Bioaccumulation assessment: new methods need new testing and assessment strategies - proposal of an ITS

C. Rauert, Umweltbundesamt / International Chemicals Management; U. Jöhncke, G. Treu, German Environment Agency Umweltbundesamt / Chemicals; C. Schlechtriem, Fraunhofer IME / Department Bioaccumulation and Animal Metabolism

Bioaccumulation assessment, usually mainly relying on the OECD test guideline 305 (the fish flow-through test) is part of the hazard and risk assessment in the context of registration and authorisation of industrial chemicals, pesticides, biocides etc. A number of alternative testing methods have been and are being developed, such as the in-vitro test guidelines for the determination of in vitro intrinsic clearance using cryopreserved rainbow trout hepatocytes and rainbow trout liver S9 sub-cellular fraction (OECD TG 319 A and B) and the new BCF test using *Hyalella azteca.* Both, standardised and non-standardised tests will need to be integrated into a coherent testing and assessment strategy including also other available tests such as OECD TG 315 and 317 covering bioaccumulation testing in terrestrial and benthic oligochaetes. Aspects which need to be considered are specific regulatory requirements, e.g. in cosmetics assessment, tests with vertebrates cannot be used. Also, substance specific testing conditions need to be addressed, as required for compounds such as surfactants, superhydrophobic or ionisable chemicals. The practical requirements for bioaccumulation testing of nanomaterials are still not clearly defined and adjustments of the established test systems are mandatory. The poster will discuss a possible integrated testing strategy (ITS), considering the different applicability domains of the tests and regulatory needs.

TH141

Bioconcentration of laurate in the freshwater amphipod Hyalella azteca

J. Raths, Institute for Environmental Research (RWTH Aachen University); S. Kühr, Fraunhofer IME - Institute for Molecular Biology and Applied Ecology / Bioaccumulation and Animal Metabolism; C. Schlechtriem, Fraunhofer IME / Department Bioaccumulation and Animal Metabolism

Regulatory assessment of bioaccumulation from water is commonly based on bioconcentration factors (BCF) derived from fish flow-through tests (OECD 305). Such experiments require a lot of laboratory animals and are time-consuming and costly. Further, the 3R principle postulates the replacement, reduction and refinement of vertebrate tests. An alternative test set-up for organic, neutral compounds using the freshwater amphipod *Hyalella azteca* was suggested. However, there is a lack of information on the bioaccumulation of ionic compounds in *H. azteca*. In this study the bioconcentration of the lauric acid anion laurate in *H. azteca* was investigated to elucidate the bioaccumulation potential of the test item in comparison to published data on zebrafish. In a first study, radiolabeled 1-^{14}C sodium laurate was applied to *H. azteca* in a flow through system. Media samples were analysed via LSC and radio TLC. Tissue concentrations were determined via LSC after combustion. Laurate showed to be rapidly biodegradable. Therefore, a second BCF-test was carried out under semi-static conditions to ensure stable exposure concentrations. Methods for tissue analysis were adjusted to allow an accurate quantification of the test item. Laurate was incorporated into various lipid fractions of *H. azteca*. However, more than 60 % of the total radioactivity found in the amphipod tissue was not extractable but could partially be driven out by acidification and captured as CO_2. The results suggest that also carbonate (CO_3^-) resulting from the mineralisation of laurate was bioaccumulated in the calcified exoskeleton of *Hyalella azteca* consequentlyleading to an overestimation of tissue concentrations,if accumulated compound was simply measured as total radioactivity and not further fractionated. The calculated BCF estimates differ from the one described in the literature for zebrafish. The results show that bioaccumulation of laurate varies between *H. azteca* and zebrafish. The mechanisms involved in the bioconcentration of the anionic compound seem to be more complex and the results cannot be extrapolated to other species without further research. Special care is required for *Hyalella* bioaccumulation studies with ^{14}C-labelled compounds which are rapidly mineralised.

TH142

How do fish bioconcentration factors for nonionic organic substances derived using dietary exposure compare with aqueous tests?

L. Camenzuli, ExxonMobil Biomedical Sciences; C.W. Davis, T. Parkerton, ExxonMobil Biomedical Sciences Inc. / Toxicology & Environmental Science; D. Letinski, ExxonMobil Biomedical Sciences Inc; J. Butler, ExxonMobil

Biomedical Sciences, Inc / Environmental Toxicology and Chemistry Laboratory; R.A. Davi, ExxonMobil Biomedical Sciences, Inc; E.J. Febbo, ExxonMobil Research Qatar; M. Leon Paumen, ExxonMobil Biomedical Sciences / ExxonMobil Biomedical Sciences TES Division; M. Lampi, ExxonMobil Biomedical Sciences, Inc. / Toxicology & Environmental Sciences
Traditional approaches to characterizing bioaccumulation based on aqueous exposure bioconcentration factors (BCFs) are often challenging for "difficult to test substances". Particularly, substances that have low solubility, or readily volatilize or degrade make it challenging to maintain constant exposures during aqueous BCF tests. An alternative dosing method, via dietary exposure offers several key advantages for these substances. Dietary exposures provide simpler, more consistent, and more relevant dosing methods for poorly soluble, difficult to test, substances as well as reduce the number of test organisms required. Further, dietary exposure and use of the resulting biomagnification factors (BMFs) allow the mitigating role of both tissue and gastrointestinal biotransformation to be quantified. Finally, the use of dietary exposures enable the BMFs (and consequently BMF-derived BCFs) to be derived using a mass-balance model framework. The purpose of this study is to compare BCFs derived from dietary BMFs with independently-determined BCFs from aqueous exposure tests, for a range of substances. These dietary-derived BCFs were compared to the aqueous BCFs to determine if these two exposure pathways are in agreement and to determine if dietary BMFs can be reliably used to estimate aqueous BCFs, which are currently used as the primary metric for "B" criteria in PBT assessment. This work has implications for applying existing and new dietary BMF data in bioaccumulation assessment frameworks.

TH143

How to determine KOA in the bioaccumulation assessment of air-breathing organisms?

S. Baskaran, University of Toronto, Scarborough / Chemistry; Y. Lei, University of Toronto / Physical and Environmental Sciences; F. Wania, University of Toronto, Scarborough / Physical and Environmental Sciences

Respiration is a contaminant elimination pathway in air-breathing organisms, that can prevent bioaccumulation of sufficiently volatile substances. In particular, a substance with an equilibrium partition coefficient between air and octanol K_{OA} at 25 °C below 10,000 may be regarded as non-bioaccumulative, because it is rapidly eliminated with exhaled air. Here we explore how this threshold could be employed in a first tier of a screening process for identifying chemicals that are potentially bioaccumulative in air-breathing organisms. Specifically, we are evaluating the performance of different K_{OA}prediction and measurement techniques within the threshold range of $3 < \log K_{OA} < 7$. This range is selected assuming that substances with a predicted $\log K_{OA} < 3$ are clearly too volatile to bioaccumulate, whereas those with a predicted $\log K_{OA} > 7$ are clearly not sufficiently volatile for exhalation to be an effective elimination pathway. Different K_{OA}prediction techniques, including various QSPRs, poly-parameter linear free energy relationships, and methods based on quantum-chemical predictions and statistical thermodynamics, are evaluated vis-à-vis a database of measured K_{OA}values reported in the literature. Based on the predictions of the methods found to perform best in the threshold range, a decision is made whether an experimental determination of the $K_{OA}$is required ("Is the predicted K_{OA} in the threshold range?"), and which technique is preferred ("Is the predicted K_{OA} at the upper or lower end of the threshold range?"). Experimental techniques relying on the analysis of the gas phase in closed vials equilibrating an octanol phase with the overlying headspace are most suitable for measuring K_{OA} at the lower end of the threshold range, whereas dynamic generator column techniques, that equilibrate a gas flow with a stationary octanol solution, are preferable for those at the higher end of that range.

Towards a Science-based Risk Assessment Framework for Nano- and Microplastic (P)

TH144

Spatiotemporal Trends of Microplastics Loading in the Sediments of River Ganga: First Observation on Occurrence, Identification and Quantification

A. Baroth, wildlife institute of india / Habitat Ecology; A. Shriwastav, Indian Institute of Technology Bombay Mumbai India / Centre for Environmental Science and Engineering; A. Pant, wildlife institute of india; r. sah, Wildlife Institute of India / Ecotoxicology; S.A. Hussain, wildlife institute of india

Microplastics (plastics less than 5 mm) with their ubiquitous presence and distribution is a newly recognized potential threat to aquatic ecosystems because of their direct toxicity to organisms or from the toxic pollutants they transport. However, the majority of the research has focused on microplastic load and toxic effect on marine ecosystems rather than on the freshwater aquatic ecosystems that are more closely connected to terrestrial microplastic contamination sources. River Ganga is the largest river in India and is a lifeline for millions of people as well as aquatic flora and fauna. However, excessive use of plastics in various sectors complemented with the scarcity of land for waste disposal and poorly developed waste management infrastructure makes River Ganga an uncontrolled dumping ground for plastics load, that may eventually put the health of its aquatic system into jeopardy. To best manage this microplastic contamination and minimize their exposure to aquatic organisms in River Ganga, it becomes highly imperative to develop comprehensive risk assessment and mitigation strategies. A well-defined monitoring strategy and quantification of microplastics contamination load, both spatially and temporally, will help to identify at-high risk zones, and thereafter accordingly develop effective monitoring and mitigation strategies. This study attempts for the first time, the spatiotemporal variation in the microplastic contamination of sediments from entire river Ganga as it passes through five Indian states starting from the rocky Himalayas to the heavily populated and industrialized plain lands. Sediments samples were collected from 55 sampling locations across the entire 2525 Km stretch of river Ganga through two seasons viz post monsoon and post-winter (2017-2018). Microplastics were extracted from these sediments with an optimized extraction protocol. Further, identification and characterization of the polymer types is performed using μ-FTIR. The results of the study provide a first time account on occurrence and levels of microplastic contamination for arguably the most sacred river of the world, i.e. river Ganga, which will help decision makers in policy formulation for managing pollution sources and combating their distribution. **Key words:** Ganga; Microplastic; Sediment; FTIR

Modelling emissions of microplastics in Europe from wastewater sources, including land applied biosolids

C.M. Holmes, Applied Analysis Solutions, LLC; J. Amos, Waterborne Environmental, Inc. / Geospatial Data Technologies; A. Ritter, M. Williams, Waterborne Environmental, Inc.; S.D. Dyer, Procter & Gamble Company / Environmental Stewardship and Sustainability Organization

Public information regarding microplastics in the environment is frequently available and comes from a variety of sources, often in the form of retrospective sources such as measured aquatic data. Science-based risk assessment must utilize both retrospective and prospective exposure information to effectively estimate potential risk to ecological receptors. While monitoring data provide information at only a few locations for several points in time, prospective models can estimate the potential for ecological exposures across many landscapes and over long periods of time, and both have a role in risk assessment. Wastewater treatment plants are often cited as a source of microplastics entering the environment. Microplastics are highly removed (generally >90%) during the waste water treatment process, via skimming of floating particles or sorption to solids and settling into sludge. Understanding the eventual fate of this sludge, and the potential for contained microplastics to re-enter surface water, is one step of many in determining the fate of microplastics in the aquatic environment. Sludge management in Europe varies geographically, with up to 90% of sludge used on agriculture in Portugal, and 0% in other countries (Eurostat, 2017) with other disposal including incineration, landfill or composting. We present a model which addresses both direct aquatic emissions into surface water via waste water effluent, as well as indirectly from land applied biosolids coupled with spatially-defined surface runoff potential. Generalized runoff potential is estimated using fate and transport models used for plant protection products found in the EFSA FOCUS scenarios. To our knowledge, this coupling of direct aquatic emission and sludge-biosolids-runoff is a novel approach for examining environmental emissions of microplastics which enter municipal wastewater treatment plants. This spatially-explicit model is based on publicly available datasets, combined with a hydrologic framework containing geographically variable emissions linked to a river network simulating environmental transport via surface water.

TH146

Following the fate of microplastics in a blue mussel exposure system

S. Rist, DTU (Technical University of Denmark) / DTU Environment; I.M. Steensgaard, DTU Technical University of Denmark / DTU Environment; O. Guven, DTU Technical University of Denmark / DTU AQUA; T. Nielsen, DTU Aqua / Technical University of Denmark; L.H. Jensen, L.F. Møller, DTU Technical University of Denmark / DTU AQUA; N.B. Hartmann, Technical University of Denmark / DTU Environment

Many laboratory studies have exposed marine invertebrates to microplastics and have reported ingestion as well as effects. A special focus has thereby been on the blue mussel *Mytilus edulis* and it is well known that blue mussels ingest microplastics of different sizes and shapes. Also, adverse effects on the animals' physiology have been reported. Particle concentrations in exposure tests are, however, often substantially higher than what is found in the marine environment. Furthermore, the fate of the tested particles in the exposure system is rarely investigated thoroughly. Both aspects are, however, important for evaluating observed effects. The aim of this study was therefore to quantify ingestion and egestion of microplastics in *M. edulis* at environmentally realistic particle concentrations and trace the fate of all particles in a controlled exposure system. Blue mussels were exposed to 50 μm polystyrene (PS) beads at concentrations of 5 or 100 beads L^{-1} for 10, 20 or 40 min and subsequently moved to clean seawater for 2h of depuration. After the respective exposure and depuration times, mussels were sampled to quantify the beads per animal. Additionally, the water bodies were filtered to retrieve all remaining beads. The number of beads in each compartment was quantified by counting them under a stereomicroscope. For this, the mussel tissues were enzymatically digested using a novel protocol with the protease Alcalase. This protocol proved to be highly efficient in digesting the tissue, while at the same time being easy to handle. It is thus promising to be used as a standard method. The quantification of PS beads in all compartments of the exposure system (i.e., mussels after exposure, exposure water, mussels after depuration, depuration water) resulted in a very high recovery and enabled the establishment of a mass balance of beads. This was achieved even at a low, environmentally realistic concentration. The distribution of the beads in the system was similar for both concentrations, indicating that mussels did not adapt their filtering activity. Two hours of depuration were not sufficient for egestion of the beads and should be prolonged. It is recommended that analyses of particle fate are incorporated more frequently in exposure studies as this can enhance our understanding of particle-organism interactions and observed responses.

TH147

Interactions and impacts of wheat plants grown in the presence of nanoplastic

A. Pradas del Real, IMIDRA; D.M. Mitrano, Eawag - Swiss federal Institute of Aquatic Science and Technology / Process Engineering; H. Castillo-Michel, ESRF-The European Synchrotron / ID; J. Reyes Herrera, M. Wazne, ESRF; G. Sarret, ISTerre Institut des SCiences de la TerreUNiversité Joseph Fourier

Plastic residues are highly resistant to degradation and persistent in the environment. Agricultural soils are an important sink for small particulate plastic (nano- and microplastic particles and microplastic fibers), either through the application of sewage sludge as amendment for nutrient replenishment or the wear and fragmentation of farming materials, such as mulch foils. A recent study has suggested that soil biophysical characteristics may be affected by the presence of particulate plastic (e.g. water holding capacity and soil structure), but it is not clear how crops are affected. In particular, in this study we aim to study the uptake and possible phytoxicity of nanoplastics in wheat plants. Because limited analytical techniques exist to measure nanoplastic particles, unique metal doped nanoplastic have been developed in our previous work, where the metal can be measured as a proxy for plastic in the system. A three-week hydroponic culture experiment was conducted where wheat plants were exposed to Pd-doped nanoplastics, added to fourth strength Hoagland nutrient solution at three different concentrations (0 mg. L^{-1}, 3 mg. L^{-1}, 30 mg. L^{-1}), and with two surface morphologies (either smooth or irregular). The zeta potential and agglomeration state of the nanoplastics and the pH of the nutrient solution were monitored during the culture. After harvest the following phytotoxicity parameters were determined: biomass, lipid peroxidation (TBAR´s) protein and chlorophyll content. Biochemical changes in plant tissues were studied by Fouried Transform Infrared Spectroscopy using Attenuated Total Reflectance (FTIR-ATR). Pd content in the roots and shoots were measured by ICP-MS, to quantitatively assess nanoplastic uptake. Nanoplastic distribution in the roots was studied by synchrotron micro X-ray fluorescence (μXRF) and scanning electron microscopy (SEM). X-ray micro computed tomography (μCT) was used to assess anatomical changes in exposed roots. In the nutrient solutions, the agglomeration state and pH increased during the culture. The increased agglomeration was consistent with the evolution of the zeta potential, which became less negative. Preliminary analysis on the harvested wheat plants showed no or limited phytotoxicity. μXRF showed nanoplastics sorbed on the root surface, which could hypothetically affect nutrient uptake. μCT and SEM-EDX data are currently being processed. This experiment is the first investigation on the possible uptake and effects of nanoplastics on plants.

TH148

Do microplastic fibers affect the toxicity of Ag nanoparticles to the water flea Daphnia magna?

P.d. Tourinho, VSCHT Praha / Department of Biology CESAM; V. Koci, Prague Inst. of Chemical Technology / Department of Environmental Chemistry; S. Loureiro, Universidade de Aveiro / Biology; C. van Gestel, Vrije Universiteit Amsterdam / Ecological Science

Microplastics (MP) are defined as plastic fragment waste having size < 5 mm. They have drawn scientific attention, as they can be abundantly found in the environment, emitted from different sources. One important source of MP is the release of fibers from textiles during wash. These fibers can reach freshwater ecosystems through the wastewater effluents. Moreover, the MP fibers can be emitted together with Ag nanoparticles (Ag-NP), since Ag-NP are incorporated in textiles due to their antimicrobial effects and are also released during the washing process. Therefore, this study aims at evaluating the joint effects of MP fibers and Ag-NP on the water flea *Daphnia magna*. Neonates (< 24h) were exposed to Ag-NP (2.56 – 250 μg Ag/L) and polyethylene terephthalate (PET) fibers (10 and 100 mg/L) in a full-factorial design, including controls. After 48h, the number of dead animals was recorded. The LC50 (95% CI) for Ag-NP in the absence of MP fibers was 204 (143-291) μg Ag/L, while values of 137 (111-169) and 164 (150-179) μg Ag/L were found in the presence of 10 and 100 mg/L of MP, respectively. Even though the LC50 decreased in the presence of MP fibers, no differences could be found among treatments, based on the overlap of the 95% CI. The main conclusions obtained in this study were: (1) MP fibers did not cause mortality of *D. magna* up to 100 mg/L when exposed alone; (2) PVP-coated Ag-NP (particle size of < 100 nm) used here was not as toxic as other Ag-NP reported in the literature; (3) the influence of MP fibers on Ag toxicity was not dose-related to MP fiber concentration in the water, as 10 and 100 mg/L of MP fiber produced very similar results regarding Ag toxicity. These are, however, preliminary results and the tests will be repeated to confirm these findings. Also, tests will be performed including ionic Ag (as $AgNO_3$) for comparison. Even though the number of studies is increasing, the toxicity of contaminants combined with MP is a very complex subject. Only a small number of toxicity studies have been conducted using irregular shaped MP, while most studies have used readily purchased spherical MP. Therefore, the outcomes from this study might give some insight into realistic exposure scenarios for daphnids. Due to the expected increasing levels of MP fibers and their high persistence in the environment, in case MP fibers really increase the toxicity of Ag-NP, their combined exposure can pose a risk to the aquatic organisms.

TH149

Biological impacts of bio-based and compostable microplastics on blue mussels (Mytilus edulis)

A. Khalid, University of Nantes; L. Poirier, Univeristé de Nantes / MMS; S. BENALI, R. Mincheva, J. Raquez, University of Mons; S. Bertrand, University of Nantes; A. Zalouk-Vergnoux, Univeristé de Nantes / MMS

The replacement of petrochemical plastics, owing to the severity of threat they impose to marine environment, to bio-based plastics need an evaluation for the toxic impacts of these new materials on marine wildlife. This study aimed to assess the toxicological effects of compostable plastic microparticles (MPs) on a marine shellfish, the blue mussel *Mytilus edulis,* combining biochemical marker analyses and a more global metabolomic approach. MPs of sizes ranging from 10 to 100 μm were produced from the fragmentation of polylactic acid (PLA). Each 15 individuals were exposed to no MPs, or MPs at two concentrations (10 μg/L and 100 μg/L) for 8 days. Significant decrease of AChE was observed in 10 μg/L compared to controls and 100 μg/L. These neurotoxic effects were similar as those depicted for petrochemical MPs. LMS and AcP activity were investigated to monitor the health of lysosomes of hemocytes. Insignificant variations of enzyme activity in mussels of all groups and no significant differences in lysosomal membrane structures were observed. Regarding oxidative stress, CAT, GST and SOD activities were significantly increased in 10 μg/L concentrations. These upregulations implied physiological challenges the organism faced after MP exposure. The OPLS-DA on metabolomic data allowed to discriminate the individuals according to their exposure condition. The loading plot highlighted 42 features down regulated in the individuals exposed during 8 days to MPs. Most of these molecules were identified as glycerophospholipids based on HRMS data. Glycerophospholipids are one of the major components of lipid membranes where they ensure several roles including regulation of the binding of protein to membranes, acting as messengers and participation in signaling such as cell cycle and appoptosis. To conclude, PLA microplastics showed effects on the blue mussel after 8 days of exposure at environmental doses with the detection of oxidative stress and neurotoxicity. Greater effects were shown at the lowest concentration (10 µg/L) compared to the highest concentration (100 µg/L). This observation could be explained by low filtration activity of gills at highest concentrations, as it was previously demonstrated for plastic nanoparticles. The lipidome of mussels was also impacted by MPs at both doses. Biochemical and metabolomic approaches appeared to be complementary tools in the assessment of environmental risk of bio-based microplastics.

TH150

Biological Effects of virgin and weathered Microplastic Particles and their Leachates in the green algae Scenedesmus vacuolatus

D. Kühnel, Helmholtz-Centre for Environmental Research / Bioanalytical Ecotoxicology; C.D. Rummel, Helmholtz Centre for Environmental Research GmbH - UFZ / Department of Bioanalytical Ecotoxicology; H. Schäfer, Helmholtz Center for Environmental Research UFZ GmbH; K. Oelschlägel, Fraunhofer Institute for Ceramic Technologies and Systems IKTS / Powder- and suspension characterization; A. Potthoff, Fraunhofer Institute for Ceramic Technologies and Systems IKTS; M. Schmitt-Jansen, Helmholz Centre for Environmental Research-UFZ / Bioanalytical Ecotoxicology; A. Jahnke, Helmholtz Centre for Environmental Research - UFZ GmbH / Cell Toxicology

Studies on the potential effects of microplastic (MP) particles in the aquatic environment are numerous. However, many laboratory studies apply pristine particles, which may be of limited environmental relevance given that factors such as UV light irradiation, mechanical stress, salinity and biofilm growth can influence the weathering of plastic debris. The aim of this study was to assess the impacts that weathering has on the effects of MP particles and their leachates on the unicellular green algae *Scenedesmus vacuolatus*. The presented work reports on two experiments performed on pristine and artificially aged plastic material: in the first experiment, focusing on the development of different size fractions during weathering LDPE and PET particles were exposed to UV (equivalent to 112 d outdoors). In a second, experiment leachates were obtained after the weathering of PE, PS, PP and PET as well as positive controls (equivalent to 510 days outdoors): (1.) Impact of MP particles on green algae: exposure to different size fractions of MP. Four different effect parameters (related to growth as well as photosynthetic capacity) for the different fractions were observed. The biological experiments were accompanied by an extensive characterization of the amount and size of polymer particles in each of the fraction. (2.) Mixture effects of chemicals liberated from the polymers during weathering toward algae. Chemicals built during UV-exposure and liberated in leachate water during simulated weathering of MP were enriched by solid-phase extraction. The concentrated leachates were then dosed into the algae assay. The results show that for LDPE and PET polymers the aging regime leads to shifts in particle masses contained in the different fraction, with a stronger impact of weathering on the PET. None of the fractions, irrespective of polymer type, impacted growth and photosynthesis of green algae. For the leachates, however, distinct effects were observed. The positive control used in the leaching experiments (electronic waste, milled keyboard) provided a proof-of-principle. Leachates from the mostly additive free reference polymers PE, PET, PS and PP showed higher effects in the UV treatments compared to the corresponding dark controls toward *Scenedesmus vacuolatus*. Our findings indicate that the biological effects of chemicals leaching out of weathering plastic material may have a stronger impact on algae compared to the weathered polymer particles.

TH151

Comparative toxicity of plastic additives toward Daphnia magna

J. Song, J. Na, Korea University; J. Jung, Korea University / Division of Environmental Science & Ecological Engineering

Worldwide, the amount of plastic production getting increased from 1.5 million at 1950 to 320 million tons at 2015. Plastics are used in many ways, such as packaging, building and construction, transportation, and so on. Recently, researchers have reported the significance of microplastics ingestion by aquatic organisms (e.g. fish, water flea, mussel). For instance, it was demonstrated that *Daphnia magna* can take microplastic fiber with size from 62 to 1400 μm. Additionally, acute toxicity of additives from polystyrene (PS) to *Ceriodaphnia dubia* was reported and LC50 of ethylbenzene leaching from PS was appeared to be 14 ppm. Most research focused on the adverse effect of micro- or nano-size plastics on aquatic organisms, while a few study reported the effect of plastic additives such as antioxidants, light stabilizer and thermal stabilizer. Especially, the study on the toxic effect of plastic additives on *D. magna* is very limited. *D. magna* has high sensitivity to pollutants and thus wildly used for toxicity testing. Therefore, the aim of this study was to compare the toxic effect of additives from plastics to *D. magna*. Acute and chronic toxicity testing was conducted according to the OECD guidelines to quantify the adverse effect of additives from plastics onto *D. magna*.

TH152

Microplastics as Pollutant Vector in Rivers and Oceans: Influence of Non-Linear Sorption and Coupled Mass Transfer

S. Seidensticker, Eberhard Karls Universität Tübingen / Center for Applied Geoscience; C. Zarfl, University of Tuebingen / Center for Applied Geoscience; O.A. Cirpka, Eberhard Karls Universität Tübingen / Center for Applied Geoscience; P. Grathwohl, Uni Tübingen / Center for Applied Geoscience

Microplastic particles are ubiquitously detected in the environment. Despite intensive discussions, an assessment of their potential to transport contaminants in rivers and oceans is still needed. Thus, we aimed to combine measurements and modelling approaches to improve the understanding of pollutant sorption to microplastics. We measured sorption isotherms and kinetics in batch experiments with phenanthrene as typical hydrophobic contaminant and different types of particles, varying in size and material. While we observed linear sorption isotherms for polyethylene (PE), polyamide (PA) and polystyrene (PS) showed nonlinear sorption which we described best by the Freundlich and Polanyi-Dubinin-Manes isotherms, respectively. In order to evaluate sorption kinetics, we developed a model that describes sorption as a combination of two diffusive resistances, namely external mass transfer governed by diffusion through an aqueous boundary layer and intraparticle diffusion within the plastic. Which of these resistances controls the kinetics depends on the sorption strength, particle size, diffusion coefficients, and time. We applied semi-analytical and numerical methods to simulate coupled mass-transfer for both linear and non-linear sorption. Mass transfer of phenanthrene to PE shifts from film to intraparticle diffusion over time. By contrast, kinetics of PS and PA are limited by intraparticle diffusion over almost the whole time as diffusion coefficients are several orders of magnitude lower. The numerical code was successfully applied to PA and PS, allowing to describe the measured kinetics and obtain reasonable values for mass transfer and intraparticle diffusion coefficients. Subsequently, we used these coefficients to estimate the transport potential and time scales for microplastic-bound contaminants under environmental conditions in river and ocean settings. Whether the particles act as a passive sampler or transport vector is strongly dependent on particle diameters, partition coefficients, and intraparticle diffusion coefficients. The potential for long-range transport increases with the particle size squared and decreases with the intraparticle diffusion coefficient. On the other hand, smaller particles equilibrate fast and thus presumably reflect the ambient concentration in water, i.e. act as a passive sampler. Furthermore, the time scales imply that particularly larger particles have the potential to transport sorbed substances to remote areas.

TH153

Do microplastics contribute to organism exposure to contaminants? Modeling contribution of microplastic to environmental exposure & implications for prioritization within a risk-assessment framework

C.W. Davis, F.A. Grimm, ExxonMobil Biomedical Sciences Inc; M. Lampi, ExxonMobil Biomedical Sciences, Inc. / Toxicology & Environmental Sciences; C. Palermo, R. Barter, ExxonMobil Biomedical Sciences Inc.

Micro- and nano-plastic particles are ubiquitous in freshwater and marine environments, including soil and sediment compartments. There has been significant work, to date, to address the potential for co-contaminants in these systems (e.g., persistent organics (PCBs, PBDEs, PFAS), hydrocarbons (PAHs), pharmaceuticals, and heavy metals) to sorb onto these small plastic particles (SPP) and to be transported both within the environment and within organisms. **This body of work, however, has largely failed to answer the practical question – are these "secondary effects" of micro-plastic co-contaminants a significant factor in assessing the risk of microplastics to (human health and) the environment?** The purpose of this work is two-fold: First – to summarize available sorption and de-sorption data for various relevant classes of organic chemicals and metals onto both pristine and weathered plastic particles (PE, PP, PVC, PA) and compare these to the sorptive capacities of other relevant environmental solid phases (i.e., organic carbon, DOM, silica, etc…) in fresh and marine water systems as well as sediments. The second aim of this work is to place the sorption of these contaminants to SPPs into the larger context of total exposure to organisms, incorporating relevant environmental exposure data for SPPs as well as other environmental particulates with a focus on relative contribution to the overall body burden within organisms. The overall goal of this work is to provide support and guidance for prioritizing these "secondary effects" of micro-plastics relative to other considerations (i.e., particle size, polymer-type, surface charge, weathering, agglomeration, etc…) within a risk-assessment framework under development for micro-plastic hazard and risk assessment.

TH154

Broad chemical industry initiative to develop a prototype environmental risk assessment framework for Microplastics (MP)and engage in relevant LRI research.

B. Hubesch, O. Albert, CEFIC LRI; O. de Matos, ECETOC; P. Hopp, BASF Personal Care and Nutrition GmbH; B. Serrano, CEFIC European Chemical Industry Council; R. Becker, American Chemistry Council; K. Inawaka, JCIA / LRI Project; J.W. Davis, Dow Chemical Company / TERC

1. Development of a prototype Environmental Risk Assessment Framework for MP There continues to be increasing concern regarding the presence of MP in the environment. There are also still many knowledge gaps around the impacts of MP in the environment. To best address data gaps requires co-operation among all stakeholders engaged in advancing our mechanistic understanding of the environmental effects, fate, and exposure of MP. To most effectively set and use research priorities and capabilities, industry started to facilitate multi-stakeholder events and developed an organisational structure to quickly convert research priorities into projects. **2. Cefic-LRI research project ECO48: "Develop Fate and Transport Model for Microplastics in the Aquatic Environment" (250.000Eur/2y, start Q1-2 2019)** A regional and global scale environmental fate and transport model for MP is needed 1.Takes into account and leverages existing fate and transport modelling frameworks for similar particulate matter; 2.Identifies physical/chemical properties of MP that are useful for informing environmental fate and transport 3.Determines environmental characteristics that are useful for informing environmental fate and transport 4.Informs the expected environmental concentrations of MP in different compartments. ECO48 RfP 3. **Cefic-LRI research project ECO49: "Evaluate factors that determine the environmental hazards of microplastics" (400.000Eur/3y, start Q1-2 2019)** Phase 1: It is proposed that a comprehensive literature review be conducted in order to identify both key ecological hazard research gaps and the appropriate methodologies for conducting hazard tests with MP materials to fill these research gaps. Phase 2: Based on this literature review, targeted ecological hazard research should be proposed and conducted to evaluate how both intrinsic and extrinsic factors influence the effects of MP on sensitive environmental species. ECO49 RfP **4. Review the state-of-the-science for aquatic toxicity testing of particles and poorly soluble liquids** The European Centre for Ecotoxicology and Toxicology of Chemicals (ECETOC) initiated a Task Force (TF) to review the literature in relation to the aquatic toxicity testing of particulates, such as nanomaterials and microplastics, and poorly soluble liquids. The TF identified an urgent need to strengthen the quantitative and mechanistic understanding of the relationship between intrinsic physicochemical properties and observed adverse effects.

TH155

Microplastics in the Environment - A Literature Trend Analysis

F.A. Grimm, C.W. Davis, ExxonMobil Biomedical Sciences Inc; M. Lampi, ExxonMobil Biomedical Sciences, Inc. / Toxicology & Environmental Sciences; C. Palermo, R. Barter, ExxonMobil Biomedical Sciences Inc.

Microplastic pollution is a growing environmental and public health concern given the ubiquity of particles identified in environmental samples. While occurrence of marine microplastics has been documented in a number of regions, potential environmental and human health impacts are less well understood. The goal of this review is to characterize the current state of the peer-reviewed literature on microplastics and to identify key literature references as well as data gaps. An emphasis is placed on analytical techniques for environmental sampling, exposure considerations, environmental fate and transport, ecotoxicology, and potential human health impacts, key focus areas required to address a risk assessment framework for microplastics. >2500 articles were initially identified through Web of Science and Pubmed database searches. Following removal of 868 redundancies and exclusion of subject-irrelevant publications by manual curation, 1219 articles relevant to the search topic were retained. Software-assisted trend analysis in "Sciome Workbench for Interactive computer-Facilitated Text-mining" (SWIFT Review) revealed a proportionally strong increase in the number of new publications per year, a trend that is consistent with increased public awareness and media coverage on microplastic pollution. Intentionally manufactured and secondary, degradation-derived microplastic particles remain the primary focus in the literature (1102 hits). Concordant with the general increased interest in the topic, the secondary effects literature addressing additives, and vector potential for environmental contaminants and pathogenic bacteria, is proportionally increasing (163 hits). Subsequent categorization of articles in "Health Assessment Workspace Collaborative" (HAWC) indicated a strong focus in the exposure, environmental fate & transport, and ecotoxicology literature. Comparably fewer articles focused on analytical method development, and the most underdeveloped focus area was represented by the human health impacts literature. This review concludes with identifying relevant data gaps and research needs.

TH156

Health risk associated with plastic debris on the Island of Zanzibar

K. Syberg, Roskilde University / Dept of Science and Environment; L. Buur, Roskilde University / Department of social science and business; V. Perold, FitzPatrick Institute of African Ornitholog / DST-NRF Centre of Excellence; L. Simonsen, L. Jelsbak, Roskilde University / Department of Science and Environment

Several studies have indicated that pathogenic bacteria bind particularly strongly to plastic pollution particles. This implies that plastic debris might serve as a vector for spreading of diseases with subsequent consequences for human health in polluted areas. In areas where (especially) poor people gather plastic waste to sustain a living for their family, and pathogens such as *Vibrio cholerae* are present, the plastic pollution paticles can be a vector for spreading disease among the local population. This potential human health risk of plastic pollution provides a substantial challenge, since there is a need to conduct mitigation efforts to preserve the environment and the ecosystem services it provides, and at the same time avoid enhanced risk of Cholera or other pathogenic bacteria such as pathogenic strains of *Escherichia coli.* Zanzibar is a pefect setting for this "one health" research project, as it features recurrent Cholera outbreaks as well as significant documented problems with plastic pollution and thus serve as a good area for a case study of this potential widespread problem. This project simultaneously aims to assess the risk of human health from plastic-associated pathogens to the local population in an epidemiological context and subsequently facilitate development of safe and effective mitigation efforts. This will be done by collecting plastic debris particles in relavant locations in Zanzibar and analysing which pathogens that are associated with the particles. The exposure to local communities will subsequently be assessed by interview and observation studies aiming at understanding how the local community is physically interacting with the debris under clean up operations. Upon having quantified the risk to the human population, we will seek to collaborate with the local community on educational campaigns about these risks, and to building the nessesary local infrastruture to handle the plastic pollution in a sustainable manner. This way the project aims at ensuring proper environmental protection and at the same time reducing health risk posed to the local community.

Bridging the Gap: Maximizing the Role of Mechanistic Approaches (Including Omics) for Better Chemical Safety Decisions Across Humans and Ecosystems (P)

TH157

Cytotoxicity of deep eutectic solvents to human skin cells

I.E. Macário, University of Aveiro / department of Biology & CESAM; C. Menezes, University of Aveiro / Department of Biology; S.P. Ventura, University of Aveiro / Department of Chemistry & CICECO; J. Pereira, University of Aveiro / Department of Biology & CESAM; A.M. Gonçalves, MARE, Dep. of Life Sciences, Coimbra University/Biologia Department & CESAM, Aveiro University; J.A. Coutinho, CICECO - Aveiro Institute of Materials & Department of Chemistry, University of Aveiro / CICECO, Department of Chemistry; F.J. Gonçalves, University of Aveiro / department of Biology & CESAM

Deep eutectic solvents (DES) emerged in the last years as surrogates for conventional solvents. Their tailor-made character turns them very attractive, being the possibilities of designing new DES almost endless. This feature allows DES to be used in chemical, electrochemical and material applications, as well as in health-related areas in the pharmaceutical, nutraceutical, and cosmetic industries. However, although DES have been touted as "green" solvents, several works with model organisms and human cell lines proved that in some cases their potential toxicity should not be neglected, and in any case it should be characterized prior to extensive application. In the present study, we used the premise of DES applicability in the cosmetic and pharmaceutical sectors. Two cell lines were chosen to work as a skin models (keratinocytes HaCaT and tumor melanocytes MNT-1), to assess DES cytotoxicity. The effect of three different hydrogen bond acceptors (HBA) ([Chol]Cl, [N_{1111}]Cl and [N_{4444}]Cl) and three different hydrogen bond donors (HBD) (hexanoic and butanoic acid, ethylene glycol, 1-propanol and urea) were evaluated through the common viability assay (MTT assay). Thus, the cytotoxicity of fifteen DES, as well as their starting materials, was assessed for both cell lines. Results were promising since [Chol]Cl and [N_{1111}]Cl- based DES showed good biocompatibility for the tested cells. [N_{4444}]Cl-based DES, however, showed cytotoxicity for both cell lines, with the HBA being the driver of the toxicity. Interestingly, some compounds increased cell viability in the HaCaT cell line. [Chol]Cl, ethylene glycol, hexanoic acid, urea, and all [Chol]Cl and [N_{1111}]Cl-based DES are such an example and should be considered as targets for future studies regarding their potential in skin regeneration. These results highlight the versatile character of some DES and their possible use in cosmetic or pharmaceutical formulations. CICECO and CESAM were financed by national funds through the FCT/MEC and when co-financed by FEDER under the PT2020 Partnership Agreement (UID/CTM/50011/2013 and UID/AMB/50017/2013). FCT funded IPE Macário, C Menezes, H Oliveira, AMM Gonçalves, JL Pereira and SPM Ventura (SFRH/BD/123850/2016, BI/CESAM/012/AMB/50017, SFRH/BPD/111736/2015, SFRH/BPD/97210/2013, SFRH/BPD/101971/2014 and IF/00402/2015), and supported the research through the project Ref. PTDC/ATP-EAM/5331/2014.

TH158

Molecular mechanism of Cadmium-TiO2 nanoparticle mixtures when co-exposed to the nematode Caenorhabditis elegans

L. Kleene, Hamburg University of Applied Sciences (HAW) / Life Sciences; A. Hursthouse, University of the West of Scotland / School of Science; S. Heise, Hamburg University of Applied Sciences / Life Sciences

Nanoscale titanium dioxide ($nTiO_2$) is probably among the most relevant engineered nanomaterials with a projected accumulation rate in European river sediments of 2 $mg*kg^{-1}*yr^{-1}$ (1). To evaluate the environmental risk of $nTiO_2$, the impact of co-exposure with other aquatic contaminants like cadmium (Cd) should be considered. While Angelstorf (2) had shown that the toxicity of $nTiO_2$ (P25) to the nematode *Caenorhabditis elegans* increases under simulated solar radiation (SSR), Samet (3) found synergistic inhibitory effects on the nematode, when co-exposed to $nTiO_2$ and Cd. The effect again was only observed when worms were irradiated during exposure (inhibition of reproduction by 80 % after SSR, 20 % under solely dark conditions). We present here experimental data which may explain this synergistic effect: (a) Cd is known to compete with Ca for ion-channels due to the chemical resemblance of the two ions (4). It also induces intracellular Ca-signalling as part of protective cell processes (5). Thus, the effect of Cd/$nTiO_2$-mixtures on Ca-ion channels in the intestinal membrane of *C. elegans* was investigated using a known human ion channel (TRPM7)-blocker: NS8593. The combination of nTiO2 and NS8593 showed the same effects under SSR as the $nTiO_2$/Cd mixture, which supports our hypothesis that the mode of action involves this Ca-channel. To validate this result, other possible receptors and their antagonists were tested: Lanthanum for TRPM3-channels in the cellular membrane and Heparin for IP_3-receptors in the membrane of the endoplasmatic reticulum. (b) In order to understand, whether the radiation has any impacts on the chemical structure of $nTiO_2$-Cd-agglomerates, not-irradiated and irradiated samples were characterized by Scanning Electron Microscopy, Dynamic Light Scattering and Energy Dispersive X-ray Spectroscopy. To also test the influence of pH changes during gut passage of agglomerates, samples were tested at pH 4 and 7. (c) Further experiments are currently undertaken, looking into the impact of $nTiO_2$-Cd-agglomerates on membrane integrity applying propidium iodide to check for non-specific effects of the Cd/$nTiO_2$-mixture on the cells under SSR. A quantitative proteomics approach to study the toxicological pathways of silver nanoparticle: A comparison of human skin carcinoma cell to zebrafish embryo

P. Samutrtai, National Science and Technology Development Agency, Thailand / Nanotechnology Centre; S. Krobthong, National Science and Technology Development Agency Thailand / Biotechnology Centre; W. Pimtong, National Science and Technology Development Agency Thailand / Nanotechnology Centre; S. Roytrakul, National Science and Technology Development Agency Thailand / Biotechnology Centre

The advance in nanotechnology has improved the properties of conventional materials into a highly-reactive form, which broaden their applications into many fields. However, this development has also raised concern regarding their high-bioactivity could lead to the risk to both human and environment. Although many reports have addressed the adverse effects from nanoparticles (NPs), the underlying mechanisms of these observations were unclear. Moreover, the majority of nanotoxicological studies were conducted under the unrealistic condition, which only predicted the worst-case scenario of NPs exposure, therefore the relevant toxicological effects from NPs might not be comprehensively understood. In this study, the molecular effects of silver nanoparticles (AgNP) were investigated under the ecologically-relevant condition in both human skin cell and environmental model, i.e. zebrafish embryo, to compare the toxicological pathways by using quantitative proteomics approach. The comprehensive sets of differentially expressed proteins were identified from HDMS-LC-MS/MS, which were further categorised by their molecular function using Progenesis® QI for Proteomics. The toxicological pathways of AgNP in both human skin cell and zebrafish embryo were indicated by STITCH protein-ligand interaction algorithm. Moreover, the enrichment analysis based on KEGG pathways were performed, in which the difference in toxicological pathways could be reported. The predominant pathway analysed from human skin cell was DNA damage, whereas oxidative stress was the major toxicological pathway observed in zebrafish embryo. The similar protein pathway disrupted by AgNP in both models was the metabolic process. Although the difference in molecular pathways was established between human cell and zebrafish embryo, it confirmed the occurrence of adverse effects from AgNP, specifically in the low concentration. Moreover, metabolic process is important to maintain cellular homeostasis, as well as the development of zebrafish embryo. The future study on metabolomics would be constructive to this finding. These omics approaches would be powerful to screen safety of other NPs, which will be applicable to help design the effective and harmless NPs in the future.

TH160
Dreissenid mussels on sertraline medication: does the mode of exposure influence their biological responses?
L. Minguez, LIEC Université de Lorraine CNRS / Laboratoire Interdisciplinaire des Environnements Continentaux, CNRS UMR 7360
The presence of pharmaceuticals in aquatic ecosystems is now established. However, the risks to aquatic organisms after chronic exposures to low environmental concentrations are still unknown and therefore remain to be determined. Pharmaceutical releases into the environment are not always continuous and can also be by pulses. In this context, both their concentrations, the duration of exposure and the frequency of this exposure may influence the biological responses of non-target organisms. However, up to now, laboratory experiments mostly mimicked continuous exposure. Therefore, it is important to determine if the mode of exposure to pharmaceuticals may affect the biological responses of non-target aquatic organisms. In order to provide answers to this question, two freshwater bivalves of the genus *Dreissena*, commonly used in ecotoxicological studies (the zebra mussel, *Dreissena polymorpha* and the quagga mussel *Dreissena rostriformis bugensis*) were chosen as model organisms. These two species have different life history traits and thus, may respond differently to the exposure. The bivalves were exposed to sertraline during 28 days, either continuously or by pulse every 5 days. Sertraline (Zoloft), a selective serotonin reuptake inhibitor, is an antidepressant commonly prescribed worldwide to treat mental disorders. During this experiment, several biological responses were followed every week, such as the contents of energy reserves, the activities of antioxidant defenses and lysosomes, or the behavior of bivalves. The concentrations accumulated by the bivalves were also measured. The first results show a higher sensitivity of *D. r. bugensis* to sertraline exposure than *D. polymorpha* during the spawning period.

Gene transcription analysis of Daphnia magna exposed to carbendazim: a multigenerational approach
A.R. Silva, University of Aveiro / Dept.of Biology & CESAM; P. Silva, Universidade de Aveiro / Biology Department and CESAM; A.R. Soares, G. Moura, University of Aveiro / Department of Medical Sciences & Institute for Biomedicine (iBiMED); A.M. Soares, University of Aveiro / department of Biology & CESAM; S. Loureiro, Universidade de Aveiro / Biology
Despite all the progress in agriculture, pesticides are still used and consequently continuously released into the environment, with possible long-term consequences for aquatic organisms. One of the pesticides still applied in several crops in some countries is the fungicide carbendazim, ending up in surface waters with concentrations reaching 5 μg/L. In the present study, *Daphnia magna* (clone k6) was exposed to a sublethal concentration of carbendazim (5 μg/L) for 12 generations. Gene expression alterations induced by this compound were assessed in the F0 and F12 generations using a *D. magna* custom microarray. Results revealed that carbendazim caused changes at the gene expression level in both generations. Genes involved in response to stress, DNA replication/repair, neurotransmission, protein biosynthesis, ATP production, lipids and carbohydrates metabolism were the most affected in both F0 and F12 generations. Compared with the F0, a lower number of differentially expressed genes was observed in the F12 generation exposed to carbendazim. The exposure of daphnids to carbendazim did not cause a stable change in gene expression from F0 to F12 generations. Effects at the gene expression level were already detected in the F0 generation after a short-time exposure (10 days), highlighting the advantages of using high throughput tools for early warning analysis and adding value to risk assessment procedures. These gene expression data complement the available information on effects at different higher biological levels oforganization and will therefore improve the understanding of effects of carbendazim under a multigenerational exposure scenario.

TH162
Chemical prioritization by computational transcriptomics: a two case studies
D. Basili, Marche Polytechnic University / Deparment of Life and Environmental Sciences; L. Marisaldi, G. Gioacchini, Università Politecnica delle Marche / Department of Life and Environmental Sciences; J. Zhang, University of Florida; J. Herbert, University of Liverpool / Institute of Integrative Biology; K.J. Kroll, University of Florida / Physiological Science; N.D. Denslow, C.J. Martyniuk, University of Florida / Physiological Sciences; F. Falciani, P. Antczak, University of Liverpool / Institute of Integrative Biology; O. Carnevali, Università Politecnica delle Marche / Department of Life and Environmental Sciences
Thousands of chemicals used worldwide have the potential to harm human health and ecosystem functioning. Toxicity information for most of these compounds are currently lacking. However, due to experimental costs and time and in agreement with the requirement of the 3Rs framework, it is not practical to evaluate toxicity for all the compounds to which humans and ecosystems are potentially exposed. Developing alternative approaches with the ability to prioritize harmful compounds is of paramount importance. In a first study, a *de novo* transcriptome assembly was performed to investigate signals involved in ovary maturation in the swordfish (*Xiphias gladius*). By focusing on differentially expressed genes, a pathway analysis was employed to investigate the molecular mechanisms driving the transition from immature to mature ovary. Genes found to be differentially expressed hence playing a key role towards maturation where used to interrogating the Comparative Toxicogenomic Database (CTD) in order to identify compounds with the potential to affect ovary maturation. Chloropicrin and Cyclosporine were identified as the best candidate compounds with the ability to disrupt ovarian maturation. In a second study, we developed a dynamic model of ovary development linking gene transcription to key physiological endpoints, such as gonadosomatic index (GSI), plasma levels of estradiol (E2) and vitellogenin (VTG), in largemouth bass (LMB) (*Micropterus salmoides*). By mapping the responses of a transcriptome from LMB collected from a polluted site, we identified a sub-network that closely linked gene expression and physiological endpoints and by interrogating the CTD, Quercetin and Tretinoin (ATRA) were identified as two potential candidates to elicit reproductive disruption. Predictions were validated by qPCR in ovary and in the liver of both male and female LMB exposed to Quercetin and Tretinoin. Both compounds were found to significantly alter the expression of key endocrine genes. These studies demonstrate that by utilizing computational approaches and online knowledge bases to understand the underlying molecular response of organisms, it is possible to identify putative chemical candidates that may impact reproductive health. This approach is highly relevant for classifying chemicals prior to conducting risk assessments, and we propose that this is a viable approach for chemical prioritization, reducing animal numbers, and developing safer chemicals in the public domain

TH163
Adverse outcome pathways for non-chemical stressors: the case of radiation
Y. Song, Norwegian Institute for Water Research (NIVA) / Ecotoxicology and Risk Assessment; L. Xie, Norwegian Institute for Water Research; C. Eastabrook, Newcastle University / School of Natural and Environmental Sciences; D.A. Brede, Y. Kassaye, Norwegian University of Life Sciences / Centre for Environmental Radioactivity; Y. Lee, Norwegian University of Life Sciences; T. Gomes, Norwegian Institute for Water Research (NIVA) / Ecotoxicology and Risk Assessment; G.S. Caldwell, Newcastle University; B. Salbu, Norwegian University of Life Sciences / Centre for Environmental Radioactivity; K. Tollefsen, NIVA / Ecotoxicology and Risk Assessment
An adverse outcome pathway (AOP) mechanistically organizes the existing (eco)toxicological information from different levels of biological organization, similarly-acting stressors and phylogenetically conserved taxa into a linear pathway by connecting a molecular initiating event (MIE), a series of subsequent key events (KEs) and an adverse outcome (AO) of regulatory concern. The AOP framework has promoted mechanistic understanding of toxicity, and the development of *in vitro* and *in silico* approaches for more efficient hazard and risk assessment of chemicals. However, organisms in the environment are not only exposed to chemicals, but also a multitude of stressors such as radiation, abiotic and biotic factors. These non-chemical stressors may cause adverse effects and affect the toxicity of chemicals. Since the current AOP framework is chemical-centric, there is need to expand it to non-chemical stressors for future application of AOPs in hazard and risk assessment of multiple stressors. The present work was therefore conducted to develop AOPs for non-chemical stressors using radiation as a starting case. Both ionizing (e.g. gamma) and non-ionizing (e.g. UVB) radiation are known to induce reactive oxygen species (ROS) and DNA

damage as common MIEs and eventually lead to reduced survival, growth and reproduction as common AOs. Extensive literature survey and data mining were performed to summarize existing knowledge and to develop a conceptual AOP network for ionizing and non-ionizing radiation. Experimental evaluation of the AOPs were conducted using the aquatic crustacean Daphnia magna as the forecaster species, and gamma and UVB radiation as the prototypical stressors. A suite of effect assessment tools such as the ROS formation assay, DNA damage assays, apoptosis assay, lipid peroxidation assay, mitochondrial membrane potential assay, ATP assay, lipid storage assay and biomarker gene expression assay were used to populate KEs of the conceptual AOPs with experimental data. The overall weight of evidence was assessed using the Bradford Hill Considerations and applicability domains defined using the NIVA Risk Assessment Database (NIVA RAdb^{TM}), which collects and organizes (eco)toxicological data from both in-house studies and public databases. The AOPs have been submitted to the AOPWiki for public review. This study has for the first time developed AOPs for non-chemical stressors, and provided mechanistic knowledge of radiation-mediated adverse effects.

Dose-response Curves for -OMICS data in soil quality assessment (DrComics)

R.R. Bakker, Vrije Universiteit Amsterdam; Y. Shapovalova, T. Heskes, Radboud University Nijmegen; T. Dijkstra, Tübingen University; K. van Gestel, Vrije Universiteit Amsterdam / Ecological Science; D. Roelofs, Vrije Universiteit / Department of Ecological Science

Traditionally, phenotypic endpoints of test organisms, such as survival, reproduction, and growth, have been used for the assessment of a compound's toxicity. However, these endpoints are influenced heavily by environmental factors such as seasonality, climate and soil type. Moreover, human activity releases more pollutants, and varying mixtures thereof, into the soil than can be tested under lab conditions. Our research consortium seeks to develop robust metrics for toxicity testing by trying to find dose-dependent effects on the gene regulation of springtails (*Folsomia candida*) upon insecticide exposure, i.e. neonicotinoids. We are measuring reproduction and obtain transcriptomics and proteomics data from springtails under a broad range of stress intensities caused by neonicotinoids as single compounds and in mixtures with other neonicotinoids or with known metabolomic inhibitors. These data will be used to help scale current dose-dependent methodology to the omics era. This allows us to identify patterns of gene regulation which remain robust under shifting metabolomic conditions and at various stress intensities. The results of this work can lead to the development of methods for rapid and cheap soil quality assessment such as insecticide detection. Moreover, it may provide policy makers with metrics of soil pollution that are biologically relevant, i.e. stress related gene regulation patterns, instead of dose limits derived from testing under controlled conditions of single compounds in artificial soils.

The Eco'n'OMICs project - an OMICs-based screening approach for ecotoxicological risk prediction

S. Eilebrecht, Fraunhofer IME - Institute for Molecular Biology and Applied Ecology / Fraunhofer Attract EconOMICs; H. Reinwald, Fraunhofer Institute for Molecular Biology and Applied Ecology IME / Fraunhofer Attract EconOMICs; S. Ayobahan, Fraunhofer Institute for Molecular Biology and Applied Ecology IME / Ecotoxicology; B. Windshügel, C. Claussen, Fraunhofer Institute for Molecular Biology and Applied Ecology IME / ScreeningPort; C. Schaefers, Fraunhofer Institute for Molecular Biology and Applied Ecology IME / Ecotoxicology

Active substances of pesticides, biocides or pharmaceuticals can display adverse effects in non-target species, which may threaten populations with far-reaching consequences for the ecosystem. Therefore, european legislation requests manufacturers to provide data for environmental risk assessment of active substances in order to become registered. The corresponding OECD tests are time- and cost-consuming and come along with a substancial number of animal tests. Thus, they are performed only in the end of industrial substance development, bearing the risk of a failing registration due to proven adverse environmental effects. The Eco'n'OMICs project aims at an early ecotoxicological risk prediction for active substance precursors based on substance-induced molecular changes in aquatic model organisms. We combine recent transcriptomics (RNA-Seq) and proteomics (LC-MS/MS) technologies with ecotoxicological approaches to identify gene expression changes induced by a number of ecotoxicologically well characterized reference substances. These substances are selected to be representative for substance classes and to cover a large range of different modes-of-action. The identified substance-specific molecular signatures are linked to a data base with adverse environmental effects and the compound structure. These biomarkers will be used to develop a targeted molecular screening approach for ecotoxicological risk prediction. Together with a structure-based prioritization of substance precursors, the availability ofsuch a molecular screening will enable for a time- and cost-efficient, development of environmentally friendly active substances.

Effects and concentrations of the ß2-adrenergic agonists salbutamol in fish - do they confirm the fish plasma model?

A. Coors, ECT Oekotoxicologie GmbH; M. Weil, ECT Oekotoxikologie GmbH / Institute for Technology Assessment and System Analysis ITAS; A. Falkenhain, ECT Oekotoxikologie GmbH; M. Scheurer, TZW DVGW-Technologiezentrum Wasser / Analysis and Water Quality; J. Ryan, GlaxoSmithKline / Corporate Environment Health Safety Sustainability

The hypotheses of the fish plasma model (FPM) were tested using the anti-asthmatic pharmaceutical salbutamol, an agonist of the ß2-adrenergic receptor. Salbutamol was tested in fathead minnow *(Pimephales promelas)* ina flow-through system at concentrations from 0.0066 to 4.1 mg/L over 120 days. Survival was recorded daily, and the apical endpoints biomass and length were evaluated at test end. From all fish, blood was sampled at test end and subjected to chemical analysis of salbutamol. In addition, triglycerides were determined in whole body of the fish after sampling of blood. The measured fish blood plasma concentrations in relation to the measured water concentrations were in reasonable agreement with the predictions of the FPM. This confirms the hypothesis of the FPM that fish plasma concentrations can be predicted from water concentrations using a descriptor for lipophilicity. No significant effects were detected on apical endpoints in fish (i.e. biomass and length) after 120 days of exposure up to a concentration of 4.1 mg/L. Determined plasma concentrations in fish, however, reached levels that are approximate to those in human patients under salbutamol treatment. Hence, the hypothesis of the FPM that no adverse toxic effects occur below human therapeutic concentrations was consistent with the results of this experiment. Determination of total triglyceride levels in whole body indicated significant metabolic impacts of salbutamol at the highest tested concentration of 4.1 mg/L. This finding provides evidence that sub-lethal effects in fish are linked to the pharmacological target as salbutamol is also known to induce cardiovascular and metabolic side effects in humans. Overall, the present study provides supporting evidence for the FPM applied to a therapeutic class of pharmaceuticals for which so far little information was available. With regard to environmental concerns, it can be stated that concentrations at which effects were observed after long-term exposure of early life stages of fish were significantly above the predicted and measured environmental concentrations.

TH167

Revisiting the Mycophenolic Acid Chronic Surface Water PNEC in the Light of Immunotoxicity

J. Straub, F.Hoffmann-La Roche Ltd / Roche Group Safety, Health & Environmental Protection; M. Berrera, F.Hoffmann-La Roche Ltd / PS Pharmaceutical Sciences; M. Caballero, 3PBiopharmaceuticals; A. Coors, ECT Oekotoxicologie GmbH; P. Egeler, D. Gilberg, ECT Oekotoxikologie GmbH; A. Häner, F. Hoffmann-La Roche Ltd / Group SHE (LSO); D. Meinel, F.Hoffmann-La Roche Ltd / pRED Pharmaceutical Sciences; A. Muriana, BioBide / RD; T. Singer, F.Hoffmann-La Roche Ltd / PS Pharmaceutical Sciences

A surface water predicted-no-effect–concentration (PNEC) for mycophenolic acid (MPA) was derived from chronic no-observed-effect-concentration (NOEC) data developed in ecotoxicity tests with green algae, cyanobacteria, daphnids and fish that were performed in accordance with OECD test guidelines under GLP quality assurance. MPA is used to prevent organ rejection in solid organ transplants as its mode of action is immune inhibition. During planning the chronic tests, an additional investigation of immune-toxicological endpoints was envisaged. This comprised an assessment (up- or downregulation) of immune-related and other gene transcripts in the young fish at the end of the early life stage test as well as a parallel daphnid reproduction study with daphnids being challenged with the parasitic bacterium *Pasteuria ramosa* in addition to MPA exposure. The immune-related endpoints are compared with the standard apical endpoints from the chronic tests, in order to address the question whether standard ecotoxicity endpoints and the PNEC based thereon are also protective for immune-related effects.

TH168

Mechanisms of Action: a new classification scheme unifying human health and ecotoxicology, supporting non-animal testing approaches: example of the use with Fish Embryo Toxicity test.

F. Bauer, P. Bicherel, P.C. Thomas, KREATiS

The Mechanisms of toxic Action (MechoAs) scheme has been developed mainly based on toxicological data on fish and mammals, and other species when available[1,2]. Therefore, in the majority of cases, it is capable of predicting both the differences and similarities in MechoA between these species and can be used in cross-species extrapolation. Some chemicals can be identified as sharing the same key events in fish and mammals, while others have very different AOPs, which potentially leads to differences in toxicity between species[1,2]. For example, an adaptation of the Fish Embryo Toxicity test (FET) can be used to study the teratogenicity, neurotoxicity, endocrine disruption and genotoxicity potentials of chemicals and the subsequent results could be extrapolated to humans[3]. Nevertheless, some applicability domain restrictions of this method have been stressed, notably a lack of predictivity for neurotoxicity[3]. Moreover, fish embryos have similar, if more limited, metabolic capacity than adult fish together with various organs which are not fully developed and at the pre-hatch stage with a thick protective membrane (chorion), all resulting in a difference in ADME profile. This adds another layer of complexity when trying to predict toxicity mechanisms in mammals from studies on fish[3]. Some case studies are given where the results from a FET test would not correctly predict the toxicity mechanisms of the substance of interest. Many of these cases can be identified through the use of the MechoA scheme, which can be used for free online[4]. Thus, the use of MechoAs is proposed, first to support and interpret FET test outcomes, then to ensure their extrapolation to another species is relevant depending on the expected AOP. Therefore, MechoAs can be used in a transversal language, supporting the FET test to help to unify both human and environmental toxicology. (1) Bauer *et al*. From gene orthology to functions and pathways: a new framework to identify conservation of toxicity pathways across species

C. Rivetti, Unilever / Safety and Environmental Assurance Centre SEAC; E. Butler, Unilever RD Colworth / Safety and Environmental Assurance Centre SEAC; G. Hodges, Unilever Research / Safety and Environmental Assurance Centre; S. Gutsell, Unilever / SEAC; R. Kanapathywasam, P. Russell, F. Uyulur, A. White, Unilever / Safety and Environmental Assurance Centre SEAC; B. Campos, Unilever R&D / Safety and Environmental Assurance Centre SEAC

There is a growing recognition that an improved understanding of both molecular targets and pathways in the context of the Adverse Outcome Pathway (AOP) framework will allow for a more informed extrapolation to unravel impacts across chemicals and species. However, current approaches mainly focus on historical research that was not specifically intended for AOP development, leaving present methods deficient to adequately assess impacts across the whole chemical and relevant species space. An increased understanding of cross-species conservation of pathways would catalyse a tangible shift toward adopting Next-Generation Risk Assessment (NGRA) approaches. Genomes for a vast collection of different organisms are already publicly available, but there is still an overall lack of functional annotation. Additionally, although gene function can be inferred from sequence-homology, such approaches are based on several assumptions (not always correct) and have limited application. It is also important to consider that even though upstream signalling processes are likely to be similar across species, downstream processes may diverge, resulting in very different apical outcomes. Understanding the similarities / dissimilarities in physiological cascades of whole pathways across species is critical to assess conserved response patterns and associated outcomes. In this perspective, gene functional families may offer a more relevant metric of relative pathway conservation and potential perturbation, than the individual gene level. The overall goal of this project is to reduce the uncertainty inherent to cross-species extrapolation by utilising existing data to add evidence to the process of functional pathway re-construction. We propose an integrative use of available knowledge from different disciplines i.e. comparative biology, functional genomics and bioinformatics and chemistry, to create a new (multi-species) functionally-driven "orthology" framework to identify the conservation levels of pathways of toxicological concern. Data derived both experimentally and computationally, looking at genes/proteins, families and pathways and comparisons across species will all contribute to a weight of evidence approach to support risk-based decisions using conservation of pathways across species and improving the confidence in how we can use data from multiple sources.

TH170

RT-PCR arrays: a useful tool to analyze toxicity on invertebrates

A. Muñiz-González, J. Martinez-Guitarte, UNED / Fisica Matematica y de Fluidos

Most of the studies of environmental toxicology use ecologically relevant endpoints to study the effects. However, the molecular level is often neglected because of the lack of enough previous information to perform the experiment. For a long time, molecular analyses have been limited to biochemical methods detecting enzymatic activities but technological advances now allow to extend them to other molecular fields, like gene expression. By the end of the 20th century, massive sequencing methods were used to obtain the genome of different species. From there, next-generation sequencing methods (NGS) has evolved to provide transcriptomes of almost any organism thanks to new sequencers and bioinformatics. A final step in these advances has been mapping the reads of a biological sample back to the transcriptome in order to reveal the presence and quantity of RNA at a given moment, rendering thus an estimate of gene expression. NGS is becoming a methodology of the election in many studies, being now affordable for many laboratories. However, it is still too expensive when the number of samples to be analyzed is high; something usual for environmental toxicology. Multiple conditions need to be analyzed in order to obtain robust conclusions. Then, alternative methods are necessary to analyze gene expression with a balance between cost and a high number of genes that provide a good picture of cell metabolism. Invertebrates account for most of the species of animals and are key elements in ecosystems. Many transcriptome projects are available for several invertebrate species in databases ready to be used by researchers. Most transcriptomics studies focus on the identification of putative pathways or cell processes by massive analysis, often with homologies to proteins not confirmed. The sequences are rarely studied in depth. Here the transcriptome of *Chironomus riparius*, an insect, has been analyzed to identify genes and design arrays covering cell processes relevant to toxicant response. The arrays have been tested and the results obtained are presented. The workflow used in this work can be implemented in other species whose transcriptomes are available in databases. This way the value of the available sequencing projects can be increased, improving our knowledge about these species offering new tools for basic research and environmental toxicology studies. Funding: Ministerio de Economía y Competitividad, CICYT (Spain), CTM2015- 64913-R.

Quantifying Ecosystem Responses to Stress: An Environmental DNA (eDNA) Approach

J. Feller, Ohio State University / Department of Evolution, Ecology, and Organismal Biology; P.S. Ulrich, Ohio State University / College of Public Health Human Sciences; R.M. Swab, S.F. Spear, The Wilds Conservation Center; R.P. Lanno, Ohio State University / Department of Evolution, Ecology, and Organismal Biology

To better understand ecosystem responses to anthropogenic stress, new biomonitoring methods are needed that assess biodiversity in a quick and cost-efficient manner. The emerging field of environmental DNA (eDNA) potentially offers such an approach, as it may provide rapid, low-cost identification of species present in an area. To test the effectiveness of this new technology, eDNA was collected from ponds along an acid-mine drainage (AMD) gradient within The Wilds Conservation Center (Cumberland, OH). Here there are several AMD-gradient watersheds, with each system often consisting of one AMD-affected headwater pond that filters downstream to several smaller ponds where pH returns to background levels. We previously observed fish recolonization downstream from AMD sources and plan to use eDNA samples to quantify biodiversity in fish, amphibian, and invertebrate communities along a specific AMD gradient. The gradient here consists of 5 primary ponds separated by abandoned beaver dams each with highly different AMD characteristics. The goal of this proof-of-principle study is to estimate biodiversity and community structure at each pond using eDNA and then compare these results with traditional ecological assessment methods (e.g., netting, electrofishing, invertebrate sampling). Water quality parameters (pH, metals, conductivity) were also assessed along the gradient for comparison to derived community structures. The main source of metal contamination in our gradient is manganese (~6-10mg/L) with aluminum (~1-4mg/L) and iron (~0.5-3 mg/L) contributing as well. pH values range from 3.5-7.5 across the 5 ponds that were sampled. Our workinghypothesisis AMD reduces biodiversity and simplifies community structure at ponds closest to the AMD source and that these ecosystem changes can be detected via eDNA. Results from this study will provide a wealth of species information to be used in future remediation efforts by The Wilds. The extensive species data along a pollution gradient will allow for construction of site-specific species sensitivity distributions (SSDs) for pH, metals, and other AMD characteristics. Knowing which levels of AMD correspond to desired community structures can help create AMD benchmark levels for any future attempts to restore affected areas.

How does knowledge about SVHCs affect individual consumption?

U. Klaschka, University of Applied Sciences; S. Hartmann, University Ulm

Many consumers with minor knowledge in chemistry have difficulties in understanding information about hazardous substances in everyday products and in using this information properly. We conducted a survey among 1321 consumers who showed high motivation and interest in harmful substances in everyday products. We laid a special focus on the consumers' awareness of their right to inquire whether a consumer article contains substances of very high concern

('SVHC right to know') according to the European chemical legislation. There seems to be a big gap between the general desire to know more and the extra efforts needed for learning more: Every second participant declared that she or he wanted to know more about SVHC containing articles, whereas only four per cent of them indicated to use the SVHC right to know. We found that knowledge about SVHCs in articles would very much affect participants' behavior. Only one percent of all participants indicated that they would buy an SVHC-containing article. Ten per cent would even throw SVHC-containing articles, which they had bought already, into the garbage. We found significant differences in answers given by persons with very good self-reported knowledge in chemistry ("chemists") compared to those given by "non-chemists". Twice as many non-chemists compared to chemists would neither buy, nor use SVHC containing articles which they had bought already. Apparently, survey participants - even persons with good self-reported chemical knowledge - were not aware that today SVHCs are present in most electronic articles, vehicles and many textile articles. It seems to be very difficult for consumers to interpret the information about the SVHC content in articles and use this information for a suitable risk reduction behavior.

TH174

Lessons learned from bottom-up communication - Demands of information recipients must be taken seriously

U. Klaschka, University of Applied Sciences; S. Hartmann, University Ulm

We present a case study where a specific regulation concerning communication to consumers is scrutinized. We asked 1321 highly motivated consumers about their awareness of harmful substances in commodities. This online survey focused on the right to inquire whether a consumer article contains substances of very high concern ('SVHC right to know') according to the European chemical legislation. In general, the results of this survey showed that the 'SVHC right to know' is very complicated, also for motivated consumers, and we must assume that only a small minority of persons understand this provision correctly. Participants could indicate whether and how the 'SVHC right to know' should be improved. Only 1.6% of the study participants declared that the 'SVHC right to know' is good as it is. A third of the participants indicated that they did not use it and had, therefore, no suggestions for improvements. Nearly half of the respondents wished that substances of very high concern should be prohibited as soon as possible. On average, every participant gave two suggestions to improve the information on the packaging. More than a third of participants demanded more controls by authorities. Participants had a low interest in smartphone applications to inquire about SVHCs in articles (less than a fifth). There were significant differences in several answers given by persons with high self-reported knowledge in chemistry compared to answers given by non-chemists. Lessons learned: Procedures and legal provisions that are evident to experts are not necessarily so for laymen. Bottom up communication (asking recipients of information about their demands) is urgently needed for regulations that involve consumers. The differences in the answers given by chemists and non-chemists question whether decisions in environmental policy which are usually based on suggestions made by chemistry experts are suitable for stakeholders with little or no knowledge in chemistry. Considering the heterogeneity of the communication recipients and respecting their needs should be key elements in the implementation process of environmental policy to ensure that science-based solutions meet stakeholder needs.

TH176

How do we communicate chemical status of waters in Europe?

J. Mannio, K. Siimes, Finnish Environment Institute SYKE / Centre for Sustainable Consumption and Production; E.S. Vähä, Finnish Environment Institute / Centre for Sustainable Consumption and Production; V.A. Junttila, Finnish Environment Institute SYKE / Centre for Sustainable Consumption and Production

Harmonized assessment of the quality of European waters has taken large steps in the 2010's with commonly defined Environmental quality standards (EQS) within both Water and Marine Directives (WFD, MSFD). However, monitoring practices, preferences and thresholds still vary between countries leading to different "chemical status". It is now evident that persistent, bioaccumulating and toxic compounds (ubiquitous PBTs) determine the non-compliance of chemical status of surface waters all over Europe – if measured. We have measured these contaminants (Hg, PBDE, PFOS/PFAS, HBCDD, PCDD/F) in perch trough out Finland during this decade. There are several examples of communication risk in assessing the chemical status: EQS set for human exposure, while food authorities have not set limits (PBDE, PFOS). EQS for PAHs is adopted from food sector, some PAHs are found in molluscs, but the indicator (BaP) is hardly found in our experience. In the 2nd WFD status assessment, mercury was estimated to exceed the EQS in ca. 50 percent of the waterbodies in Finland. Without calculated background concentration adopted in Finland, Hg would exceed the EQS all over country – as it would exceed anywhere in Europe, which is the case for PBDE as well. Also the strict dichotomy (only good/no-good) in status assessment is problematic to communicate, when data oscillates close to the EQS value. Conventions and directives thirst after proof of the long-term changes of restricted PBT substances. In the absence of multi-decade data on these substances in biota the historical development of contaminant fate can only be confirmed using undisturbed sediment stratigraphy. Risk management is not possible without first knowing where the problems are. Screening and monitoring will help us to focus the risk reduction and risk communication, but the principles should be similar geographically and among policy sectors (environment vs. food), especially if the target exposure end-point is the same – human health. Revision of the WFD will most likely include also a revision of the EQS derivation principles as well as the updating of individual EQS values. Increasing (eco)toxicological data can change the EQS values of the currently listed priority substances and also bring new substances in.

TH177

Managing chemicals in circular economy - communication actions are needed

S. Kauppi, Finnish Environment Institute SYKE / Programme for Sustainable Circular Economy; J. Bacher, VTT Technical Research Centre of Finland Ltd; S. Laitinen, Finnish Institute of Occupational Health; K. Suomalainen, Finnish Safety and Chemicals Agengy Tukes; H. Kiviranta, National Institute for Health and Welfare / Health Security

Circular economy (CE) development has significant environmental, economic and social benefits. The CE is paradigm for economic development, aiming to system change from linear to cyclical closed-loop systems. It is crucial to minimize the intake of natural resources. Opportunities in remaining the value of materials have driven the political decisions to set high percentage targets in recycling materials. However, reusing and recycling products and materials that might contain hazardous substances need risk management. Some of the most dangerous substances, such as persistent organic compounds (POPs) and substances of very high concern (SVHCs) remain as legacy in materials that have long life cycles. Environmental, health and occupational safety needs promotion in same time as promoting towards CE. The project 'Managing chemicals and ensuring safe and sustainable economy SIRKKU' seeks to promote CE by enhancing the management of chemicals. Main aim is to find ways to enhance chemical management and knowledge of hazardous substances especially in S/M companies. There is crucial need for new kind of communication. We investigated the present management practice regarding hazardous substances in companies by electronic questionnaire. Secondly, a workshop for authorities and experts was arranged. Discussions related environmental risks, health and especially occupational health, and various chemicals of concern in different fields of industries. As a preliminary result, we can conclude that the industries wish to have science based knowledge of wider impact assesments, LCA perspective and the potentials for standardising recycled materials. By the people operating in the field was especially required expert support e.g. pragmatic councelling. In the next steps the project is investigating 1) the Applicability of identification, separation and treatment processes (technical point of view), 2)Work safety risks associated with the use of recycled material, 3) Regulatory requirements and the development of policy instruments and 4) Impacts on environment and health. The investigations are in process and the results will be discussed with the construction and demolition industry in workshops. Transition to sustainable CE requires actions to support industries. Increase in awareness of hazardous substances in CE need communication actions. New technical development and occupational safety instructions in CE related work are essential for safe CE.

TH178

Framework to support creation of Safe and Sustainable material Loops in a Circular Economy

J.T. Quik, RIVM / DMG; J. Lijzen, RIVM / Centre for Sustainability Environment and Health; J. Spijker, RIVM; J.H. Ganzevles, National Institute for Public Health and the Environment RIVM; M. Zijp, RIVM / DMG; T.P. Traas, National Institute for Public Health and the Environment (RIVM)

Recycling options for waste streams are often assessed in terms of either their sustainability or their safety. These concepts are usually assessed by separate and specific methods, requiring specific expertise. The Safe and Sustainable Loops (SSL) framework is developed to provide one coherent and practical approach for policymakers, regulators and industry to assessing safe and sustainable reuse of materials recovered from waste streams. The framework consists of seven different modules. Some modules address the potential sustainability benefits related to reduced environmental impact and increased resource efficiency, while others address chemical or microbiological safety concerns. The chemical safety concerns can, for instance, be due to the presence of and potential exposure to substances of very high concern (SVHC). An example of an outcome of such an integral assessment is the clear benefit in terms of CO_2 footprint to recycle Polystyrene foam, while the assessment also shows that there is a clear challenge to deal with the presence of the flame retardant HBCDD (a SVHC used in the foam), posing a safety concern. The integral assessment shows that by extracting HBCDD with the solvolysis technique, this concern is adequately addressed, while the environmental benefit is maintained. Two other case studies are conducted: phosphate recovery from wastewater and rubber granulate from old tires. Some challenges for further rollout of the framework are the availability of assessment criteria and the need for guidance for practical use by different stakeholders. The developed framework aims to support evidence-based decision-making towards responsible and efficient use of materials and resources, and helps to address safety concerns by providing the context for further implementation of risk management options. This is a requirement for the transition towards a circular economy.

TH179

Environmental classification and labelling under the CLP Regulation: key principles, case-studies and downstream consequences

S. Uphill, European Chemical Agency (ECHA); K. Prevedouros, European Chemicals Agency; E. Luschutzky, ECHA

Regulation (EC) No 1272/2008 (the CLP Regulation) refers to the classification, labelling and packaging of substances and mixtures and was introduced to ensure a high level of protection of human health and the environment, as well as the free movement of substances, mixtures and articles. Under CLP, hazard information on physical-chemical, environmental and human health hazards is compared to established classification criteria, described in Annex I of the CLP Regulation. Environmental classification refers to short- and long-term hazards to the aquatic compartment and "taxifies" aquatic hazard into different categories based on information on aquatic toxicity (acute and chronic), aquatic degradation and bioaccumulation. The key information relating to these endpoints will be presented and the key aspects taken into account during evaluation will be outlined, with a specific focus on the different related decision schemes. Different studies will be presented to highlight the application of the legal criteria for classification and de-classification (removal of existing classification). Different key considerations and encountered issues, both from a data-holder and from a regulatory perspective, will be reported and further analysed. Mixture classification principles will also be introduced and downstream implications elaborated on by use of example cases. Key hazard communication aspects will be discussed, mainly referring to labelling and its implications for the different actors. Importantly, downstream consequences of environmental classification and labelling will be tackled. These may refer to obligations/ implications to other chemical regulations for example, the Biocidal Products Regulation, the PIC Regulation, waste legislation, etc. Finally, the interlinks with the Seveso Directive will be highlighted in terms of containment, transport and general handling of substances with different environmental classifications. It is hoped that the interplay between (good quality) environmental information, hazard assessment and identification as well as hazard and risk communication will be highlighted.

TH180

Condensed, yet reliable - providing information of environmental safety of nanomaterials on a web-based knowledge base

D. Kühnel, Helmholtz-Centre for Environmental Research / Bioanalytical Ecotoxicology; K. Nau, C. Marquardt, Karlsruhe Institute of Technology KIT / Inst Applied Computer Science; H.K. Krug, NanoCASE GmbH; N. Bohmer, Society for Chemical Engineering and Biotechnology e.V. (DECHEMA); C. Steinbach, DECHEMA

Nanomaterials have found their way in our everyday life, and are on the market in numerous applications, ranging from electronics to health care and environmental remediation techniques. Nanomaterials offer a great innovative potential and they are assumed to be beneficial to mankind and the environment by e.g. reducing material usage and energy consumption. As ultimately nanomaterials will enter the environment, concerns on transport, fate and adverse effects towards environmental organisms were raised. This initiated various research effort in the field, which to date resulted in an enormous body of scientific literature on this topic. Nonetheless, citizens in general, consumers of specific products, but also journalists or scientist from other fields often miss condensed, reliable and understandable information on nanomaterials and their potential effects on the environment. Hence, the DaNa2.0 project with support from many experts aims at providing such information for a broad audience on a web-based knowledge base (www.nanoobjects.info). One major challenge the DaNa 2.0 team is facing is the retrieval of relevant information from the continuously increasing collection of nanotoxicology related publications. In this context, a fast and effective information query for the evaluation of nanosafety related data is a first and very important step for activities such as the DaNa knowledge base. To facilitate the search and selection process, a novel IT-tool is currently under development, which will allow for an intelligent, concept-based search approach by means of extracting more semantic information from the text. This will enable the user to apply words describing the concepts and not just the search terms he is looking for complemented by an auto-completion system and further analysis tools for larger document sets. This poster intends to present an overview on the web platform that offers easy-to-understand, up-to-date and quality-approved information on 26 market-relevant nanomaterials concerning their effects on safety of humans and the environment. Specifically, the challenges in providing condensed but at the same time reliable information from a huge body of literature are being addressed. The knowledge base www.nanoobjects.info is making an important contribution to science communication in the field of nanosafety. *Acknowledgement:* The funding for the DaNa2.0 project is provided by the German Federal Ministry for Education and Research (BMBF) under grant no. 003X0131.

TH181

The role of epidemiology data in informing chemical risk assessment

M. Maffini, Independent Consultant; B. Geueke, K. Groh, Food Packaging Forum Foundation; L. Trasande, New York University School of Medicine; J. Muncke, Food Packaging Forum Foundation / General Management

Preventing human harm from chemical exposures is fundamental to protect individuals and populations, and ensure the well-being of future generations. It is a foundational principle of public health protection. Nationally representative biomonitoring programs as well as smaller cohort studies have been tracking human exposure to environmental chemicals for many years. Some of the chemicals monitored for potential health effects are used in the manufacturing of plastics. Their uses are regulated based on risk assessments that largely rely on toxicity testing in animals, although many of these tests are considered outdated and not particularly driven by issues of public health concern. In contrast, epidemiological data continues to receive poor attention in regulatory decision-making. As currently performed, risk assessment relies primarily on animal data and chemical structure considerations to estimate a 'safe dose'; regulators consider this to be the amount of a chemical a person can be exposed to in a lifetime without causing harm. In the last two decades, mounting evidence has shown that some chemicals can cause adverse health effects at doses once considered safe. This is not uncommon for chemicals known to affect organ development or act as endocrine disruptors. Recent human data have shown that at least for some ortho-phthalates, members of a large family of plastic ingredients, early life exposures were associated with a number of health effects including delayed cognitive development, behavioural problems, advanced puberty and increased body weight. Other effects observed in children and adolescents were insulin resistance, increased blood pressure and disturbance in vascular function. We are currently testing the hypothesis that there is a discordance between the animal data used to determine safe levels of ortho-phthalates and the health effects associated with these chemicals observed in humans, a discordance that could potentially result in unsafe levels of exposure. We will discuss data showing that regulatory 'safe' levels of five ortho-phthalates (diisobutyl phthalate, dicyclohexyl phthalate, dibutyl phthalate, benzylbutyl phthalate and diethylhexyl phthalate) estimated using traditional toxicology testing protocols and endpoints may not be as health protective as once assumed, especially when exposures occur early in life.

TH182

Efficient and safe nutrient recovery from wastewaters

R. Malila, S. Lehtoranta, Finnish Environment Institute SYKE; L. Äystö, Finnish Environment Institute, SYKE / Centre for Sustainable Consumption and Production

The diminishing global phosphorus reserves and highly energy intensive nitrogen fertilizer production are inducing the need to seek for more sustainable sources of these nutrients. Recovering nutrients from a variety of industrial and societal side streams is becoming an important way to produce organic fertilizers. However, there are many constraints to reuse the recovered nutrients in a safe and efficient manner. In Finland, approximately 4,000 t of phosphorus and 27,000 tons of nitrogen are supplied to wastewater treatment plants annually. On average, approximately three quarters of the influent phosphorus remains in the final sludge, but is in a poorly soluble form and therefore unusable for plants in the short term. Only a fraction of nitrogen remains in the sludge, while most of it ends up in the air, effluent waters and reject water of the sludge drying/digestion. In 2016, 40% of sewage sludge was utilized in agriculture in Finland. Recently, the acceptability of sewage-based fertilizer products in agriculture has been questioned because of the remaining harmful substances and the risks and uncertainties related to them. These harmful substances include e.g. pharmaceuticals, flame retardants, surfactants and micro-plastics. Significant questions arise regarding the safety of sludge and wastewater based products. Although the effects of harmful substances on human health might be manageable, their effects on soil and biota are not sufficiently known. There are various technologies for recovering nutrients from wastewater. However, the introduction of new technology is expensive and the industry is not ready to invest if the guidelines are unclear. In NORMA-project (2019-2020, financially supported by Ministry of the Environment Finland), novel, innovative options to recover wastewater nutrients are evaluated. In order to create guidelines, a more holistic understanding of the possibilities to recover nutrients with different process technologies and their combinations is needed. The fate of harmful substances and the environmental and financial sustainability are important criteria influencing decision making. As a result of the project, various process alternatives and their pros and cons as well as possible data gaps are identified and presented in an informative way for decision makers and other stakeholders.

TH183

Applying an ecological framework to Yucheng rice oil poisoning incident: 40 years later

M. Li, National Taiwan University / Geography

In 1979, a rice oil mass poisoning occurred in central Taiwan. This epidemic was later referred to Yucheng and identified to be caused by the ingestion of commercial rice bran oil which had been accidentally contaminated with large amounts of polychlorinated biphenyls (PCBs) and their related compounds such as polychlorinated dibenzofurans (PCDFs). More than 2000 persons were identified as Yucheng victims. In fact, these Yucheng victims and offspring have still present health complaints or suffered from different symptoms up to the present. Although many epidemiological studies have been conducted for Yucheng, this incident hardly examined from the point of social-ecological framework. In past two decades, many health-related disciplines applied the ecological approach to understand different issues in disease prevention, health promotion and education. The ecological approach is a theory-based framework for understanding and exploring close relationships between individuals and society across multiple levels. By adopting the ecological framework as an analytical lens, this study will summarize and discuss epidemiological research of Yucheng and analyze society's responses to this incident through the individual, interpersonal, institutional, community, and public policy levels. At first, scientific studies published between 1979 and 2018 on Yucheng are summarized and updated to understand health effects of victims from PCB and PCDFs exposure. Next, historical newspapers are used as a tool to view how community and institution respond to this incident when Yucheng happened as well as to trace the historical development of this event over time. Finally, other sources of information, such as documentary films, magazines, unpublished theses or dissertations, will also include to address society's responses to this unfortunate incident at institutional, community, and public policy levels. Applying an ecological approach can help to provide a more holistic perspective of Yucheng incident. We shall emphasize the need to consider not just investigating health outcomes of victims from an epidemics event but also supporting with health care services for victims to reduce the consequences of an unfortunate incident. In sum, this review will discuss lessons learned from a food poisoning incident and how implementation of appropriate health policies to help victims and to prevent future poisoning incidents.

TH184

The trials and tribulations of working with Americamysis bahia: A mysid success story

M. Fox, Scymaris Ltd / Ecotoxicology; R. Maunder, Scymaris Ltd

The mysid shrimp *Americamysis bahia* has a reputation of being a difficult to species to work with; they are cannibalistic, easily stressed, prone to disease, can have variable fecundity and cultures can unexpectedly crash. Mysid shrimp studies are used in regulatory ecotoxicology in both the USA and Europe. In Europe, if a plant protection product (PPP) has an insecticidal mode of action (MOA) then the acute toxicity of an additional arthropod is required. This obligation can be satisfied by *A. bahia*, as well as any subsequent chronic testing if required. We decided to investigate the feasibility of mysid shrimp testing at our laboratory and after numerous challenges have recently started to reap the rewards of our hard work and determination. The main culturing challenge was the production of large numbers of healthy < 24 hour old mysids according to a pre-planned schedule for testing (140 and 420 for standard acute and chronic studies, respectively). We also solved various problems in husbandry methods and juvenile separation by developing novel in house procedures. We currently conduct flow-through acute and chronic studies to GLP as well as static high throughput screening tests. Each study design is carefully planned to incorporate the specific client needs, and can draw on a growing body of historic data to influence decisions on the required statistical power and experimental design. A recent challenging example is the requirement to use acetone as a carrier solvent to satisfy a client request that has led to several learning opportunities in very challenging testing conditions. This poster discusses the husbandry techniques and practical methods required to obtain a healthy, highly productive stock culture. We also show case studies of some of the interesting challenges faced and highlight our dedication to the novel problem solving required to produce a successful study.

Safety assessment of nanoparticles- A global regulatory perspective on data requirements

N. Rehman, Envigo Consulting Limited / CPC Consulting; S. Moore, Envigo

This poster will describe some of the key global regulatory frameworks e.g. EU REACH, US TSCA, FDA that are addressing the data requirements to demonstrate the safety of nanoparticles for both human health and the environment. Broadly speaking all these schemes are working towards a science and risk based approach. The use of nanotechnology is rapidly expanding in a wide range of household and personal care products such as clothes, electronic and cosmetics. Most of the current research is focused on carbon-based and metal oxide based nanoparticles e.g. nanosilver. In addition, there is huge potential in the use of nanotechnology to revolutionise healthcare in applications such as cancer treatment where nanoparticles are engineered so they are attracted to diseased cells only, which reduces damage to healthy cells in the body, allowing for earlier detection of disease. Regulatory schemes such as EU REACH Regulation, are developing specific requirements for the assessment of safety, with the new guidance expected to be published in Jan 2020. Key considerations for regulatory risk assessment i.e. characterisation, metrics and the fate/accumulation of nanoparticles in the environment will be discussed. The EU Inventory on Nanomaterials (EUON) also hosts health and safety information on nanomaterials on the EU market, and a recent study identified gaps in the hazard and risk assessment of 81 nanopigments. Under US TSCA, the EPA have assessed 160 nanomaterials and this includes a comparison of chemicals in their bulk and nanoform to understand the change in property causing an unreasonable risk. The US FDA also considers the effects of nanomaterials in the particular biological and mechanical context of an individual product and its intended use. For example, if the route of administration is inhalation, respiratory toxicity of nanomaterials can differ from larger particles, and OECD 412/413 Guidelines have recently been revised to incorporate this requirement. Data requirements for the FDA's pre-market review process data requirements for clinical and nonclinical studies will also be discussed.

TH187

Environmental safety assessment of nanomaterials: tools and needs

A.K. Jantunen, European Commission - Joint Research Centre / Directorate F Health, Consumers and Reference Materials; S. Gottardo, European Commission JRC; K. Rasmussen, Joint Research Centre / Nanobiosciences Unit

The NANoREG framework for the safety assessment of nanomaterials (2017) analysed how EU regulation, with focus on REACH, applies to nanomaterials, and discussed the availability and regulatory acceptance of approaches developed by NANoREG and others for addressing nanospecific issues. Since the publication of this report, the REACH annexes have been revised to contain specific information requirements concerning nanomaterials (to enter into force in 2020), the updating process of the ECHA guidance has started, and method development and standardisation for nanomaterials (e.g. by the OECD and various research projects) has continued. Progress has mainly been made on testing methods for physicochemical properties and human toxicity; the environmental side of nanosafety assessment is made difficult particularly by the complicated environmental fate phenomena and the monitoring of concentrations in complex environmental media. Using as inventory the contents of the NANoREG Toolbox for the safety assessment of nanomaterials (2017-2018), this poster will provide an overview of the regulatory requirements for the environmental safety assessment of nanomaterials under REACH and discuss how well the currently available and expected tools address these requirements.

TH188

EU Regulatory developments on the characterisation of nanoparticles

N. Rehman, Envigo Consulting Limited / CPC Consulting; D. Howes, Envigo Consulting Limited / Envigo Consulting Limited

Regulatory requirements for nanoparticles have been under development in EU, US and Canada. This includes data required on characterisation, and the safety of nanoparticles. Under EU REACH regulatory framework, the basic characterisation requirements for identity and composition for organic and inorganic substances are clearly described e.g. UV-VIS, X-ray diffraction etc. However, the requirements for nanoparticles have not been so well prescribed until very recently. In May 2017, ECHA provided a significant update in new guidance 'How to prepare registration dossiers that cover nanoforms: best practices', this included ; '*When the registrant manufactures or imports the substance in the nanoform as well as in the bulk form, the registration dossier should include the information of the substance in both the bulk form and nanoform'.* For some substances such as nanoparticles, other parameters in addition to chemical composition need to be considered in order to determine their impact on properties relevant for the hazard profile, and each registrant has to specify these parameters in their own dossier. Substances may be manufactured as nanomaterials and non-nanomaterials. For example, for a substance that is manufactured as a nanomaterial, there may be multiple nanomaterials that have a composition giving them the same substance identity, but different shape and surface chemistry. The three common elements for any nanomaterial are size, shape and surface chemistry, and these are the minimum requirements for data sharing and joint registration obligations. Nanomaterials may have different properties and thus different classification(s) for the relevant physicochemical, human health or environmental endpoint compared with the bulk (non nanoform) of the same substance. In addition, characterisation methods often require specialised equipment and expertise, and although nanomaterial manufacturers will have some expertise they may need to contract some of this analyses to specialist analytical laboratories. This poster will illustrate examples of the various nanoforms that could be obtained and the influence of characterisation i.e size, shape and surface chemistry on the hazard profile.

TH189

Colloidal stability and bioactivity of Fe3O4 nanoparticles functionalized with humics and silica

P. Uchanov, Institute of Ecology and Evolution RAS / Laboratory for soil ecological functions; T. Kuznetsova, National University of Science and Technology MISIS; L. Bondarenko, Moscow Aviation Institute; V. Terekhova, Lomonosov Moscow State University / Lab of Ecotoxicological Soil Analysis; A. Sybachin, Lomonosov Moscow State University; K. Kydralieva, Moscow Aviation Institute

Investigations of Fe_3O_4 nanoparticles (NPs) functionalized by different inorganic and organic ligands are being increasingly reported in the literature due to the importance for biomedical and ecological applications. The huge diversity of polymers allows for different types of Fe_3O_4 NPs surface functionalization, i.e., introduces charges on the system that can prevent the aggregation of the particles in liquids and improve their chemical stability through surface charge control. In addition to studying the size, structure and composition of the colloidal particles, control of their colloidal stability is very important. Controlling the stability of the magnetic fluids against aggregation is important because the formation of aggregates alters their specific surface area and dispersibility as well as their bioactivity. In the present work, the influence of humic acids (HA) and/or silanes (tetraethoxysilane, TEOS and 3-amino propyl-triethoxysilane, APTES) was studied and correlated with the colloidal stability and bioactivity. The control of the functionalization nature and density (number of layers) on the Fe_3O_4 surface was investigated, electrokinetic measurements (zeta-potential and hydrodynamic diameter), bioactivity analysis were performed. The higher plant − whitemustard *Sinapis alba* L., green algae *Scenedesmus quadricauda* (Turb.) Brev., and infusorians *P?ramecium caudatum* were used as test organisms for bioactivity evaluation. The results suggest that surface charge and bioactivity can be controlled by grafting Fe_3O_4 NPs with HA and/or silanes. The sequential layer-by-layer grafting of precursors onto the NPs surface demonstrated an logical increase in the hydrodynamic diameter (measured b? DLS) in the row: Fe_3O_4/TEOS < Fe_3O_4/TEOS/APTES < Fe_3O_4/TEOS/APTES/HA. Zeta potential for silica grafted NPs varied considerably with layering from -20 mV (Fe_3O_4/TEOS) to -0.6 mV (Fe_3O_4/TEOS/APTES), which correlates with surface charge provided by the surface amino group of APTES. For the Fe_3O_4 coated by HA zeta-potential increased from 15 mV (bare Fe_3O_4) to -40 mV (Fe_3O_4/HA). The bioactivity of bare and functionalized NPs by silica and/or HA with respect to test-organisms demonstrated higher toxicity for multilayered nanoparticles as Fe_3O_4/TEOS/APTES/HA in compare with Fe_3O_4/HA. *Acknowledgement.* This research has been financed by the Russian Foundation for Basic Research (*#18-33-01270/18)* and the Russian Science Foundation (#16-14-00167).

TH190

Suitability of Chlamydomonas reinhardtii and Chlorella vulgaris as test organism in a growth inhibition test according to OECD 201

P. Obert-Rauser, Eurofins Agroscience Services Ecotox GmbH; V. Mingo, Eurofins Agroscience Services Ecotox GmbH / Aquatic Ecotoxicology; L. Weisser, Eurofins Agroscience Services Ecotox GmbH

The OECD guideline for the testing of chemicals No. 201 describing the freshwater alga and cyanobacteria growth inhibition test recommends as green algae test species *Pseudokirchneriella subcapitata* and *Desmodesmus subspicatus*. To draw a comparison and potentially identify suitable candidates for SSD (species sensitivity distribution) testing, the green algae *Chlamydomonas reinhardtii* and *Chlorella vulgaris* were examined. The aim was to assess the growth of the two species under the conditions stipulated by the guideline and to compare the effect levels observed for the two species to the effect levels observed for *Pseudokirchneriella subcapitata* and *Desmodesmus subspicatus*.

TH191

Graphene oxide ecotoxicity assessment using the amphibian Xenopus laevis: from toxicological effects to mitigation strategies

L. Evariste, ECOLAB UMR5245 CNRS UPS INPT; F. Mouchet, ECOLAB UMR 5245 CNRS / Integrative ecotoxicology; A. Mottier, C. Laplanche, ECOLAB UMR5245 CNRS UPS INPT; M. Barret, ECOLAB UMR CNRS UPS INPT; S. Cadarsi, L. Lagier, ECOLAB UMR5245 CNRS UPS INPT; G. Daffe, Université de Bordeaux / UMR EPOC CNRS 5805; P. Gonzalez, University of Bordeaux / UMR EPOC CNRS 5805; P. Lonchambon, C. Sarrieu, CIRIMAT-UPS-CHIMIE; E. Flahaut, CIRIMAT/LCMIE, UMR CNRS 5085; E. Pinelli, L. Gauthier, ECOLAB UMR 5245 CNRS

Carbon-based nanoparticles such as graphene oxide (GO) possess unique properties triggering high expectations for development of new technological applications. This raises the question of potential adverse outcomes on living organisms and support the need to find innovative solutions to produce sustainable and safer nanomaterials for human and environmental health. This study focuses on the ecotoxicological assessment of GO towards tadpoles of the amphibian larvae (Xenopus laevis). The complete characterization of the tested materials as well as the measurement of multiple biological endpoints allowed to identify physico-chemical characteristics and toxicological pathways involved in the adverse effects observed on growth and genotoxic response. Larval growth inhibition was shown to be driven by GO surface area and metagenomics survey of gut bacterial communities was performed to understand the implication of adverse effects on gut microbiota in growth response. In addition, surface groups and toxicological pathway involved in the GO-related genotoxicity were determined through analysis of cellular and molecular responses. Thermal reduction of GO was shown to remove oxygen-containing functional involved in genotoxic response and may constitute a “safer-by-design” approach, allowing maintain of good processing ability, while avoiding the genotoxicity of GO.

TH192

Effects of ZnO nanoparticles on Algae, Daphnia and Zebrafish larvae

N. Brande-Lavridsen, Heriot Watt University / Institute for Life and Earth sciences; T. Henry, Heriot-Watt University / The School of Energy, Geoscience, Infrastructure and Society; T. Chen, M. Antal, S. Morris, Heriot Watt University; R.S. Idriss, Heriot Watt University / Institute of Life and Earth Sciences; D. Boyle, University of Plymouth / School of Biological and Marine Sciences; Z.A. Gajda-Meissner, Heriot Watt University / Institute of Life and Earth Sciences; T.F. Fernandes, Heriot-Watt University / Centre for Marine Biodiversity and Biotechnology, Institute of Life and Earth Sciences

The aquatic toxicity of metal oxide nanoparticles (NPs) is related to NP physicochemistry and the characteristics of the exposure medium. Toxicity of metal NPs has frequently been attributed to dissolution of metal ions; however, the contribution of particles to toxicity (or “nano-specific” effects) has not been resolved for most NPs. In this work, the toxicity of ZnO NPs (coated (152 nm) and uncoated (70-90 nm)) was studied, in parallel with the ionic $ZnSO_4$ in three different aquatic organisms: an algae (*Raphidocelis subcapitata*), a crustacean (*Daphnia magna*), and a vertebrate (zebrafish, *Danio rerio*). The toxicity of ZnO NPs in *R. subcapitata* was tested following OECD algal growth inhibition assay (guideline 201). Algal cells were exposed (96 h) to ZnO NPs (10 - 76 μg/L), and samples were extracted for chlorophyll analysis as a surrogate measure for algae population growth. Data indicates a decreased growth with increasing NP concentration. The daphnia acute immobilization test (48 h, following OECD test guideline 202) and chronic reproduction tests (21 days, OECD test guideline 211) were performed to determine the toxicity of the ZnO NPs and $ZnSO_4$. Results revealed an EC50 of 2.38 mg/L for the uncoated NPs, 3.07 mg/L for the coated ZnO NPs and 9.98 mg/L for $ZnSO_4$ after 48 hours. The chronic reproduction test (180-1400 μg ZnO/L) showed that reproduction decreased significantly in all treatment groups compared to the control group, and a higher mortality was observed in response to exposure to uncoated NPs compared to the coated version. The toxicity of ZnO NPs to zebrafish larvae was assessed following exposure (24 h) in two different media: 60 mg/L Seasalt and standard OECD media. Aqueous exposure media had a significant effect on the mortality of zebrafish larvae in resonse to ZnO NPs exposure. The LC50 for larvae exposed to ZnO NPs in Seasalt was 16.3 mg/L while only one larvae died in OECD medium. We show here that for both daphnia and zebrafish larvae there was no significant difference in the effects of the coated and uncoated ZnO NPs in the acute studies. However, chronic exposure to daphnids showed a higher mortality for the uncoated ZnO NPs. It is possible that release of Zn ions over time from the uncoated NPs contributed to chronic toxicity. Determining the contribution of ionic Zn and ZnO particles to induce lethal toxicity as well as the effect of test media in toxicity testing is critical for assessment of the toxicity of ZnO NPs.

TH193

The effect of short term exposition to silver nanoparticles and ions on testicle morphology and fertility of zebrafish (Danio rerio).

M. Kamaszewski, H. Szudrowicz, A. Gwiazdowska, P. Jabłońska, Warsaw University of Life Sciences / Department of Ichthyobiology Fisheries and Aquaculture Biotechnology; J. Frankowska-Łukawska, Warsaw University of Life Sciences / Department of Botany; T. Ostaszewska, Warsaw University of Life Sciences / Department of Ichthyobiology Fisheries and Aquaculture Biotechnology

One of the main places of deposition of nanoxenobiotics are aquatic ecosystems, however theirs toxicity, and especially the effect on fertility of aquatic organisms, has not yet been well-known. The aim of the work was to demonstrate the effect of nanoparticles and silver ions on zebrafish (*Danio rerio*) fertility and morphology of testicles. Fish at the age of 5 months were exposed on 0.01, 0.05, 0.1, 0.5, 1 and 2 mg/L of nanosilver solutions (AgNP group) or silver ions with concentrations of 0.01 and 0.05 mg/L (Ag + group). The duration of exposition was 7 days. Fish in control group were kept in conditions without xenobiotics. The fish were fed *Artemia salina* and commercial *ad libitum*. On the last day of the experiment the fish reproduction was applied according to zebrafish breeding procedure. After spawning, the fish were anaesthetized in MS222, fixed in Bouin's solution and then subjected to a standard histological procedures. Obtained histological slides were stained with the hematoksylin/eosin method to analyze morphology of the testicles. On the section across tubules in testicles the percentage of spermatogonia, spermatocytes and spermatids were calculated. After 6 hours incubation of eggs, the degree of fertilization was evaluated. On the last day of the experiment, statistically significantly lower survival was detected in the Ag+0.05 mg/L group, compared to the another experimental groups.

Microscopic analysis did not show histopathological changes in the structure of zebrafish testicles. In zebrafish males exposed to Ag + 0.05 mg/L, the percent of spermatocytes on the tubules cross section decreased, whereas the percent of spermatids significantly increased. It was observed that with the increase in the concentration of tested xenobiotics, the percentage of successful spawning decreased. However, no statistically significant effect of the studied xenobiotics on the degree of fertilization was found. The obtained results indicate that short-term exposure to a high concentration of the silver ions affects on spawning potential and the participation of various groups of germ cells in the parenchyma of testicles, which may lead to a reduction in breeding potential of zebrafish.

TH194

Cytotoxic effect of graphene oxide in rainbow trout monolayer cultures of primary hepatocytes without apparent cellular internalization

J. Kalman, Instituto Nacional de Investigación y Tecnología Agraria y Alimentaria / Environment; J. Navas, INIA - National Institute for Agricultural and Food Research and Technology / Environment

Graphene oxide (GO) is commonly used in many industrial and commercial applications, consequently, their release into the aquatic systems is inevitable. Thus, aquatic organisms including fish can be affected by these potential pollutants. In order to determine their mechanisms of toxic actions, the use of in vitro approaches based on fish cells appear as a suitable tool. Of particular relevance are primary cultures of isolated fish hepatocytes, since they maintain similar functionalities as those of the original tissue. Taking all this into account, the objectives of this study were to investigate the potential toxic effects and intracellular fate of GO on primary cultures of rainbow trout (*Oncorhynchus mykiss*) hepatocytes. Primary hepatocytes were exposed to a concentration range of 4-128 μg ml^{-1} of GO. Cytotoxicity of GO was determined on the same set of cells by means of the Alamar Blue (AB) assay (informing about alterations in the metabolic status of the cell) and the 5-carboxyfluorescein diacetate-acetoxymethyl ester (CFDA-AM, reflecting alterations in the plasma membrane integrity) assay following 3, 8, 24 and 72 h exposure. Additionally, the Neutral Red Uptake assay (informing about lysosomal membrane integrity) was applied after 72h exposure. GO caused cytotoxicity preferentially through alterations on cell membrane integrity after 3 h exposure at a concentration of 8 μg ml^{-1}. This cytotoxic effect was maintained at 8, 24, and 72 h. Reduced metabolic activity was detected only after 72 h exposure at 32 μg ml^{-1} or higher. However, GO did not affect lysosomal functionality at the tested concentrations. Transmission electron microscopy was used to further investigate the interaction of GO with cellular structures. Cells were exposed to GO at concentrations of 8, 16 and 32 μg ml^{-1} for up to 72 h. Interestingly, there were no signs of GO uptake so that intracellular GO could not be observed, and the cell membrane appeared to be intact. These findings are in accordance with the decrease of cell viability detected with the CFDA-AM and the AB assays (that reflect alterations in plasma membrane and metabolic activity) and the lack of effect in the NRU assay that would imply the internalization of GO. This research is supported by the EU's Horizon 2020 research and innovation programme (MSCA-IF-2016, Grant Agreement nº 746876)

TH195

Assessing human exposure risk and lung disease burden posed by airborne silver nanoparticles emission from consumer spray products

W. Wang, National Taiwan University / Department of Bioenvironmental Systems Engineering; Y. Yang, National Taiwan University / Bioenvironmental Systems Engineering; C. Liao, National Taiwan University / Department of Bioenvironmental Systems Engineering

Silver nanoparticles (AgNPs) have been applied to antimicrobial agent, disinfecting and deodorant spray products due to its high antimicrobial efficacy. However, lung adverse response may be induced by inhalation of aerosolized AgNPs while using spray products. Studies have proved the toxic effects of inhaled AgNPs. Related health risk was considered to exist in the application of AgNPs-containing spray products. The main aim of this study is to estimate potential human health risk of inhaled AgNPs by integrating the exposure analysis and rat-related effect data. A compartmentalized physiologically based alveolar deposition model was employed to estimate the lung AgNPs burden for long-term exposure in non-intensive and intensive applications. A Hill-based dose-response model was used to describe the relationship between the lung adverse effect and AgNPs accumulation. A Weibull threshold model was used to estimate the threshold dose of AgNPs causing 1%, 5%, and 10% increases of inflammation response. Moreover, we used the probabilistic risk model and hazard quotients (*HQ*s) to characterize the potential health risk. The results indicated that the total AgNPs lung burden could reach 0.87 mg from 2-year chronic exposures for an intensive application. The most conservative threshold accumulation amounts were 0.32 and 1.08 mg for exposing to 30 nm and 60 nm airborne AgNPs. In the most severe scenario, the probability of estimated *HQ*s being higher than 1 was 0.50. Based on levels of threshold accumulation amounts, we estimated the median threshold daily exposure durations (ranging from 2.5 – 22.3 h d^{-1}) as recommendation for occupational workers or consumers using AgNPs-containing sprays. We conclude that intensive application of spray products under long-term exposure is likely to pose higher risk on human health. We also provide the threshold daily exposure duration as recommendation for users of AgNPs-containing spray products. This study provides a mechanistic approach on estimating potential health risk for the long-term exposure to airborne AgNPs from spray products. *Keywords*: Silver nanoparticles; Spray product; Physiologically based alveolar deposition model; Risk assessment

Incorporating Ecosystem Functioning into Environmental Quality Assessment (P)

Assessment of chemical risk to ecosystem services: a proof of concept study

L. Maltby, The University of Sheffield / Dpt. of Animal & Plant Sciences; P. van den Brink, J. Faber, Wageningen Environmental Research; S. Marshall, Consultant

Ecosystem services are the direct and indirect contributions that ecosystems make to human well-being. The ecosystem services concept is gaining broad interest in regulatory and policy groups for use in landscape management and ecological risk assessment (ERA). A recent multi-stakeholder evaluation of the use of an ecosystem services approach in guiding chemical environmental risk assessment has identified clear advantages of using the approach, but also highlighted a number of challenges related to its implementation[1,2]. This proof-of-concept project evaluates the feasibility of adopting an ecosystem services approach to chemical risk assessment using current knowledge and tools. The outcomes of this project will inform research and regulatory agendas. The project is focussed on three regulatory-relevant case studies: prospective ERA for plant protection products (Regulation 1107/2009 EC), prospective ERA for general chemicals (REACH) and a retrospective ERA for aquatic systems (Water Framework Directive). The rationale, approach and initial findings are presented. [1]Maltby et al 2018. Sci Total Environ 621:1342-1351; [2]Faber et al 2018 Sci Total Environ 651: 1067-1077

Functional endpoints as new perspectives for the definition of protection goals in regulatory ecotoxicology

M. Faupel, Rifcon GmbH; S. Höss, Ecossa / Animal Ecology; A. H�gerb�umer, W. Traunspurger, Bielefeld University / Animal Ecology

Currently the development of guidance documents by EFSA for regulatory ecotoxicology under regulation (EC) 1107/2009 is lacking by the definition of specific protection goals. To this aim, we provide data comprising a comprehensive ecotoxicological data set highlighting the importance to use structural and functional endpoints to describe and understand ecological entities. Specifically, data of freshwater nematodes and other sediment-dwelling organisms, based on long-term indoor microcosm studies with metals and PAHs as model pollutants, is provided on the typical structural parameters abundance, diversity, and biomass (B) as well as on the functional parameters secondary production (P) and its ratio to biomass P/B. The concurrent investigation of an extensive range of nematode species in the context of a complex benthic food web gives insight into general ecosystem functioning. The data shows sensitivities of different endpoints and gives a hint to mutual dependencies.

Biochemical characterization of six economic valuable marine bivalve species from the Portuguese coast

D.C. Silva, MARE - Marine and Environmental Sciences Centre, Department of Life Sciences, Faculty of Sciences and Technology, University of Coimbra / Department of Life Sciences; J.M. Neto, MARE Marine and Environmental Sciences Centre, ESTM, Instituto Politécnico de Leiria; C. Nunes, CICECO - Aveiro Institute of Materials & QOPNA Department of Chemistry, University of Aveiro / Department of Chemistry CICECO; F.J. Gonçalves, University of Aveiro / department of Biology & CESAM; M.A. Coimbra, CICECO - Aveiro Institute of Materials, Department of Chemistry, University of Aveiro / Department of Chemistry CICECO; J.C. Marques, MARE - Marine and Environmental Sciences Centre, Dep. of Life Sciences, Faculty of Sciences and Technology, University of Coimbra / MARE, Dep. of Life Sciences, Coimbra University; A. Gonçalves, MARE - Marine and Environmental Sciences Centre, Department of Life Sciences, Faculty of Sciences and Technology, University of Coimbra & Dep. of Biology and CESAM, University of Aveiro / MARE (Marine and Environmental Sciences Centre), Department of Life Sciences, Faculty of Sciences and Technology / Dep. of Biology and CESAM

Marine bivalves are distributed worldwide through diverse habitats, including estuaries andcoastal lagoons, and play important roles in the trophic webs, as they can connect primary producers to consumers, and are able to control several ecosystem' processes, like the oxygen penetration in the sediments. As well as other seafood, bivalves are highly appreciated by humans and represent an important economic value. Consequently, marine bivalves are under pressure due to an increasing demand for seafood resources. Aquaculture production can be an approach to overcome this demand. Aquaculture development has a stronger manifestation in some Asiatic, American and European countries, like Portugal. In the present study, six commercially valuable species of marine bivalves (*Cerastoderma edule*, *Crassostrea gigas*, *Mytilus galloprovincialis*, *Ruditapes* *decussatus*, *Scrobicularia plana* and *Solen marginatus*) were sampled in two distinct areas of harvest and aquaculture production in Portugal, the Mondego estuary and the Ria Formosa lagoon, and in two seasons, winter 2016 and summer 2017, in order to 1) determine the biochemical composition in terms of total protein content, fatty acid and carbohydrate profiles, 2) identify potential spatial and seasonal variations in the biochemical composition and 3) assess feeding behaviour of the bivalve species in both seasons and study areas. All species demonstrated higher total protein content, followed by diverse fatty acid content, specially DHA and EPA, and glucose and glycogen as the main neutral sugar and polysaccharide, respectively. A tendency for omnivory was confirmed in all bivalve species, with only *S. marginatus* presenting clear herbivorous behaviour in summer. *M. galloprovincialis* and *R. decussatus* showed the highest nutritional value in the Mondego estuary, in both seasons, although more noticeable in winter. In Ria Formosa, *C. edule* and *R. decussatus* presented the highest nutritional value in both seasons, while *C. gigas* exhibited higher nutritive value in summer. The bivalve species with higher nutritional value are suggested, in this study, as best suited to be produced in aquaculturein each area, respectively. This study was supported by Fundação para a Ciência e a Tecnologia (FCT) through the strategic projects UID/AMB/50017/2013 granted to CESAM and UID/MAR/04292/2013 granted to MARE. FCT funded A. M. M. Gonçalves and C. Nunes (SFRH/BPD/97210/2013 and SFRH/BPD/100627/2014).

River bacteria community analysis by flow cytometry as bioindicator of Water Quality

M. Santos, University of Aveiro / Department of Bilogy; H. Oliveira, Universidade de Aveiro / Biology Department and CESAM; J.L. Pereira, Department of Biology & CESAM, University of Aveiro / Department of Biology & CESAM; M.J. Pereira, University of Aveiro / Department of Biology and CESAM; F.J. Gonçalves, University of Aveiro / department of Biology & CESAM; T. Vidal, University of Aveiro / Biology department

Freshwater ecosystems are suffering enormous pressure from anthropogenic activities, such as agriculture, industry and climate changes, leading to its degradation. The purpose of the Water Framework Directive (WFD) implementation within European Union members, in 2000, was to regulate all water bodies reaching at least good ecological status in all water bodies. The major WFD disadvantages is being costly and time-consuming. In order to address that disadvantages the objective of this study was to use the scoring provided by flow cytometry analysis (FCM) of river bacterial communities into high DNA content (HNA) and low DNA content (LNA), a fast and easy screening methodology, as bioindicators. Caima river was used as case study in 3 sampling sites with different levels of environmental impact (site 1- no anthropogenic impacted site; site 2- downstream wastewater treatment plant and site 3- downstream a deactivated mine) were analysed along the 4 seasons of the year 2017 (winter, spring, summer and autumn). The ecological status evaluation of the sampling sites was assessed following the methodology described by WFD. The results obtained for macroinvertebrates and periphyton communities in terms of standard biotic indices as well as biological oxygen demand (BOD_5), were compared with the bacterial HNA and LNA content of the samples. FCM data analysis showed high bacteria density at site 2 associating with high amounts of organic input by a wastewater treatment plant (WWTP). Also, HNA bacteria were found to be in higher quantity at site 2, related to the increase of nutrients, while LNA bacteria were present in higher density in river headwaters (site 1), corresponding to an oligotrophic environment. Correlations between biological indices and bacteria community composition were very strong, showing that bacteria communities may serve as bioindicators of water quality assessment pending further investigation considering a wider array of samples.

TH200

Planktonic vs benthic community sensitivity towards 3,5-dichlorophenol, potassium dichromate and lead chloride

T. Vidal, University of Aveiro / Biology department; J.I. Santos, University of Aveiro / Biology Department and CESAM; L. Queirós, J. Pereira, University of Aveiro / Department of Biology & CESAM; A. Re, University of Aveiro / Department of Biology and CESAM; N. Abrantes, University of Aveiro-CESAM / CESAM/DAO; F.J. Gonçalves, University of Aveiro / department of Biology & CESAM

Biological diversity represents a major challenge in ecotoxicological assessment, since each species will respond differently to similar levels of exposure to toxic substances. By including in this assessment approach organisms which are representative from different functional groups, one theoretically captures the community range of variability regarding toxicant sensitivity. The variation of the sensitivity of species within a community or an assemblage towards one or more toxicants can be expressed in terms of cumulative distributions known as Species Sensitivity Distributions (SSDs). SSDs have been increasingly employed in the determination of chemical concentration benchmarks that represent protective levels for most species in the environment. Besides this practical application, SSDs could be an interesting tool to compare the sensitivity of several freshwater organisms, positioning them in a curve according to a sensitivity rank. This is the arena for the development of the present study, where the representativeness of standard organisms widely used to build SSDs was particularly challenged on whether they reflect the responses of benthic communities in lotic ecosystems. SSD are constructed mostly based on ecotoxicological tests with standard species that typically represent lentic freshwater ecosystems, and their use for environmental hazard in lotic ecosystems is somehow limited since planktonic species have no expression in these systems. The comparison of HC_5 and HC_{50} for each SSD curve, and for each community and chemical tested, allowed us to conclude that SSD built based on planktonic organisms might not be protective enough to benthic organisms, and consequently for lotic environments. Furthermore, benthic diatoms showed to be the most sensitive organisms to all chemicals tested evidencing that this specific community might be at risk if typical benchmarks based on testing with standard species are used for regulation.

TH201

Size spectra analysis reveals structural changes of natural communities under realistic exposures to pharmaceuticals and personal care products

D. Baho, Nowegian Institute for water research NIVA; E. Leu, Akvaplanniva AS; F. Pomati, Eawag Swiss Federal Institute of Aquatic Science and Technology / Aquatic Ecology; J. Moe, Norwegian Institute for Water Research (NIVA) / Section for Ecotoxicology and Risk Assessment; D.O. Hessen, University of Oslo / Department of Biosciences; J. Norberg, Stockholm Resilience Centre; L. Nizzetto, Norwegian Institute for Water Research NIVA

The extent of freshwaters contamination by a multitude of bioactive organic pollutants collectively classified as pharmaceuticals and personal care (PPCPs) products calls for concern. Ecological assessments of the burden that PPCPs might impose on natural aquatic ecosystems are still scarce. In a field experiment, we tested whether a realistic single time exposure to mixture of 12 pharmaceuticals and personal care products, commonly found in European inland waters, can influence the size structure of natural lake phytoplankton communities. Size is generally considered as one of the most influential determinants of community structure and functioning. Using an *in-situ* microcosm approach, phytoplankton communities in two lakes with different nutrient levels (mesotrophic and eutrophic) were exposed to a concentration gradient of the PPCPs model mixture at five levels. We tested whether sub-lethal PPCP doses can affect the slope of size spectra, which describe changes in the abundances of small compared to larger phytoplankton. Size spectra was drawn from a power-law distribution. PPCPs were found to induce changes in the size distribution of natural phytoplankton communities in both lakes. The two highest treatment levels of PPCPs were found to consistently decrease the abundance of the most dominant size class (nano-phytoplankton: 2-5 μm). The slope of size spectra became shallower with increasing PPCPs concentrations reflecting the decline in the density of small phytoplankton. These results strongly indicate that environmentally realistic exposure to PPCPs can have cascading effects in the aquatic food webs by favoring the larger non-edible algae at the expense of small edible species.

TH202

Artificial algal communities under Cu stress: effect of functional diversity on biomass production

E. Joonas, National Institute of Chemical Physics and Biophysics / Laboratory of Environmental Toxicology; K. Olli, Estonian University of Life Sciences; V. Aruoja, A. Kahru, National Institute of Chemical Physics and Biophysics / Laboratory of Environmental Toxicology

Standard toxicological testing with single species does not capture the complexity of toxicant effects in natural ecosystems. We aimed to narrow this gap by measuring how functional diversity (FD) affects primary biomass production - an important ecosystem function - of artificial microalgal communities at different levels of algicidal toxicant stress. In a modified OECD 201 test, we evaluated the biomass yields of all 15 single- and multi-species combinations of four functionally different algal species (green algae *Chlamydomonas reinhardtii* and *Raphidocelis subcapitata*, diatom *Fistulifera pelliculosa* and cyanobacterium *Synechocystis sp*) after a 72-hour incubation with 0, 0.01 and 0.02 mg Cu/l in triplicate. FD of the communities was assessed by community-weighted means (CWMs) of 10 algal functional traits and mean pairwise distance (MPD) calculated based on the traits. Overall, biomass yield significantly decreased at 0.02 mg Cu/l compared to lower toxicant levels. Significantly lower biomass ($p< 0.001$) at higher levels of MPD was observed at 0 and 0.01 mg Cu/l, while no effect was detected at 0.02 mg Cu/l, indicating that higher FD did not lead to more biomass production. However, because the four tested species are functionally distinct, species richness (SR) can be used as a proxy for FD. SR had a significant positive effect ($p< 0.01$) on biomass yield at each toxicant level, which may be explained by highly productive species in our selection being represented more often in multi-species communities. CWMs of two size-related traits, greatest linear dimension and logarithm of cell size, caused a significant ($p< 0.01$) increase in biomass yield at every toxicant level. Binary trait (motility, colony-forming, pigment content, Si content) CWMs also significantly affected biomass yield, but they were mostly intrinsically related to one species, impeding the interpretation of the effect. In conclusion, we observed a positive effect of SR and cell size on algal community biomass at all Cu concentrations, but a negative biomass effect of the functional diversity index MPD at 0 and 0.01 mg Cu/l. Our novel experimental approach allows for more environmentally relevant toxicity testing that reveals patterns in ecosystem functioning in response to toxicant stress, while retaining the advantage of being conducted in controlled laboratory conditions.

TH203

Biomonitoring of phytoplankton communities changes following heavy metals fluctuations in lake Balkhash ecosystem

A. Abilkas, Nazarbayev University / National Laboratory Astana; V. Dashkova, Nazarbayev University / SCHOOL OF SCIENCE AND TECHNOLOGY; D. Malashenkov, Moscow State University / Department of Hydrobiology; A. Zhantuyakova, A. Baishulakova, Nazarbayev University / SCHOOL OF SCIENCE AND TECHNOLOGY; A. Yagofarova, Nazarbayev University / School of Engineering; V.J. Inglezakis, Nazarbayev University / EREC, Environmental Science & Technology Group and Chemical & Materials Engineering Department; I.A. Vorobyev, N.S. Barteneva, Nazarbayev University / SCHOOL OF SCIENCE AND TECHNOLOGY

In the world threatened by multiple anthropogenic impacts, innovative approaches to lake ecosystems monitoring and assessment are required for proper water management. We have designed an innovative approach combining the characterization and counting of microalgae groups based on imaging flow cytometry (IFC; FlowCam) coupled with detailed chemical analysis. The aims of our multi-parametric approach are to monitor the lake waters for phytoplankton diversity, composition, abundances, and correlate it with physico-chemical parameters and heavy metals concentrations. We performed biomonitoring of 14 sampling stations at Lake Balkhash, one of larges lakes in Asia located in southeastern Kazakhstan. The shallowing of Balkhash lake and environmental impacts of emissions due to mining, metallurgical processes, and inflow of polluted water from Ili river (comes from China) creates serious concerns about the functioning of the lake ecosystem. In details, IFC biomonitoring of phytoplankton communities was performed in parallel with chemical analysis of surface water for heavy metals (Fe, Cu, Zn, Mn, Cd) and ions (potassium, ammonium, nitrates/nitrites) by atomic absorption spectrometry with Analyst 400 (Perkin-Elmer) and ion chromatography with Methron Compact IC FLEX 930 (Methron). Our characterization of morphological traits of microalgal cells by IFC offered a high level of statistical reproducibility and allowed to characterize the response of phytoplankton communities to applied stressors such as fluctuations in heavy metals concentrations and ions. RDA and bivariate correlation analysis demonstrated the positive correlation of nanoplankton abundance with increased levels of Fe (r=0.83) and large pennate diatoms (including *Ulnaria sp* and *Entomoneis sp*) with manganese and copper. Identification of microalgal groups that may serve as bioindicators of changes in phytoplankton communities structure and diversity towards heavy metals and other pollutants is expected to lead to better monitoring and environmental management of lake aquatic biosystems. The poster presents methods and results with a major focus on multi-parametric innovative approach and a correlative analysis of heavy metals levels and phytoplankton taxonomic group abundances and diversity.

TH204

Soil microbial activity in relation with stages of plant colonization in mine tailings soils of a Mediterranean area

A. Peñalver Alcalá, Escuela Técnica Superior de Ingeniería Agronómica. Universidad Politécnica de Cartagena / Departamento de Ciencia y Tecnología Agraria; J. Alvarez-Rogel, Escuela Técnica Superior de Ingeniería Agronómica. Universidad Politécnica de Cartagena / Ciencia y Tecnología Agraria; M. González-Alcaraz, Department of Biology & CESAM - University of Aveiro / Biology & CESAM

Mine tailings show high metal levels, extreme pHs, limited organic matter and deficient physical properties. As a consequence soil biota activity and biogeochemical cycling might be hindered, affecting soil functioning. Most tailings are abandoned without any restoration and might be spontaneously colonized by plants. This colonization occurs along with changes in functional soil properties. Identifying these changes helps to understand those processes underlying natural ecosystems recovery, and might be used to design more effective management for reducing tailings environmental risks. This study aims to assess soil microbial activity in mine tailings soils related to different stages of spontaneous colonization by native vegetation under Mediterranean climate. Six environments were studied in an abandoned mining area (SE Spain, n=4): A) Within mine tailings: 1. Bare soils (S); 2. Small groups of *Pinus halepensis* trees (2-5) ≤≈2.5 m high growing scattered (P); 3. Isolated *P. halepensis* trees >≈4 m high with shrubs and herbs under the canopy (P+MS); 4. Dense patches with several *P. halepensis* trees (>5) >≈4 m high and shrubs and herbs under the canopy (DP+MS). B) Outside mine tailings: 5. Contaminated forest with *P. halepensis* trees >5 m high and shrubs and herbs under the canopy (PF); 6. Non-contaminated control forest with *P. halepensis* trees >5 m high and shrubs and herbs under the canopy (CF). Soil microbial activity (upper 15 cm) was assessed by quantifying microbial biomass carbon (MBC), dehydrogenase/β-glucosidase activities and soil respiration. CF showed the highest MBC, β-glucosidase activity and soil respiration (1523 mg C kg^{-1}, 3.76 μmol p-NP g^{-1} h^{-1} and 0.74 g m^{-2} h^{-1}, respectively) which could be related to less stressful conditions in non-contaminated forest soils. However, inside mine tailings, resources scarcity could have led to lower microbial activity (e.g., 170 mg C kg^{-1}, 1.09 μmol p-NP g^{-1} h^{-1} and 0.34 g m^{-2} h^{-1} in DP+MS). P showed the highest dehydrogenase activity (4.75 μg INTF g^{-1} h^{-1}) which could be related to the presence of some adapted functional groups. CF also showed high dehydrogenase activity (3.28 μg INTF g^{-1} h^{-1}), while it was lower in the other stressed environments (0.02 – 2.66 μg INTF g^{-1} h^{-1}). The characteristics observed in the different environments showed that it could exist functional differences among them. Soil microbial activity was closer to CF in those tailing environments with higher plant colonization.

Effects of imidacloprid exposure on reproduction and survival of two Collembolan species

S. Sengupta, Department of Biosciences, University of Oslo / Department of Biosciences; S.M. Kristiansen, H.P. Leinaas, K. Borgå, University of Oslo / Department of Biosciences

Exposure of non-target organisms to pesticides may have serious ecological implications. To address this issue, we used our recently-developed experimental framework to compare how reproduction and survival of two different soil community species (Folsomia quadrioculata and Hypogastrura viatica) of the keystone arthropod order, Collembola, are affected by dietary exposure to the pesticide, imidacloprid, under different exposure scenarios. We focused on comparing the responses of these two species across selected doses of imidacloprid. The food (cyanobacteria growing on the bark of a tree in the campus of the University of Oslo) was spiked by scraping off the cyanobacteria and soaking in 0.429 and 4.29 ng mL^{-1} aqueous solutions of imidacloprid (equivalent to imidacloprid concentrations of 0.01 and 0.1 mg kg^{-1} dry soil) overnight, followed by filtration. The dried filters covered with the cyanobacteria were offered to the Collembolans. All the experimental replicates and controls started with 20 adult Collembolans, and the exposure lasted for 14 days at 15°C. Thereafter, the animals were reared in a clean environment for 25 days. Cumulative egg production per animal and survival, recorded throughout the rest of the experiment, were compared. The effects of imidacloprid exposure, species, and exposure x species interaction on reproduction and survival were compared. We expected that imidacloprid exposure as well as the responses of the two species would be significantly different. Specifically, we expected that F. quadrioculata to be more sensitive than H. viatica. The findings would provide the foundation for more detailed studies on the effects of pesticide residues in soil Collembola communities.

Microplastic contamination in bivalves from the Korean Coast
Y. Cho, Korea Institute of Ocean Science and Technology / oil and POPs reserch group; M. Jang, Korea Institute of Ocean Science and Technology / oil and POPs reserch group OPRG; G. Han, Korea Institute of Ocean Science and Technology; W. Shim, S. Hong, Korea Institute of Ocean Science and Technology / Oil and POPs research group
Microplastic contamination in the marine environment is an increasing concern. Bivalves are useful bioindicators of microplastic contamination in the marine environment due to several advantages such as extensive filter feeding activity and broad geographical distriburion. This study investigated microplastic contamination in bivalves at 12 sites along the Korean coasts. The concentration of microplastics in bivalves are in range of 0.05 – 1.27 n/g (0.20 – 6.68 n/individual). The major polymer type was polypropylene (PP), polyethylene (PE), polystyrene (PS) and polyester (PES). The fragment was dominant shape, and the most common size class was 100 – 200 μm.

Analysis of Microplastics in German Drinking Water
Y.K. Müller, M. Pittroff, C.S. Witzig, N. Zumbülte, TZW- DVGW German Water Centre / Department of Water Chemistry Research
As microplastics have been found in many environmental matrices like lakes and rivers, the question arises whether microplastics can also be transferred into drinking water that is derived from these raw water sources. In this study, a fractionated filtration unit with stainless steel filters sieves (100 μm, 20 μm, 5 μm mesh size) was developed and validated (recovery rate of 81%) for the sampling of microplastic particles in drinking water. A sample volume of 0.3-1.3 m^3 processed drinking water was sampled in three German waterworks, which use different raw water sources (groundwater or surface water), and one tap water respectively. After an extraction of the filter sieves in an ultrasonic bath and subsequent vacuum filtration over a PTFE filter membrane, all particles with diameters of 5 μm and above were analysed with micro-Raman spectroscopy. For all drinking water and tap water samples, the microplastic content (180-801 microplastic particles per m^3) was in the range of the process blank values (ranging from 51-531 particles per m^3). Primarily polyethylene (PE) and polyoxymethylene (POM, part of the filtration unit) were found in the samples, besides polypropylene (PP), poylamide (PA), polyethyleneterephthalate (PET) and polyvinylchloride (PVC). An investigation of blank values is crucial for an assessment and evaluation of microplastic data, this is particularly important in matrices that contain very low numbers of microplastic. Thus process blank values were done for each sample and measures were taken to avoid contamination during sampling, sample preparation and analysis. The number of microplastics strongly increased in the lower micrometre range below 20 μm (76% of all microplastics). This observation stresses the necessity to sample and analyse particularly microplastics in the lower micrometre range due to their high numbers and potential toxicological relevance. Whereas first results indicate very low numbers of microplastics in drinking water, further research and method optimization is crucial to get a holistic overview about microplastics in drinking water.

MOPC04
High levels of microplastics on exposed rocky beaches ; hotspots that allow for compositional comparisons, while introducing new exposure data regarding environmentally relevant concentrations
T.M. Karlsson, M. Threapleton, University of Gothenburg; M. Hassellöv, University of Gothenburg / Department of Marine Sciences
Researchers have analyzed surface waters and sediments, from all over the world, for the presence of microplastics (MPs). The findings show that MPs are ubiquitous in the marine environment. However, the low number of particles in most samples, in combination with high variations between replicates complicates compositional comparisons. Floating plastic debris is known to accumulate outside the Swedish west coast as they are transported from both the North Sea and the Baltic with surface currents. This debris also strand on the exposed beaches of the archipelago, especially following stronger winds and waves. Through modelling and field experiments with drifters it has also been shown that local sources are likely to strand along the coastline of the inner part of the archipelago, at least temporarily. Here a screening of three exposed beaches and three beaches outside coastal urban areas was performed using pooled samples over a 3 m transect and a 'worst case scenario' sample where plastics were seen to accumulate. The beach characteristics differed significantly between the different locations, complicating direct comparisons. Initial analysis however shows that with more than 1700 microplastics >300 μm per g sample, the most exposed beach had ten times the average concentrations for the urban beaches. These high numbers also show that exposed rocky beaches can accumulate microplastics, providing new data on exposure levels at microplastic hotspots. In addition the high number or particles per sample, also for the urban samples, allows for discussions on relative compositions of microplastics.

MOPC05
Fate of microplastics at Nenäinniemi wastewater treatment plant, with special emphasis on discfilter -based tertiary treatment
K. Ryymin, P. Salmi, University of Jyvaskyla / Department of Biological and Environmental Science; A.K. Karjalainen, FCG Design and Engineering Ltd / FCG Finnish Consulting Group Ltd; A. Mikola, Aalto University / Department of Built Environment; J. Talvitie, Finnish Environment Institute / Marine management
Wastewater treatment plants (WWTPs) equipped with secondary treatment systems have been shown to remove up to 99% of microplastics (MPs, polymer particles < 5 mm). However, considerable amount of MPs are still released within the final effluent. This study was conducted on the Nenäinniemi WWTP in Central Finland, where we aimed to quantify the MP retaining capacity of an advanced discfilter -based tertiary treatment. Samples taken after each treatment from influent to dried sludge and final effluent were purified using newly established purification protocols developed especially for MPs. Purified microplastics down to 20 μm in diameter were photographed, counted and their chemical composition analyzed using micro-raman spectroscopy. Finally, a comprehensive analysis of the WWTP's microplastics balance was done to determine removal rate and the fate of MPs in the Nenäinniemi WWTP. Our results demonstrated that the discfilter was efficient, although not explicit, setup to remove microplastics from wastewater. We also report empirical modifications on the state-of-the-art MP purification protocols that facilitate purification of samples with high content of solids. \n

MOPC06
Spatial Study of Microplastic Pollution in the Mississippi River Basin
J. Cizdziel, University of Mississippi / Chemistry; A. Scircle, Z. Gao, University of Mississippi
Microplastic (MP) concentrations along the northern Gulf of Mexico are among the highest levels reported globally. The most likely source of the particles is the Mississippi River (MR) which drains much of the central portion of the United States. Yet, surprisingly little is known about the concentrations, types, sizes, and loadings of MPs in the MR and its major tributaries. This lack of data is hindering our understanding of the magnitude and sources of the problem. Because the Mississippi River is an intricate system of waterways, tributaries, and commercial routes, an in-depth spatial study is needed to fully assess MP pollution in the system. Our research aims to systematically quantify the concentrations and loads of MPs and characterize their shapes, size distribution, and chemical composition in the MR system—a source of drinking water to over 18 million people. To that end, we used nile red staining and subsequent fluorescence microscopy for MP counting and vibrational spectroscopy to confirm the identity of plastics found in samples. The morphology of the MPs was dominated by fibers (~75%), followed by fragments (~23%) and beads (~2%), with the proportion of fragments increasing slightly moving down the main stem of the river. The concentration of MPs is lower for small tributary rivers (Tennessee and Yazoo) than in the MR; however, some larger tributaries (Ohio and Missouri) have higher concentrations than the MR at the area where they converge. This is important to assess possible relations between MPs levels and characteristics with sources and different watershed attributes. Counts and loads of MPs generally increased down the main stem of the MR until past New Orleans, where loads declined, possibly due to deposition with slowing water. Sites near population centers (e.g. Memphis) had higher MP concentrations. Finally, we will report on a "one pot" method where MP samples can be collected, stored, digested, density separated, and stained to minimize contamination and avoid transfer losses.

LCA Applications and Critical Methodological Developments for Sustainable Nutrition (PC)

Environmental impacts of food: variability and mitigation potentials through producers and consumers

T. Nemecek, Agroscope / Agroecology and Environment; J. Poore, University of Oxford / School of Geography and the Environment
Global food production is a major driver of environmental impacts. Today's food system occupies 38% of the desert- and ice-free land, causes 26% of greenhouse gas (GHG) emissions, 32% of terrestrial acidification, 61% of freshwater withdrawals, and 78% of eutrophication. To keep environmental impacts within the platenary boundaries, drastic changes in food production and consumption are needed. The present study carried out a meta-analysis of 570 studies, with data from 119 countries. A harmonised database was derived for five environmental indicators: land use (land occupation), freshwater withdrawals (and scarcity-weighted freshwater withdrawals), global warming, acidification and eutrophication potentials. The data were standardised in several steps by: correcting differences in functional units, emission factors, characterisation factors, allocation methods, and system boundaries. Missing life cycle phases were filled by standard data. Emissions and environmental impacts were recalculated, whenever needed. The global totals were found to be consistent with global estimates. The meta-analysis of food LCA studies showed that large variability exists between producers of the same product, indicating substantial mitigation opportunities. The 90th percentile impacts were between 4-11x higher than the 10th percentile impacts for global warming, land use, acidification and eutrophication and even 5500x higher for scarcity-weighted water use. The impact distributions are hightly skewed, with 25% of the producers causing about half of the environmental impacts. We found that different producers require different ways to reduce their impacts; no universal solutions exist. To define a mitigation strategy a detailed analysis of each production system in its context is therefore indispensable. Furthermore, trade-offs between different environmental impacts have to be taken into account. Consumers can mitigate environmental impacts by reducing their consumption of animal-based food and by avoiding producers with high environmental impacts, with synergies between these two strategies. To achieve these improvements, better information on the environmental impacts must be made available and communicated along the value chain. Reference: Poore J, Nemecek T. 2018. Reducing food's environmental impacts through producers and consumers. Science 360, 987-998.

Defining sustainable food products by integration of nutrition to food LCA

M. Saarinen, Natural Resources Institute Finland (Luke)
Introduction of nutritional values to the food LCA appears necessary when sustainable food products are aimed to be defined. The method should be related to a scope and goal of the study, as all methodological solutions in an LCA. Accordingly, validity of the methods is related to the purpose of the study. This study aims to evaluate an introduction of nutrition to the food LCA from the point of view of consumer education towards sustainability. Building on recent developments in the field (Saarinen et al. 2017; Stylianou et al. 2017) this study presents a framework and a stepwise process to evaluate and define sustainable food products including environmental and nutritional aspects in the assessment. The positive product-group-specific nutrient indexes are suggested to be used as a baseline functional unit (FU) in an integrated food LCA. Mass-based FUs for individual essential nutrients specific to a product group in question is suggested to be used as complementary FUs. Alongside these measures a reference flow (RF) for a nutrient indexes based FU and a reference amount (RA) for Daily Recommended Intake of individual essential nutrients are suggested to be utilised as a mean to take an effect of a portion size into account in a process of defining sustainable food products. Nutrients harmful to health in typical portions are suggested to include in an assessment as a separate LIM index based on harmful nutrients or as an impact indicator based on adverse impact of harmful nutrients on human health. The procedure is demonstrated by an assessment of case-products from the product groups of protein sources.

MOPC09

GHG emissions and nutritional quality of home cooked meals: a fair comparison.

E. Lemaire, ESCI, Universitat Pompeu Fabra; L. Batlle-Bayer, ESCI, Universitat Pompeu Fabra / UNESCO Chair in Life Cycle and Climate Change; A. Bala, UNESCO Chair in Life Cycle and Climate Change (ESCI-UPF) / UNESCO Chair in Life Cycle and Climate Change; R. Aldaco, Universidad de Cantabria / Department of Chemical and Biomolecular Engineering; P. Fullana, UNESCO Chair in Life Cycle and Climate Change (ESCI-UPF) / UNESCO Chair in Life Cycle and Climate Change
Abstract To date, many studies have assessed the environmental impacts of food products or diets, using different methodologies or approaches. However, few of them have considered their nutritional quality. This study aims to evaluate, on the one hand, the greenhouse gases (GHG) emissions of four home cooked meals composed of multiple ingredients, through a Life Cycle Assessment (LCA), and, on the other hand, to link the GHG emissions to the nutritional qualities of those meals. The selected meals suit different types of diets: vegetarian, carnivorous, pescetarian and omnivorous. Those meals are homemade according to traditional recipes, and different ways of cooking the ingredients (pan fried, boiled, oven baked) are taken into account. The LCA of the meals is performed from cradle to consumer, including all the relevant stages of their life cycle: food production, manufacturing, distribution, cooking and consumption. The nutritional quality of the meals is assessed using the nutrient rich food index 9.3 (NRF9.3), which takes in account 9 nutrients to encourage (protein, fiber, Vitamins A, C and E, Ca, Fe, Mg, K) and 3 nutrients to limit (saturated fat, added sugar, Na). To compare the GHG emissions of the meals, three functional units are considered: one meal adjusted by grams, kcal, and NRF9.3. The study aims to discuss the importance of introducing the nutritional quality in LCA when comparing the environmental impact of meals, in order to go beyond the traditional results based on mass or energy intake only, as mainly found in the literature. **Acknowledgement** This research study is carried out as part of the Ceres-Procon Project: Food production and consumption strategies for climate change mitigation (CTM2016-76176-C2-1-R) (AEI/FEDER, UE), financed by the Spanish Ministry of Economy and Competitiveness. Incorporating health and nutritional quality of food in LCA to create sustainable and healthy meals for catering

B. Takacs, A. Borrion, University College London / Department of Civil, Environmental and Geomatic Engineering
Our current way of food production and consumption is not only one of the major sources of environmental impacts but is also responsible for a number of health challenges we face today that are directly linked to global dietary transition and the food we eat. As the frequency of eating out increases, catering has a great potential to lead the transition to more sustainable food systems by offering healthy and sustainable meals. Life Cycle Assessment (LCA) can serve as a useful tool for assessing the environmental impact of menus and for creating low environmental impact meals. However, LCA studies on catering and menus often fail to incorporate the health dimensions of meals, which are equally important, if we are to create meals that are able to safeguard both human and planetary health. Without the inclusion of health and nutritional quality of food in LCA, we are risking the chance of creating meals that may be more sustainable from an environmental point of view (e.g. have lower GHG emissions and environmental impacts) but would still not promote the most optimal dietary pattern for health. The aim of this paper is to contribute to the development of a set of tools and criteria that can used in the LCA process to assess not only the environmental impacts of different meal options but also their health implications. This will help us to maximise the health benefits of certain food items (e.g. unprocessed whole foods) and create meals that not only have low environmental impacts but are also naturally abundant in health-promoting properties. This study employs desk-based research and reviews existing dietary, nutrient and food-based guidelines and UK government dietary recommendations for public institution catering, and compares them with the latest, evidence-based scientific literature on what is considered a healthy diet. A particular focus is on how the latest scientific evidence on the most healthful food groups and dietary patterns can be incorporated into the LCA process in order to increase the robustness of LCA in helping us identify options that yield truly sustainable outcomes. Building on that, a set of criteria on health and nutritional quality is identified which can be used as a tool alongside LCA to evaluate the health outcomes of different meal options.

MOPC11

How to integrate nutritional recommendations and environmental targets into food labels: a university canteen example

M.H. Cooreman-Algoed, Ghent University (UGent) / Green chemistry and technology; S. Huysveld, J. Dewulf, Ghent University / Department of Green Chemistry and Technology; C. Lachat, Ghent University / Department of Food technology, Safety and Health
Certain shifts in dietary patterns are leading to an increased incidence of noncommunicable diseases such as diabetes and heart diseases. About 30% of the total resource consumption of EU-citizens is related to food consumption. In addition, the nutritional value and environmental impact of food is not always clear to consumers. For this reason, promoting healthy and environmentally friendly meals are of vital essence. To decide what these meals are**,** environmental targets and nutritional recommendations can be adopted to classify meals. The aim is to classify meals based on environmental policies and nutritional recommendations in function of the proposition of a food label. To achieve this goal, we quantified the environmental impact and nutritional value of meals. As a case study, we analyzed hot meals served in the canteen of Ghent University. Every meal contained three meal components: a protein, vegetable, and carbohydrate component. Every day three or four different protein, two vegetable, and five carbohydrate components were served. Consumers could chose one of each meal component. All meal combinations of three consecutive days were evaluated, i.e. 100 meals in total. The main groups of meals were ruminant meat, non-ruminant meat, fish, and vegetarian meals. To classify the meals, we introduced three threshold values for both environmental impact and nutritional value. This corresponds to four environmental and four nutritional classes which results in 16 classes in total. The environmental and nutritional threshold values were based on the 2020 European target on reduced emissions of greenhouse gasses (EC, 2018) and the Flemish food recommendation (Vlaams Instituut voor

Gezondheidspromotie en Ziektepreventie, 2012), respectively. We translated the results of the classification in a label, which communicates the score of a meal and why a meal did not get the best score by mentioning the hot spots (Cooreman-Algoed et al., in preparation). The main conclusions are that meals with fish had the best overall score and meals with ruminant meat the worst score. Vegetarian meals had the best environmental and, similar to ruminant meat meals, the worst nutritional score. The environmental hot spots were, in descending order in terms of magnitude, ruminant meat, deep-fried products, meat portion, greenhouse vegetables, and rice. The nutritional hot spots were, from most to least prevalent, total fat, salt, calories, and saturated fat.

MOPC12

Life cycle indicators for sustainability in Food Chain Practices and Diets

G. Arcese, Università Niccolò Cusano / Business Studies; L. Ruini, Barilla G.e.R. Fratelli Societa per Azioni; C.A. Pratesi, Università di Roma Tre / Departimento of Business Studies; M.C. Lucchetti, Roma Tre / Business Studies

The food sector has become the subject of increasing attention as they are among the production chains with the greatest environmental impact. the object of more international companies is pushing food systems to converge towards models of sustainability and consumers to a healthier and balanced diet. In particulary, the factors linked to food sustainability find in the diversity of the Mediterranean diet a valid support to the environmental balance. The main aim of this researchs are to demonstrate how the improvement in food choices can contribute to increasing the environmental sustainability performance of the entire food chains analyzed in all phases of their life cycle. Barilla use for this objectives the Life Cycle Tools and verify the conditions for which it is possible to obtain a real trade-off between nutrition and environmental sustainability. The results of their mainly studies consist in the verification of the most recommended products in the diets for their nutritional indicators have also a lower impact on the environment. The results are shown alongside the traditional food pyramid; the food pyramid is built according to the ecological footprint of each of them. In terms of the life cycle, a factor that is still very critical and needs development is the estimation of the environmental impacts of the cooking phase.\nAlong the food chain there is a need to establish which are the key variables for the estimation of the same, how to build inventories, which impact categories to use and at the same time what are the nutritional differences between raw and cooked food and the differences in terms food safety. The purpose of this research consists precisely in filling this gap and at the same time providing suggestions on the variables to be used.

The STREAMcom model - Linking time variable exposure to effects on individuals, populations and community in realistic landscapes

K. Rakel, Research Institute gaiac / gaiac- Research Institute for Ecosystem Analysis und Assessment; T. Strauss, Research Institute gaiac / gaiac - Research Institute for Ecosystem Analysis and Assessment; A. Gergs, Bayer AG - Crop Science Division / Department of Environmental, Social and Spatial Change

The ecological risk assessment of chemicals aims to protect non-target populations and the communities they comprise while the underlying effect assessment is largely based on individual level toxicity information. Effects caused by the exposure of organisms to chemicals can however to a great extent depend on environmental scenarios as well on the states, behavior and interactions of organisms with consequences for individual life history, population responses and community dynamics. The quantitative contribution of the environmental scenario, including biotic interactions, to the chemical effect in a multiple stressor situation is however unclear. For analyses, we use the STREAMcom model, which integrates spatial explicit habitat information in form of raster maps, temporal information on abiotic factors such as temperature and chemical exposure, functional trait data bases, dynamic energy budget models and process based effect models to simulate macroinvertebrate assemblage and fish dynamics. In model applications, we explore to what extent the ecological scenario will affect the adverse outcome of chemical exposure.

Accounting for environmental complexity in pesticide risk assessment by the use of integrated models

A. Focks, T. Brock, Wageningen Environmental Research / Environmental Risk Assessment Team; H. Baveco, Wageningen University and Research / Wageningen Environmental Research; C. Topping, University of Aarhus; P. van den Brink, Wageningen Environmental Research

Environmental risk assessment (ERA) of pesticides is under continuous discussion. This asks for refined and more realistic ERA approaches for pesticides, which account for the variability of environmental factors and differences in landscape structures. On the other hand, authorities are already challenged by the effort to evaluate complex ERA dossiers, especially those from higher tier refinements. This contribution discusses the hypothesis that the development and the use of integrated mechanistic models for exposure and effect dynamics within a landscape context can account for parts of the environmental variability, increase the real-world relevance of ERA for pesticides and at the same time provides options to optimise risk mitigation and management. It is postulated that this can be achieved without further increasing the complexity of the ERA process when trusted modelling approaches would be available. A simple application example for integrated exposure and effect modelling in a landscape context showed that following the application of cypermethrin, about 10% of the ditches were within a factor of 10 from the onset of effects only, whereas about 40% of the ditches had no exposure or no risk. This appears as typical example for an agricultural landscape, and indicates how by an integration of fate and effect modelling the variability of environmental factors, in this example temperature and variation of hydrology in a small catchment, can be explicitly considered for exposure assessment and connected to state of the art effects analyses by TKTD models. The results raise the question of appropriate protection goals for such landscape-scale risk assessment results. In general, an impact assessment step where spatially and temporally explicit calculations of integrated risk measures in a landscape context could be added to the current generic risk assessment as a reasonable extension of the current RA paradigm. Such impact assessment would require the systematic collection of information on landscape properties, pesticide use, crop coverage, in combination with the further development of integrated exposure and effect modelling approaches that can be applied at large scales.

MOPC15

Aquatic risk assessment at landscape scale - conceptual development and an application example

L. Wipfler, Wageningen Environmental Research / Environmental Risk Assessment Team; H. Baveco, Wageningen University and Research / Wageningen Environmental Research; W. Beltman, Wageningen Environmental Research / Environmental Risk Assessment; S. Multsch, DR. KNOELL CONSULT GmbH / Environmental Fate / Modelling / GIS; F. Krebs, DR. KNOELL CONSULT GmbH; T. Schad, Bayer AG Crop Science Division / Environmental Modelling; T. Preuss, Bayer Ag / Environmental Safety

Risk assessment at landscape scales is currently discussed in Europe as a serious option to improve the realism and relevance of regulatory Environmental Risk Assessment (ERA) for plant protection products (PPP). Conceptually, geographical information can be used by spatially distributed models to predict the emission, exposure and environmental effects of the use of PPP at the region scale. This enables the assessment of local specific risks with a high level of realism. In practice, however, several challenges need to be solved before such landscape scale ERA can be used in a regulatory context. For example, there is a need for a proper framework for linking protection goals to landscape scale assessment endpoints, including associated spatial and temporal scales. Also, the multitude of possible combinations and complexity of different exposure and effect assessment and modelling approaches needs to be organised and selection criteria identified. Other issues to be addressed are the identification of the relevant environmental parameters, uncertainty propagation and how to present the assessment endpoints and the definition of decision making criteria for the risk evaluation. Our contribution will show preliminary results of a new project that aims to provide a possible framework for organising the challenges given above and develop practical modelling tools for aquatic ERA at landscape scales. First a systematic and comprehensive characterisation of possible modelling approaches will be presented. Secondly, an example will illustrate how landscape scale modelling results can be translated into predicted risk for the survival of aquatic macroinvertebrates.

Outcomes from an ECETOC Task Force on Geospatial approaches to increasing the ecological relevance of chemical risk assessments.

S. Marshall, Consultant; A. Ireland, ExxonMobil Biomedical Sciences / Toxicology & Environmental Science; J.C. Otte, BASF; L. Maltby, The University of Sheffield / Dpt. of Animal & Plant Sciences; C.M. Holmes, Applied Analysis Solutions, LLC; P. Sweeney, Syngenta / Environment Product Safety

For several decades, the prospective risk assessment of chemicals has followed a generic approach of comparing estimated exposures to toxic thresholds designed to be protective of all species (i.e., assessing exposure to the most sensitive species assumed to be located anywhere the chemical may occur in the environment). This approach does not recognise geographic patterns of species distributions or acknowledge that particularly sensitive species may not occupy potentially exposed habitats. Therefore, risk assessments could be overly conservative and restrictive for some uses of chemicals. Approaches for making spatially explicit assessments of chemical exposure are relatively advanced but this is not the case for mapping and assessing ecological data. However, geo-referenced ecological data appear to be increasingly available at spatial resolutions applicable to chemical risk assessment, potentially facilitating enhanced environmental relevance of such risk assessments. In 2017 a Task Force was initiated by European Centre for Ecotoxicology and Toxicology of Chemicals (ECETOC) to assess the capability of making chemical risk assessments using available geospatially referenced chemical exposure, ecological receptor and ecosystem services data. Two case studies were developed to illustrate the potential to assess geo-referenced risks to ecological receptors in fresh water and terrestrial environments exposed to i) a chemical used in consumer cleaning products discharged via municipal WWTPs across the EU and ii) a range of representative active ingredients used in plant protection products on selected crops in Germany. After initially compiling a catalogue of available geo-referenced ecological data for Europe, geo-referenced exposure concentrations were derived by combining accessible chemical use and fate data with conventional exposure models. However, use of many ecological data sets over a pan-European range proved problematic due to data access issues, limited geographic coverage and unreliable quality. Nevertheless, several suitable ecological data sets were accessed after making specific requests to various organisations within national authorities and these were integrated with the exposure maps. The results of these case studies give an indication of the potential value of making geo-referenced chemical risk assessments as well as the limitations to current capability.

MOPC17

briskaR: A spatio-temporal exposure-hazard model for assessing environment risk of Bt-maize on Non-Target Lepidoptera

V. Baudrot, CNRS / BioSP; S. Soubeyrand, E. Walker, A. Messéan, M. Leclerc, INRA

Field cultivation of Genetically Modified Bt-plants has a potential environmental risk toward non-target organisms (NTOs) such as butterflies larvae through the consumption of Bt-maize pollen. Bt-maize produces a toxic protein, Cry, acting as an insecticid on pest such as the European Corn Borer (*Ostrinia nubilalis*) or the Mediterranean Corn Borer (*Sesamia nonagrioides).* While the Bt maize primarily targets pests that are detrimental to the crop, the Bt toxin is also active against some NTOs that might be of conservative interest. As the Bt toxin is expressed in pollen which is dispersed by wind, exposure to Bt toxin is likely to occur outside maize fields over large distances and can thus reach habitats of NTOs. In order to assess the current environmental risk of Bt maize at landscape scales and how management measures might mitigate the risk in a given agro-ecosystem, modelling tools are needed. Over the last ten years, several models have been proposed for assessing the risk of Bt-maize on non-target Lepidoptera. Whereas there is a better understanding of factors affecting mortality of non-target populations, the management of GM crops at the landscape level for protecting NTOs is still at an early stage of development. High spatial and temporal variability of ecosystems challenges the extrapolation of ecological effects of toxicants from one-dimensional tests. As a consequence, there is a controversy on the actual risk for sensitive species as well as on the management measures (e.g., isolation distances) that should be implemented. The generic R-package *briskaR* implements a spatially-explicit exposure-hazard model for environmental risk assessment, and can be used for assessing the impact of Bt-maize on non-target organisms. The model considers the dynamics of pollen dispersal of each individual maize field as well as the dynamics of each Lepidoptera group of larvae in order to infer the larvae exposure to Bt toxin. Then, using the exposure model, a toxicokinetic-toxicodynamic model accounts for the impact of the dynamics of toxin ingestion on lethal and sublethal effects at individual larvae level. The present spatio-temporal modelling application on Bt-maize impact on Lepidoptera is dedicated to be a support for environmental risk assessors and managers in running quantitative risk assessment. It also allows to test management strategies within an explicit landscape approach.

The Overlooked Hazard of Small Creeks - Elucidating the Input and Fate of Organic (Micro-)pollutants in Streams (PC)

Simulation of Diclofenac concentrations in small German rivers with GREAT-ER

V. Lämmchen, University of Osnabrueck; G. Niebaum, University of Osnabruck / Institute of Environmental Systems Research; J. Klasmeier, University of Osnabrueck / Institute of Environmental Systems Research

Simulation models can be used to estimate predicted environmental concentrations (PEC) based on chemical and physical properties and consumption data. The Geography-referenced Regional Exposure Assessment Tool for European Rivers (GREAT-ER) constitutes a model tool for exposure and risk assessment of chemicals in surface waters. The main objective of this study is to show that the model can be used to support risk management of surface waters not only in large rivers with high flow values, but also in small creeks receiving wastewater from treatment plants with unsatisfactory dilution ratios. The study area contains the German part oft the catchment of the river Vecht, whichbecomes a tributary to the dutch river Ijssel later on. This basin covers an area of only 1800 km², but covers with around 400,000 inhabitants the relatively large amount of 22 wastewater treatment plants (WWTPs) and six hospitals. The Vecht river itself is a medium sized cross-border river with many small tributaries of mean discharge values below 2 m³/s. Model simulations intend to show the impact of emissions of pharmaceuticals into small creeks with unsatisfactory dilution factors. In addition to the emissions of sewage treatment plants, emissions from hospitals in the catchment area will be taken into account. In this work, the focus is on the application of the model to Diclofenac. Since the drug is not completely removed during conventional sewage treatment, it is detected almost ubiquitously in European surfacewaters. Although Diclofenac is prone to photodegradation in surface waters, concentrations in surface waters may exceed the environmental quality standard (EQS). Thus, Diclofenac was added as priority substance under the EU Water Framework Directive, but monitoring efforts are often focusing on the large waterways neglecting smaller creeks and tributaries due to their small flow values. To represent the status quo of Diclofenac contamination in the whole Vecht watershed including small creeks, probabilistic simulations with 10,000 runs were performed. Simulations show that exceedance of the EQS is predicted to occur in a number of small creeks as well as in parts of the Vechte river itself. Predicted PEC/EQS exceedances are in a range also measured by monitoring campaigns in Europe. Evaluation of simulation results will be performed by comparison with measurements to be obtained in the Meduwa project later.

MOPC20

Combined biological and chemical assessment of natural estrogen input from agriculture in tributary waters of Lake Baldegg

D. Rechsteiner, Agroscope / Environmental Analytics; E. Vermeirssen, Swiss Centre for Applied Ecotoxicology EawagEPFL / Aquatic Ecotoxicology; J. Hollender, Eawag / Environmental Chemistry; T. Bucheli, Agroscope ART / Environmental Analytics

Estrogens in surface waters have negative effects on reproduction and development of aquatic organisms [1]. Agriculture may be a significant source for natural estrogens in surface waters [2]. Several studies in different countries have demonstrated that the application of manure from husbandry animals to soil causes the release of natural estrogens to surface waters [3, 4]. As it is still unclear for Switzerland, we aimed to determine the contribution of agricultural-derived estrogens to the total estrogen load in surface waters. Our study area is the catchment of Lake Baldegg, where the highest husbandry animal densities in Switzerland, meaning 2.5 livestock units per hectare, are situated. Consequently, large amounts of manure are produced and applied in this catchment, leading to potentially elevated concentrations of natural estrogens in surface waters. To verify this hypothesis, we took water samples of the small to medium sized tributary waters of Lake Baldegg. All sampling sites are free of wastewater treatment plant effluents to ensure that we measure only agricultural-derived estrogens. In the vegetation period 2018, we took water samples every 22nd day. Only in March 2018, 17ß-estradiol concentration was above limit of quantification in four tributary waters. Based on our findings in the vegetation period 2018, we are currently studying more systematically the natural estrogen input in the tributary waters of Lake Baldegg. In order to capture peaks of natural estrogen input in the tributary waters of Lake Baldegg, we are collecting daily time proportional composite water samples for 30 days. We will chemically analyse the concentration of estrone (E1), 17α-estradiol (E2α), 17β-estradiol (E2β), estriol (E3) and total phosphorus. Additionally, we will daily measure average discharge for every sampling site to calculate loads of natural estrogens emitted. Furthermore, we will weekly assess estrogenicity of the tributary waters with ERα-Calux bioassays. We aim to present results of the sampling campaign in which we monitor the estrogen input in the tributary waters of Lake Baldegg systematically for 30 days. References: 1. Assessing the micropollutant burden in small agricultural streams using in vitro bioassays

P.A. Neale, Griffith University / Australian Rivers Institute; R. Gunold, Helmholtz Centre for Environmental Research UFZ; K. Foit, Helmholtz Centre for Environmental Research / System-Ecotoxicology; S. Knillmann, Helmholtz-Centre for Environmental Research (UFZ) / System-Ecotoxicology; M. Koenig, Helmholtz Centre for Environmental Research GmbH - UFZ / Cell Toxicology; M. Liess, Helmholtz Center for Environmental Research - UFZ GmbH / System-Ecotoxicology; R. Schlichting, B. Escher, Helmholtz Centre for Environmental Research GmbH - UFZ / Cell Toxicology

Micropollutants can enter small streams from a number of sources including point sources, such as wastewater effluent discharge, and diffuse sources, such as agricultural run-off. The current study aims to assess the chemical burden in small agricultural streams using cell-based bioassays in parallel with chemical analysis. Water samples were collected from over 40 sites in eleven German states from April to September 2018 with sampling triggered by rain events. The water samples were extracted with solid-phase extraction and run in *in vitro* bioassays indicative of activation of the aryl hydrocarbon receptor (AhR), binding to the peroxisome proliferator-activated receptor (PPARγ), activation of the estrogen receptor (ER) and oxidative stress response. While effects in the extraction and solvent blanks were very low, the majority of samples induced a response in the studied bioassays, with a wide dynamic range observed. Binding to PPARγ and activation of ER were the most responsive assays, with some of the samples exceeding preliminary effect-based trigger values for surface water for activation of AhR, activation of ER and oxidative stress response. To better understand which chemicals were contributing to the observed effect in the bioassays, the effects of some of the detected chemicals were fingerprinted in the bioassay test battery. Iceberg modelling using the bioanalytical equivalent concentration (BEQ) approach was applied to determine the fraction of the effect explained by detected chemicals. This study shows that small streams can have a considerable micropollutant burden, emphasising the need for reevaluating regulatory monitoring measures.

Impact of organic micropollutant dynamics on the water quality of a small river

M.E. Müller, University of Tubingen; C. Glaser, Center for Applied Geosciences / Center of Applied Geoscience; M. Werneburg, Center for Applied Geoscience (ZAG), Eberhard-Karls-University Tübingen / Center for Applied Geoscience; M. Koenig, R. Escher, Helmholtz Centre for Environmental Research GmbH - UFZ / Cell Toxicology

Rivers integrate water of their entire catchment and pose an important environmental compartment in which transport and transformation processes of anthropogenic chemicals take place. To trace changes in the water quality and to identify potential input sources of organic micropollutants into the river an integrated analytical and bioanalytical approach was applied. One stretch of the Ammer River, a tributary of the Neckar River close to Tübingen (South-western Germany), was sampled in July 2018 at two sites downstream of a wastewater treatment plant (WWTP) with large volume-solid phase extraction (LV-SPE) devices. Both LV-SPE devices integrated a total period of 24 hours divided into four sampling intervals. Additionally, grab samples of tributaries of the river between both sampling sites were collected. The water extracts, including extraction blanks, were measured by three *in-vitro* bioassays covering the environmentally relevant modes of action: activation of the aryl hydrocarbon receptor (AhR), estrogenicity (ER), and oxidative stress response (AREc32). In addition, mitochondrial toxicity was measured by the cellular oxygen consumption rate (OCR) assay using the Agilent Seahorse XF^{e}96 Analyzer. Furthermore, all samples were screened for 88 target analytes by LC-MS/MS. Iceberg modelling using the bioanalytical equivalent concentration approach was applied to estimate the contribution of the detected target analytes to the observed effects. The water extracts showed temporal and spatial variability in the assays AhR and AREc32 with most samples being active. The OCR assay showed initial uncoupling activity at the upstream sampling site just below the WWTP, which transitioned to marginal uncoupling at the same sampling site at later sampling periods and strong electron transport chain inhibition at the downstream site. The uncoupling effect coincided with estrogenic activity, which is a marker of the water being dominated by wastewater treatment plant effluents. In all other samples and in the tributaries the mitochondrial toxicity was dominated by inhibition of the electron transport chain. This study shows the dynamics of organic micropollutants in one stretch of a small river and demonstrates that the impact of anthropogenic chemicals on the water quality maybe highly variable. This work was supported by the Collaborative Research Centre 1253 CAMPOS (Project P1: Rivers), funded by the German Research Foundation (DFG, Grant Agreement SFB 1253/1 20147).

MOPC23

Coupling of water quality and toxicokinetic models to predict the internal concentrations of wastewater-derived chemicals in gammarids in small streams

M.J. Arlos, Eawag - Swiss federal Institute of Aquatic Science and Technology / Biology/Civil and Environmental Engineering; C. Stamm, Eawag, Swiss Federal Institute of Aquatic Science and Technology / Environmental Chemistry; J. Hollender, Eawag / Environmental Chemistry

Water quality models for predicting environmental concentrations of target contaminants are well established within the environmental chemistry field, but the use of toxicokinetic (TK) modeling for estimating internal concentrations in target organisms remains underutilized in exposure science. A combination of both modeling techniques can be indispensable (e.g., water quality and TK), especially when information on the mechanistic linkages between contaminant exposure and effects is eventually desired. In this study, we employed a model that first predicted the time-varying concentrations of 36 wastewater-derived compounds downstream of wastewater treatment plants for a year. Then, we coupled the results to a toxicokinetic model that estimated the internal concentrations in field gammarids. The models were intended to predict transient conditions (non-steady state) which were then compared to the measured river and internal concentrations. The simulations yielded satisfactory results which demonstrate the utility of the coupled models in describing the temporal dynamics of contaminant exposure at sites previously determined to be heavily impacted by wastewater-derived chemicals. A similar work is currently being undertaken for high-flow conditions. In the future, the time-varying field simulation of exposure media and internal concentrations will be combined with higher-level effects modeling to finally link exposure and effect.

Hazardous chemical impacts of effluents from pharmaceutical industry on sediment quality in a small stream

M. Ahel, S. Terzic, I. Senta, I. Mikac, N. Mikac, Rudjer Boskovic Institute / Division for Marine and Environmental Research

Surface waters often serve as primary recipients of wastewater effluents from urban agglomerations and industrial facilities. Due to their low base-flows, small, wadeable streams are especially vulnerable to increased anthropogenic inputs. In this work, we investigated distribution of hazardous chemical contaminants in a small stream, receiving effluents from pharmaceutical industry and bakers's yeast production. Samples of surface sediments were collected at 20 locations along the longitudinal profile of the Gorjak creek, located near the city of Zagreb, Croatia. The aim of the study was to assess the sediment quality, in particular to reveal the signatures of the contamination related to industrial activities. The analytical approach comprised comprehensive analysis of both organic and inorganic constituents, using gas chromatography/mass spectrometry (GC/MS) and liquid chromatography/tandem mass spectrometry (LC/MS/MS) for a wide-spectrum analysis of organic contaminants and inductively coupled plasma mass spectrometry (ICP/MS) for multi-elemental analysis, covering 25 metals and metaloids. The results revealed a strong impact of industrial inputs on the quality of the examined sediments. The impact of baker's yeast production was reflected primarily in significantly enhanced levels of organic matter. However, the major concern is related to high levels of some toxic contaminants such as polycyclic aromatic hydrocarbons, surfactant-derived compounds, and a suite of pharmaceutical compounds (macrolide antibiotics, zolpidem, torsemide, chlorthalidone, terbinafine and warfarin) as well as some toxic metals (Ni, Hg, Cu and Pb). The longitudinal distribution of all contaminants in this predominately lentic system rapidly decreased with the distance from the wastewater discharge point, indicating their fast deposition near the source. Further longitudinal transport was probably associated with increased stream water discharges following rain events. It was noticed that the geochemical fractionation and the mobility resulting from the transport of contaminated sediments was different for different contaminants. Nevertheless, several kilometers downstream, the concentrations of the majority of critical contaminants returned to the levels close to the background values.

Heterogeneous residues change pesticide-induced behavioural responses in predatory mites

J. Witton, Chemicals Regulation Division, Health and Safety Executive / Environment; T. Alvarez, EcoRisk Solutions Ltd / Dept of Ecological Sciences; M. Reed, HSE; G. Weyman, Gabe Weyman Consulting Ltd; M. Hodson, University of York / Environment Department; R. Ashauer, University of York / Environment

For a pesticide to be approved for use, the lethal and sublethal effects on non-target arthropods (NTAs) must be studied. Reproductive effects are routinely explored, but behavioural changes are less well understood. Such changes have been reported in NTAs exposed to some pesticides, with avoidance behaviour, where individuals display signs of irritation or repellence when exposed to residues of a pesticide, being of particular interest. Moreover, NTA responses to heterogeneous pesticide coverage also requires further investigation. We aimed to develop an efficient method to quantify changes in individuals' movement behaviour and thereby identify avoidance behaviour in relation to pesticide exposure in the predatory mite *Typhlodromus pyri*, a model species and natural predator found in fruit orchards globally. Using video analysis, we exposed individual adult mites to 3 insecticidal active ingredients (acetamiprid, deltamethrin, dimethoate), each at 3 concentrations, and evaluated mite movement behaviours when exposed to these in choice and no-choice test arenas. Residues were at the same level per unit of treated area in both studies. We report the varied effects on a range of movement behaviours in *T. pyri*, including distance walked, time moving, velocity and meandering behaviour. We also discuss avoidance behaviour and compare responses in choice and no-choice exposure scenarios. In no-choice arenas, we found that deltamethrin residues of 0.002 g Ha-1 reduced distances walked by mites by up to 87% compared to the control, and that 54% of individuals exhibited repellence through becoming trapped in the test arena boundary compared to 0% in the control. However, these effects were not observed in mites exposed to the same residue rates in choice arenas, with only 17% of mites becoming trapped at the 0.02 g Ha-1 rate in choice arenas. In choice arenas, mites spent less time on deltamethrin residues than on untreated surfaces. We observed no clear effect of acetamiprid on behaviour. When in choice arenas, mites preferred to avoid dimethoate, thereby reducing contact with residues, though no clear response was observed in no-choice arenas. Our studies highlight the need for further understanding of how NTAs respond behaviourally at a micro scale to heterogeneous exposures of pesticides. Our findings can be used to improve realism in pesticide risk assessment and complements the existing knowledge of sublethal pesticide effects in NTAs.

Mayflies in Ecotoxicity Testing: Methodological Needs and Knowledge Gaps Identified in a Virtual Workshop
P.K. Sibley, University of Guelph / School of Environmental Sciences; I. Roessink, Wageningen Environmental Research / Environmental Risk Assessment; A. Markiewicz, Pacific Northwest Regional Chapter / Institute of Environmental Toxicology; M. Raby, Ministry of the Environment, Conservation and Parks / School of Environmental Sciences; L.L. Lagadic, Bayer Ag / Environmental Safety; M. McCoole, Bayer CropScience / Environmental Toxicology and Risk Assessment; T.J. Norberg-King, U.S. Environmental Protection Agency / NHEERL/Mid-Continent Ecology Division; D.J. Soucek, University of Illinois, Urbana-Champaign / Illinois Natural History Survey; T. Watson-Leung, Ministry of the Environment, Conservation and Parks / Aquatic Toxicology Unit
Among the sensitive EPT (Ephemeroptera, Plecoptera, Trichoptera) group of insects, mayflies (Ephemeroptera) have been applied most successfully in water and sediment toxicity testing. For example, the recent development of a culture-based, life-cycle test with *Neocloeon triangulifer* and the long-standing sediment test with *Hexagenia* in North America, and the routine application of field-collected *Cloeon dipterum* in European testing reflect commensurate advancements in understanding the biology of these organisms and their behaviour under lab holding and testing conditions. With growing interest in expanding the arsenal of mayfly species used in toxicity testing, a virtual workshop was held in September 2018 to identify and discuss knowledge gaps constraining advancements in the use of new mayfly species in culture-based or field-collected protocols for water and sediment toxicity testing. Participants from industry, government, and academic sectors, representing both Europe and North America, took part in the workshop. Discussions were guided by several questions: 1) Should the emphasis be placed on further development of lab-cultured species or on a more standardized use of field-collected species? 2) What criteria should be used to select suitable test species (e.g., relative sensitivity to chemicals and test conditions, ecological traits, culturability)? 3) Should regulatory requirements play a role in determining species selection? 4) In tests emphasizing field-collected species, how can holding, feeding, and testing conditions be improved to maximize organism health and successful use in testing? In this poster presentation, we summarize the outputs of the workshop using, where appropriate, a data-driven approach based on species sensitivity distributions comparing the relative sensitivity of mayflies to various chemical classes based on ecological traits classification. *Disclaimer: This presentation does not necessarily reflect the views or the policies of the U.S. Environmental Protection Agency.*

TUPC03
Which is the most suitable native bee species from the Neotropical region to be proposed as model-organism for exposure to pesticides during the larval phase?
A. Rosa-Fontana, Unesp - Institute of Biology / Departamento De Biologia, Centro de Estudos de Insetos Sociais; A.S. Dorigo, UNIVERSIDADE ESTADUAL PAULISTA - UNESP / Department of Biology; R.C. Nocelli, UFSCar / Departamento de Ciências da Natureza Matemática e Educação; O. Malaspina, Unesp
Brazil has the greatest diversity of native stingless bees of the world and makes intensive use of pesticides. Studies on larval phase focus on *Apis mellifera*, since for this species the rearing method is already standardized by the OECD*. An *in vitro* larval rearing method has already been described for the Brazilian native stingless bee species *Melipona scutellaris*, for application in studies of exposure to pesticides during larval phase. Our study aimed to propose an *in vitro* larval rearing method for other stingless bee (*Scaptotrigona postica*), and to compare the results to those obtained from *M. scutellaris*. The acrylic plates with 100 brood cells were placed in glass Petri dishes containing distilled water. Larval food was collected from brood combs, each artificial cell receiving 25μL of larval food and, afterwards, 24-hour-old larvae were placed in the food. Then, the plates were kept in an incubator at 30ºC and 75% of relative humidity. After 72h and 120h of the larval transference, the humidity within the Petri dishes was reduced, respectively, to 85% (adding KCl) and to 75% (adding NaCl). This technique was carried out three times (total 900 larvae), evaluating (A) developmental standards, (B) emergence and mortality rates, and (C) morphometry of newly emerged workers (from *in vitro* and *in vivo*). T test for independent compared the means of the morphometry from both experiments. Moreover, we applied the method for determining (D) the average lethal concentration (LC_{50}) of the insecticide dimethoate. We also compared our results from the B and D parameters to those already stablished for *A. mellifera*. Regarding the emergence and mortality rates, *S. postica* produced above-expected results, comparing to those of *A. mellifera*, and even those of *M. scutellaris*. The LC_{50} of dimethoate indicated that *S. postica* is, approximately, 3 times more sensitive than *M. scutellaris* and, about 1047 times more than *A. mellifera*. The T test indicated similarity between *in vivo* and *in vitro* experiments for morphometric parameters in *S. postica*, as was also observed in *M. scutellaris*. Considering *S. postica* and *M. scutellaris* species, our results lead us to point out the first one as the most suitable native species to be proposed as model-organism. We presented the first comparative approach of responses to *in vitro* larval rearing methods between two native bee species from Neotropical region, for use in risk assessment.

TUPC04
Guttation as an exposure route in the risk assessment for plant protection products - Review of the available data
U. Zumkier, Tier3 Solutions GmbH / Regulatory Science; A. Sharples, FMC / Global Regulatory Sciences; N. Ruddle, Syngenta Ltd / Product Safety; M. Miles, Bayer CropScience UK / Environmental Safety
While the risk assessment scheme for bees proposed by EFSA (2013) is not yet in force, additional studies and endpoints, as well as the assessment of additional exposure routes, are already required for the registration of Plant Protection Products (PPP). One of these exposure routes is via the foraging on guttation droplets potentially contaminated with PPP residues. A standard procedure to assess the risk in the regulatory context of PPP is the comparison of toxicity and exposure. While the toxicity is inherent to a certain substance and can be measured in standardized laboratory tests, the exposure part in connection with guttation is more complex. Three elements need to be considered in order to assess exposure via guttation to foraging honey bees: 1. The amount of residues in guttation water after PPP application. 2. The occurrence of guttation on a certain plant species. 3. The extent to which honey bees are actually foraging on guttation droplets. The proposed assessment scheme (EFSA 2013) for risk the from guttation water is highly conservative, which often leads to the need for a higher tier risk assessment. While it is possible to conduct higher tier studies e.g. in a residue trial or field effect study for the specific substance, the data that is already available should also be considered, especially for the more generic, i.e. not substance specific, part (points 2 and 3). In this review we evaluated field studies on guttation, which were conducted by the industry for registration purposes between 2010 and 2017. Aim was to find a realistic estimate (90th percentile) for the occurrence of guttation in a certain crop species as well as an estimate for the number of honey bees foraging on guttation water (90th percentile) on a certain crop. Results show that guttation was frequently observed for numerous crops. The number of honey bees actually foraging on guttation droplets was low for all crops. Data which was available for two seasons (autumn and spring) show that there was a tendency that more honey bees were observed taking up guttation fluid in spring. As the uptake of guttation fluid by honey bees foraging for water seems to be a rare phenomenon, it could be worthwhile to re-assess the risk by the exposusre to guttation water for honey bees in order to come to a more realistic and not overly conservative risk assessment.

TUPC05
Effect of agricultural landscape structure on response of the ground beetle Poecilus cupreus to Proteus 110 OD insecticide
G.S. Sowa, Institute of Environmental Sciences, Jagiellonian Univeristy / Biology; A. Bednarska, R. Laskowski, Jagiellonian University in Krakow / Institute of Environmental Sciences
Intensification of agriculture and the widespread use of pesticides during the last few decades have led to significant reduction of the abundance of non-target arthropods (NTA). One of the main reasons of this is the widespread insecticides use, focusing on eradication of pest species without paying attention to NTA. In addition, the growing demand for agricultural products leads to changes in agricultural landscape, resulting in disappearance of non-cultivated elements (field margins, hedgerows, meadows). In this study we investigate the effect of agricultural landscape structure on response of the ground beetle *Poecilus cupreus* to Proteus 110 OD (active ingredients: Thiacloprid and Deltamethrin), the insecticide commonly used in the study area. Beetles were collected from two types of agricultural landscapes in central Poland, dominated by small- or large-scale farming (S & L, respectively). Within each landscape type 9 sites were established. In S landscape there were 3 reference sites (meadows) with 0 oilseed rape coverage (ORC) (S0), 3 sites with small ORC (10-14%; SS), and 3 sites with medium ORC (20-52%; SM). In L landscape there were also 3 reference sites with 0 ORC (L0), 3 sites with medium ORC (28-33%; LM), and 3 sites with large ORC (80-98%; LL). Beetles were exposed individually to a single topical application of 1 µl of the insecticide solution or to control treatment (acetone) applied on scutellum with a Hamilton syringe with repeater. The commercial formulation Proteus 110 OD was dissolved in acetone to obtain the concentration equivalent to 0.2 recommended concentration for field use. Statistical test comparing all habitats together revealed statistically significant differences in beetles survival ($p< 0.001$). Further pairwise comparisons showed that meadows S0 ($LT50=7{,}31 \pm 4{,}42$ SE) and L0 ($LT50=10{,}27 \pm 1{,}97$ SE) did not differ from each other ($p=0.649$), and the only groups differing from these reference habitats were the two agricultural habitats from the L landscape: beetles from LM ($23{,}26 \pm 1{,}64$ SE) and LL ($21{,}25 \pm 3{,}41$ SE) habitats survived significantly better than any other group. Our results indicate, that *P. cupreus* beetles from habitats with medium and high ORC have elevated resistance to the commonly used insecticide, but only if they live in large-scale agricultural landscape. This study was supported by National Science Centre, Poland (2016/23/N/NZ8/01679) and Jagiellonian University in Kraków, Poland (DS/WBiNoZ/INoS/759/2018).

TUPC06

The importance of synergy for risk assessment: pesticides, nutrition, and behaviour
S. Tosi, University of California, San Diego / Division of Biological Sciences; J. Nieh, University of California San Diego / Division of Biological Sciences Section of Ecology Behavior and Evolution
Animals are exposed to multiple stressors simultaneously, such as pesticides (including chemical mixtures of multiple active ingredients), nutrition deficiencies, and diseases. Combined exposure to multiple stressors can cause interactive effects, amplifying the risk if the two agents (i.e. two pesticides) interact synergistically altering animal survival and behaviour. However, the Regulatory Risk Assessment (RA) generally evaluates the risks posed by only one agent at the time (i.e. one pesticide), and mainly addresses effects on animal survival. Risk assessors have identified the RA of chemical mixtures as one of its current priority tasks, but synergistic effects on animal behaviour, as well as synergies caused by non-pesticide stressors, are not yet implemented in the RA. The lack of appropriate scientific studies and methodologies about these key topics partially explains the respective lack of advances in RA. However, the difference between the complexity of real-world situations (i.e. exposure to multiple stressors affecting survival and behaviour) and the simplified RA scenario can lead to uncertainties in RA conclusions. Thus, we developed methodologies to assess synergistic effects of key animal stressors on bee survival and behaviour. Our work was based on the LD_{50} standard test, which is already commonly used in RA, to facilitate implementation and comparisons. Honey bees were used as RA animal model. Our work demonstrated that animal health can be synergistically impaired by the combination of two major common stressors, pesticides and poor nutrition, at field-realistic exposures. We also demonstrated that combined chemical stresses synergistically impaired animal behaviour and survival.

Fish Model Species in Human and Environmental Toxicology (PC)

Effects of pH on toxicity and bioaccumulation of ionisable substances using the fish embryo test (FET) with Danio rerio
M. Schweizer, University of Tuebingen / Animal Physiological Ecology; J. Kuttler, C. Heid, Tuebingen University; N.S. Thomaidis, National and Kapodistrian University of Athens / Department of Chemistry; D.E. Damalas, National and Kapodistrian University of Athens / Chemistry; R. Aalizadeh, National and Kapodistrian University of Athens; P. Von der Ohe, UBA - Federal Environment Agency / IV 2.2 Pharmaceuticals; R. Triebskorn, University of Tuebingen / Animal Physiological Ecology; H. K�hler, University of Tubingen / Animal Physiological Ecology
The fish embryo test (FET) with *Danio rerio* is a well-established and standardised (OECD Guideline 236) *in vivo* toxicity test that is commonly used to evaluate potential effects on early development of fish. Thus, it is a helpful tool for risk assessment in aquatic environments. However, until now, neither pH nor the particular properties of ionisable organic compounds (IOC) have sufficiently been considered in risk assessment. Characteristics of IOC vary, depending on their presence either as ions or as neutral species, in particular in respect to the uptake into organisms. Due to their electrical charge, ions pass poorly through biological membranes, whereas neutral species permeate more easily through membranes and are, thus, potentially of higher toxicity. The pH is one major factor influencing the proportion of dissociated and non-dissociated ions. Shifts in ambient pH cause alterations of the ionic proportions and thus, are key to IOC toxicity. Although many IOC are partly or completely ionised under environmental relevant conditions and already slight variances of pH can cause considerable changes in toxicity, little attention has been paid to pH and its consequences in toxicity testing. Therefore, the project PHION focusses on pH-induced effects of IOC in *Danio rerio* embryos. Apart from differing toxicities, also pH-dependent bioaccumulation is investigated based on the lethal body burden (LBB) concept which assumes that there is no toxicity without previous bioaccumulation. The goal is to evaluate to which extent pH is influencing IOC uptake, potential bioaccumulation and toxicity on the basis of 30 representative substances to eventually derive a generally valid prediction on the toxicity of compounds previously not being tested at different pH. The FET with *Danio rerio* will be complimented with acute and chronic tests with *Daphnia magna* and *Lemna gibba* to compare the potential pH-dependent effects of IOC at three different trophic levels. Data presented refer to *Danio rerio* FET results for the first subset of ionisable pharmaceuticals.

TUPC08
The Baltic populations of Atlantic salmon (Salmo salar) at risk? A multi-biomarker study as contribution to the understanding of a pressing health issue
F. Weichert, University of Gothenburg, Sweden / Department of Biological and Environmental Sciences; N. Asker, University of Gothenburg / Department of Biological and Environmental Sciences; C. Axén, Swedish National Veterinary Institute; L. F�rlin, University of Gothenburg / Department of Biological and Environmental Sciences; A. Welling, Evira Finnish Food Safety Authority; J. Sturve, University of Gothenburg / Department of Biological and Environmental Sciences
The Baltic Sea is highly influenced by its nine neighbouring countries. River discharges from highly populated and agricultural areas, pollution from marine traffic and other anthropogenic activities as well as multiple other biotic and abiotic factors challenge the marine organisms inhabiting the Baltic Sea. Atlantic salmon (*Salmo salar*), one of the top predators and a migratory keystone species has been facing severe health issues for half a decade. Within the last 5 years, symptoms such as skin haemorrhage, traumatic injuries and ulcers were reported from different rivers mainly from Sweden and northern Finland. These primary symptoms precede a secondary fungal infection (mycosis), lethargy and ultimately high mortality rates. Even though research has been conducted on the Baltic salmon populations, the focus has been towards yolk-sac fry mortality (commonly known as M74 syndrome), which is caused by thiamine deficiency. Recent investigations into the current health issues of returning salmon have not yet elucidated the main causative factors. In the summer of 2018, returning salmon were caught from four rivers along the Swedish east coast from Torne river in the north to river Mörrumsån in the south. Moreover, a sampling site on the west coast (river Lagan) was included. Different tissues were collected for assessment of (eco)toxicological parameters, which will be evaluated by using common, pollution-driven biomarkers. Disease prevalence will be assessed, using different criteria (e.g. histopathology). Furthermore, levels of vitamins (including thiamine) and antioxidants are going to be analysed. The oxidative stress-related hepatic enzyme activities of catalase (CAT), glutathione reductase (GR) and glutathione *S*-transferases (GST) were analysed. In plasma, ions (i.e. K^+, Na^+, Ca^{2+}, Cl^-) were determined Immunological assays, i.e. lysozyme and complement system activities in plasma and other biomarkers (e.g. protein oxidation, AChE and EROD activity) will also be included in the final assessment and presented at the SETAC conference. Preliminary results on oxidative stress show slight differences between mycotic and non-mycotic fish, but no clear regional patterns were observed. Initial data analysis on plasma ions shows reduced levels of Na^+ and Cl^- in fish with mycosis, but no conclusive regional pattern. With this comprehensive study, we hope to shed more light on the health status of Baltic salmon.

TUPC09
Evaluation of the acute toxicity, uptake and biotransformation potential of citalopram in zebrafish (Danio rerio) embryos at three environmentally relevant pHs
D.E. Damalas, National and Kapodistrian University of Athens / Chemistry; R. Aalizadeh, National and Kapodistrian University of Athens; M. Schweizer, University of Tuebingen / Animal Physiological Ecology; C. Heid, Tuebingen University; H. K�hler, University of Tubingen / Animal Physiological Ecology; P. Von der Ohe, UBA - Federal Environment Agency / IV 2.2 Pharmaceuticals; R. Triebskorn, University of Tuebingen / Animal Physiological Ecology; N.S. Thomaidis, National and Kapodistrian University of Athens / Department of Chemistry
The contamination of the aquatic environment has raised concerns in the scientific community and regulatory authorities. Given the large number of xenobiotics, for most of them there is a striking deficit in the literature concerning their adverse effects on aquatic organisms. Citalopram (CTR) is a worldwide highly consumed antidepressant which has demonstrated incomplete removal by conventional wastewater treatment, hence resulting in the contamination of aquatic ecosystems. Consequently, it is urgent to evaluate its potentially toxic effects on aquatic organisms. Zebrafish (*Danio rerio*) has emerged as a powerful model organism to study various aspects of developmental and cell biology as well as physiology, while it provides a promising alternative model for acute toxicological studies. The objectives of this study were (1) to assess to what extent CTR induces toxicity to zebrafish embryos. In addition (2), we evaluated the uptake and biotransformation processes of CTR by zebrafish and examined whether biotransformation data could be used in a complementary way to the concentration of the parent compound to interpret the induced toxicity. The final goal was to evaluate to which extent the pH is influencing CTR's uptake, potential bioaccumulation and biotransformation, as well as toxicity. More specifically, the zebrafish embryo toxicity assay was used to calculate the LC_{50} of CTR, as well as to evaluate potential sub-lethal endpoints (e.g. the hatching rate). Exposure experiments were conducted at three different pH values (6, 8 and 9), to assess potential pH-dependent differences in an environmental relevant pH range. Concerning the toxicokinetic part of the study, exposure water samples and zebrafish extracts were analysed by RPLC and HILIC methods, in both positive and negative ionization mode, to cover the widest possible range of polarities, using LC-QTOF-HR-MS/MS. Detection and identification of tentative CTR biotransformation products were performed through in-house developed suspect and non-target screening workflows. Finally, the biotransformation pathway of CTR in zebrafish embryos was proposed.

TUPC10
Organochlorine pesticides in Tigerfish (Hydrocynus vittatus) in Phongolo, South Africa
N. Vogt, North-West University / Environmental Sciences and Management; R.

Pieters, North-West University / Unit for Environmental Sciences and Management; Y. Ikenaka, M. Ishizuka, Hokkaido University / Graduate School of Veterinary Medicine; V. Wepener, North-West University - School of Biological Sciences / School of Biological Sciences

Persistent organic pollutants like organochlorine pesticides (OCPs) are common environmental pollutants. Although these compounds have been banned because of various detrimental effects, including cancer, they are still found in the environment due to their persistence, and widespread and large volume use. Dichlorodiphenyltrichloroethane (DDT) is a banned OCP in most parts of the world, but is permitted for use to combat the malaria vector mosquito. Phongolo is one of the areas where it is still used. Due to bioaccumulation it is expected that top predators would be especially affected by these compounds. For this reason concentrations of OCPs (DDT and metabolites, chlordane, hexachlorocyclohexane (HCH), hexachlorobenzene (HCB), and aldrin, dieldrin and endrin that are collectively termed cyclodiens) were quantified in the top predator, Tigerfish (*Hydrocynus vittatus*). Muscle tissue was extracted using automated soxhlet and cleaned with Florosil solid phase extraction. The target compounds were quantified using gas chromatography electron capture detector (GC ECD). Concentrations of ΣDDTs were 11.1 ng/g wet mass (wm), with *p,p*-DDE making up the greatest proportion. ΣChlordanes were low (0.13 ng/g wm), and only trans-chlordane and trans-nonachlor having detectable concentrations of the eight chlordanes analysed. ΣHCH (four isomers) were low, 0.25 ng/g wm. Concentrations of HCB and cyclodienes were below the detection limit. Concentrations of DDTs and HCHs in this system were lower than those recorded in Tigerfish from rivers in and around the Kruger National Park, South Africa. Fish from the iSimangaliso Wetland Park, south of the current study, recorded similar to slightly higher concentrations to those reported here. Concentrations of DDT are a possibility for concern because of the various health implications and their bioaccumulation potential, indicating the food web is exposed to these compounds, and there is a great potential for humans to be affected. Monitoring of this system, and the health of the fish should be assessed in further studies.

TUPC11

METABOLOMIC ANALYSIS OF GONADS AND LIVER OF FISH EXPOSED TO EFFLUENT OF PULP AND PAPER MILLS.

C.H. Soares, Universidade Federal de Santa Catarina / Biochemistry Department; I. Baptista, Universidade Federal de Santa Catarina

Effluents from pulp and paper mills are internationally recognized as containing toxic substances with properties to alter the reproductive capacity of fish. The objective of this study was to evaluate the metabolic modifications (using metabolomics tools) of fish gonads and liver (*Danio rerio*) exposed to effluent from the pulp and paper industry, as well as the embryonic development of embryos generated by the respective fish. The effluent was diluted by a factor of 1/25. The fish (10 males and females) were exposed to the effluent, and males and females were kept separated for 7 days at 28 ºC and a light / dark cycle of 12/12 h in 3.5 L glasses. After pre-exposure period, males and females were mated (1 couple per Becker containing a net at the bottom) and monitored for 6 days with daily water/pollutant renewal and fed twice a day. The eggs were collected and placed on plates containing the test agent, kept protected from light. The fish were sacrificed for liver removal and gonads, from which a homogenate was prepared. Then, extraction was performed with chloroform/methanol/water (3:2:1). The extract obtained was prepared for the analysis by gas chromatography (GC/TOF-MS). For the exposed fish, there was a significant reduction in egg production, 65%. A high percentage of the eggs presented dark staining, which is not feasible. Chromatography results revealed significant changes in the amino acid, sterol and fatty acid profile in both tissues, liver and gonads. The results showed a strong impact on the metabolism, egg production and embryo development for the studied fish, which point to the alteration of their reproductive capacity.

TUPC12

Histopathological changes in gills and livers of shorthorn sculpin (Myoxocephalus scorpius) exposed to lead

K. Jantawongsri, Institute for Marine and Antarctic Studies (IMAS), University of Tasmania / Institute for Marine and Antarctic Studies (IMAS); R.D. Nørregaard, Aarhus University AU Arctic Research Centre / Department of Bioscience; L. Bach, Aarhus University AU Arctic Research Centre / Department of Bioscences; C. Sonne, Aarhus University AU Arctic Research Centre / Department of Bioscience; R. Eriksen, CSIRO Marine And Atmospheric Research; B. Nowak, University of Tasmania / Institute for Marine and Antarctic Studies (IMAS)

Mining operations worldwide have caused significant heavy metals contamination of the local environment, including marine ecosystems. Sculpins have been used as fish species for environmental monitoring of heavy metal contamination such as lead and zinc in the mining areas in Greenland. However, the effects of heavy metals have not been validated in laboratory experiments. In this study, shorthorn sculpin (*Myoxocephalus scorpius*) were exposed to lead (Pb) in a controlled laboratory experiment. After acclimatization for two weeks, fish were placed in 4 tanks (15 fish/ tank) – 2 exposure tanks (200 μg/L Pb) and 2 control tanks. After 28 days of exposure, the fish were dissected and samples of gills and livers were collected. The samples were fixed in 10% buffered formalin. Samples were processed using standard protocols for histology, embedded in paraffin, sectioned at 4 μm, and stained with haematoxylin and eosin (H&E). Metal analyses were done using ICP-MS. Pb was significantly higher in the liver of exposed sculpins (0.45±0.03; mean±SEM) than in the control fish (0.13±0.03; mean±SEM) (*p< 0.01*). The histological examination showed a number of lesions in gills (telangiectasia and lamellar fusion) and livers (megalocytic hepatosis). Relationships between heavy metals residues and quantitative histopathology of gills and livers will be presented and discussed. Overall, the results suggest that Pb exposure could alter structure of gill and liver of the sculpins. This will help to interpret results of sculpin studies from mining areas.

Fate and Effects of Metals: Advances in Metals Risk Assessment and Regulatory Guidance (PC)

TUPC13

Metal mixture toxicity on freshwater algal communities: the something-from-nothing effect

A. Fettweis, KULeuven / Department of Earth and Environmental Sciences; K. De Schamphelaere, Ghent University (UGent) / Environmental Toxicology; E.E. Smolders, KULeuven -BE0419.052.173 / Department of Earth Environmental Sciences

Metal contaminations are still a likely reason for EU freshwater systems not to reach a “good ecological status”, as defined by the European Union Water Framework Directive. Risk assessment of contaminated waterbodies is largely focused on a metal-by-metal basis, while mixed contaminations are the rule rather than the exception. This is definitely the case for toxic trace metals, such as copper, nickel and zinc, which often occur close to their environmental limits. Mixture effects of these metals have been observed in individual species, even when each individual metal shows no effect, the metals were toxic when dosed together; this is called the something-from-nothing effect. In ecological communities, we hypothesise this effect can be even more pronounced due to competition effects, but experimental data on this subject is minimal. Here, we tested metal mixture toxicity on 8 freshwater algal species individually and in some selected combinations. The cell biomass of the species varies between 0.5 and 40 x10-5 ug/cell, growth rate between 1 and 1.7 day-1 and carrying capacity between 50 and 100 mg dw./L. Mechanistic modelling based on nutrient (phosphorus) uptake and above mentioned specific species properties was explored to help interpret the results. The idea being that the faster growing species will dominate under control conditions. While under metal mixture stress, the least sensitive species, i.e. the species with the highest toxic threshold to the individual metals and/or with the least pronounced something-from-nothing effect, will outcompete the other species. Experimental and modelling work is still in progress, but will be presented at the SETAC conference.

TUPC14

Testing performance of biotic ligand models for Cu, Ni and Zn in Northern European water chemistries

M.T. Leppanen, Finnish Environment Institute; S. Baken, European Copper Institute; O. Garmo, Norwegian Institute for Water Research; S. Hoppe, County Administrative Board of Östergötland; J. Järvistö, Finnish Environment Institute; G. Merrington, WCA Environment Limited; K. Ndungu, Norwegian Institute for Water Research; S. Perämäki, University of Jyvaskyla; A. Peters, WCA Environment Limited; C.E. Schlekat, NiPERA; F. Van Assche, IZA; A. Väisänen, University of Jyvaskyla

The influence of water chemistry on the bioavailability and toxicity of metals is well acknowledged in the scientific literature. Accordingly, the EU has recently directed that the annual average Environmental Quality Standards for nickel and lead in surface freshwaters be set as bioavailable, rather than total dissolved concentrations. Also zinc, copper and manganese have bioavailable regulatory limits in use in some EU countries. For these metals, Biotic Ligand Models (BLMs) have been developed that predict their bioavailability under different physico-chemical conditions of the water. From the BLMs, practical and user-friendly tools have been derived for calculating the bioavailable metal concentrations using only few water quality parameters. Regulatory jurisdictions need to familiarize themselves with the models and find a framework to assess risks of metals in surface waters. Another challenge posed by the existing models is that they are not validated for all possible water chemistry conditions present in the EU. This is particularly evident for the Fennoscandinavian waters. The reason for lacking validation is that the standard test species used for the BLMs do not tolerate extreme conditions like highly acidic and very soft waters. This project aimed to fill this gap and address the challenge for the regulators in the Nordic countries. The project has produced chronic toxicity data using algae (*Pseudokirchneriella subcapitata*), daphnid (*Daphnia longispina*) and snail (*Lymnaea stagnalis*) conditioned or being indigenous for the low pH and low hardness conditions that can be observed in Nordic waters. The NOEC and/or EC10 values were obtained for copper, nickel and zinc. The full BLM models behind the Bio-met user-friendly tool estimated the EC10 values in the measured test water chemistries and the results were compared to the empirical endpoints. Eight surface water samples from Finland and Norway were tested and 28 modelled vs. observed pairs were produced. In general, for the daphnid and snail comparisons, the estimates stayed within a two-fold difference which is considered acceptable. In contrast, for the algae, all the observed EC10s were clearly below the modelled estimates. The results give a chance to evaluate the performance of BLM models below or close to the validation conditions and offer new data for further improvement of BLMs.

TUPC15

Critical assessment of methods for organic carbon analysis: significance for predictions of trace metal speciation and bioavailability in surface waters

B. Slootmaekers, Systemic Physiological and Ecotoxicological Research (SPHERE), University of Antwerp / Department of Biology; R.M. Town, Systemic Physiological and Ecotoxicological Research (SPHERE), University of Antwerp / Department of Biology (SPHERE Research Group); K. Van den Bergh, L. Bervoets, R. Blust, University of Antwerp / Department of Biology (SPHERE Research Group)

The development of robust approaches and criteria for protection of ecosystem functioning and ecosystem services is a challenging task that requires consideration of multiple abiotic and biotic stressors, the nature and relative magnitude of which vary across locations. Consequently, a single absolute threshold value for a given pollutant might be protective in one scenario and underprotective in another. Fortunately, legislators are increasingly recognizing the importance of contaminant speciation and bioavailability in environmental risk assessment. Under the European Water Framework Directive, the Environmental Quality Standards of some trace metals are already set as bioavailable thresholds e.g. zinc and lead. Such thresholds are typically derived from empirical correlations between the free metal ion concentration in the water and lethal accumulation and/or effect levels in biota as determined under laboratory conditions. Typically equilibrium-based metal speciation codes are used to compute free metal ion concentrations for the given water conditions. A key input parameter in this regard is the Organic Carbon (OC) content. OC forms complexes with a wide range of trace metal ions, the thermodynamic and kinetic features of which are dependent on the metal-to-binding site ratio. Thus, the predictive capability of modelling strategies may be affected by the accuracy of the OC data. During a large scale field monitoring campaign to assess links between metal speciation, bioavailability and potential toxicity, we encountered a discrepancy in measurements between the Dissolved- and Total Organic Carbon contents (DOC/TOC) when using standard protocols. Specifically, we observed the theoretically impossible outcome that DOC was higher than TOC, which led us to dig deeper into the methodology for OC measurements. In our presentation we will show several protocols for measuring both DOC and TOC, and the consequent impacts on the (i) metal speciation computed by various chemical speciation codes, e.g. Visual MINTEQ, WHAM,… and (ii) toxicological risk assessment predicted by e.g. PNEC-PRO, BIO-MET…. The outcomes of our study provide greater insight into the validity of OC measurements and will contribute to the development of more robust approaches for linking metal speciation to bioavailability under field conditions.

TUPC16

Toxicity assessment of nickel to Daphnia magna in Japanese natural waters

H. Mano, National Institute of Advanced Industrial Science and Technology (AIST) Japan / Research Institute of Science for Safety and Sustainability; N. Shinohara, W. Naito, M. Kamo, Y. Iwasaki, National Institute of Advanced Industrial Science and Technology AIST Japan / Research Institute of Science for Safety and Sustainability

To predict toxicity of nickel to aquatic organisms in natural water, nickel biotic ligand models (BLMs) have been developed. However, applicability of nickel BLMs to Japanese river waters has not been tested sufficiently. In this study, chronic toxicity of nickel in Japanese river waters was examined by using *Daphnia magna* to examine whether the BLM for chronic toxicity of nickel to *D. magna* could apply to Japanese natural waters. We collected 4 different water-quality type of Japanese river waters in terms of DOC and hardness and then obtained 3 pH-level waters for each of the 4 river waters by adding MOPS and NaOH or HCl. We conducted chronic toxicity test of nickel in each of 12 river waters by using *D. magna*. The predictive capacity of the BLM for chronic toxicity of nickel to *D. magna* was evaluated by using results of toxicity tests. Based on results, applicability of the biotic ligand model to Japanese river waters and development of the models for Japanese river waters are discussed in the presentation.

TUPC17

The effect of aqueous potassium concentrations on thallium-induced toxicity in medaka (Oryzias latipes) larvae

G. Pan, P. Chen, National Taiwan University / Agricultural Chemistry

Thallium (Tl) is a trace element commonly used in the electronic, optical and semi-conductive industries etc. With the booming of these high-tech fields, Tl usage has rapidly increased, leading to frequent detection of Tl in the aquatic environment due to various routes of human activities. Tl mainly exists in the environment as monovalent Tl (Tl^+) and it is a priority pollutant of high toxicity suggested by the US Environmental Protection Agency and the European Water Framework Directive. However, the information regarding toxic mechanisms of Tl^+ is currently limited, so the associated risk of Tl^+ exposure and toxicity to the aquatic ecosystem is currently unclear. Since ionic radius of Tl^+ is similar to that of potassium (K^+), Tl^+ may interact with K^+ ion channels(e.g. Na^+/K^+-ATPase) and interfere with its bioavailability and metabolic processes, thus causing toxicity in aquatic organisms. In this study, we used medaka (*Oryzias latipes*) larvae as a model organism to investigate the chemical and biological interaction of Tl^+ versus K^+ to aquatic organisms. We aim to assess the agonistic potency of Tl^+ versus K^+ to compete for the Na^+/K^+-ATPase in synthetic natural water of various K^+ concentrations and associated toxic mechanisms. The mortality, behavioral analysis and gene expression were used to assess the acute and sublethal neurotoxic effects. Our results showed that Tl^+ induced higher mortality to medaka larvae in dosing solutions containing lower K^+ concentrations than those with higher K^+ concentrations. After a 7 day-exposure, the locomotor activity of larvae treated with sublethal concentrations of Tl^+ was significantly altered. The average velocity of larvae exposed to 50 µg/L Tl^+ significantly decreased when compared to the control group, while the absolute turn angle of treated larvae significantly increased in a dose-dependent manner. Additionally, the mRNA expression of genes for nerve function and development including Na^+/K^+-ATPase activity, myelin basic protein and synapsin IIa significantly increased after Tl^+ exposure. However, the expression of α-tubulin was decreased. The activities of antioxidant enzymes such as catalase and glutathione S-transferase were also inhibited by Tl^+ after 7 day-exposures, indicating an induced oxidative stress in larvae. Overall, this study showed a potential neurotoxic effect of Tl^+ and itsassociation with different K^+ concentrations of dosing solutions in medaka larvae. The detailed toxic mechanisms of Tl^+ require further investigation.

Revision of the EFSA Guidance Document on Birds and Mammals (PC)

TUPC19

From seeds to plasma: confirmed exposure of multiple farmland bird species to a systemic pesticide in the field

R. Lennon, The University of York / Environment; R. Shore, Centre for Ecology & Hydrology; G.M. Pereira, Centre for Ecology & Hydrology / Centralised Chemistry; W.J. Peach, Royal Society for the Protection of Birds / Centre for Conservation Science; J.C. Dunn, The University of Lincoln / School of Life Sciences; C.J. Wheatley, The University of York; K.E. Arnold, C.D. Brown, University of York / Environment and Geography

Many farmland bird species have a high proportion of crop material in their diet, and as a result are at risk of being exposed to systemic pesticides via direct ingestion of either treated seed or crop seedlings. Current risk assessments assume that the majority of seeds will be buried after sowing and are therefore inaccessible to birds, whereas the amount of residue in crop seedlings as a result of systemic seed treatments is largely unknown. Here, winter cereal treated with the neonicotinoid clothianidin is used as a model system to test the validity of these regulatory assumptions. In 2015 and 2016, surface seed densities were recorded post-sowing, and crop seed and seedling samples were collected at multiple time points across 25 sites (East Anglia, UK) sown with neonicotinoid-treated seed. Bird abundance and observations of birds consuming treated seed were also recorded. In 2017, plasma samples were obtained from 11 farmland bird species across six sites (Lincolnshire, UK) sown with neonicotinoid-treated seed, pre- (controls) and post- (treatment) sowing. Seed, seedling and plasma samples were analysed for clothianidin via liquid chromatography-mass spectrometry. Surface seed densities were greater at headlands compared to field centres; median clothianidin residue was 181,510 ng/g wet weight in seeds (n = 109) and 1,131 ng/g wet weight in seedlings (n = 88). Clothianidin residue detected in seeds decreased over time, with the steepest decline occurring three days after sowing. Overall, 71 bird species were recorded in treated fields, 15 of which were observed consuming treated seed. In total, 37 out of 73 treatment samples (10 out of 11 species) and four out of 37 control samples (2 out of 11 species) tested positive for clothianidin. Median clothianidin residue in plasma samples was 10 ng/mL (n = 41) and the largest concentration (69,300 ng/mL) was collected from an individual yellowhammer (*Emberiza citrinella*). Results suggest that exposure to neonicotinoids occurs across multiple species of UK farmland bird, and that treated seeds are readily accessible to a range of bird species at field headlands sown according to normal agricultural practice. This study provides evidence that dietary exposure of farmland birds to insecticide seed treatments may be underestimated by current risk assessment procedures, with potential implications for non-target avian species worldwide. \n

TUPC20

Bird nest monitoring studies: standardisation of study designs for the revision of the EFSA Guidance document

M.M. Benito, Tier3 Solutions GmbH; R. Dittrich, Tier3 Solutions GmbH / Wildlife Ecology; B. Giessing, A. Russ, Tier3 Solutions GmbH

For the assessment of the risk from Plant Protection Products (PPPs) to birds, the official guidance in the EU (EFSA Guidance Document 2009, GD) indicates that one option to demonstrate acceptable risk is to conduct so-called field effects studies. Such studies are desirable as they take into account all routes of exposure as well as the natural variability. Despite these advantages, their acceptance by member states varies, because the actual GD gives recommendations but no detailed information about the required test design of such studies. Our work contributes to the standardisation of nest monitoring protocols in order to enable comparisons between individual studies. The aim is to provide a framework regarding study area selection, proper study conduct, relevant parameters and suitable statistical tools. The design of nest monitoring studies should include endpoints which are considered in the laboratory avian reproduction tests according to OECD or EPA: number of laid eggs, infertile eggs and hatched eggs, embryo development, weight of chicks at the age of 8 or 14 days depending on the species and survival of chicks. Unlike the tier1 tests, nest monitoring studies additionally cover the period of parental care of the chicks after hatching, a phase of great importance for altricial species like most European farmland birds. Furthermore, the high degree of environmental standardisation in animal lab studies can contribute to spurious findings and little external validity (Richter 2009). In comparison, nest monitoring studies provide the most realistic tool if they are appropriately designed for taking into account variation in environmental conditions (weather, food availability etc.). It should be noted that the absence of observed sublethal effects does not indicate a failure of the study design, as field effect studies do not aim to establish a dose-response relationship. What they can provide, with the help of appropriate statistics, is the assessment of the impacts of relevant environmental factors (including PPPs) on reproduction, in spite of the high natural variability. With a more detailed guidance, field nest monitoring studies can be a valuable tool in the assessment of the PPP risk to birds, as well as part of a post-registration monitoring. To accomplish this, agreed standards should be defined in the context of the revision of the EFSA GD on birds and mammals.

TUPC21

Home range and habitat use by two farmland birds in cereal landscapes in Central Europe - results from industry studies

M.M. Benito, Tier3 Solutions GmbH; J. Pascual, BASF SE / Ecotoxicology; M. Ebeling, Bayer AG Crop Science Division / Ecotoxicology - Terrestrial Vertebrates Expert Team; R. Dittrich, Tier3 Solutions GmbH / Wildlife Ecology; B. Giessing, C. Wolf, Tier3 Solutions GmbH

For the assessment of the risk to birds from Plant Protection Products (PPPs), the official guidance of the EU (EFSA guidance document), gives the option to refine exposure estimates by conducting generic field studies, which provide data on the use of specific crops by particular species in different regions and seasons. At the request of industry, several studies have been carried out based on radio-tracking, a highly accurate methodology for the monitoring of a relevant number of individuals. These studies are primarily used to estimate the Proportion of an animal´s daily diet obtained in a Treated habitat (PT). However, the scope of the studies reaches further, since they contain also a wealth of further information that allows accurate assessments of the home ranges and habitat preferences of birds in agricultural environments. Here, we will present the insights of three radio-tracking studies on two bird species (skylark and yellowhammer) in agricultural areas with predominance of cereals during the drilling season in autumn. The selected species are typical farmland inhabitants, mostly granivorous during the autumn/winter and yet with contrasting ecologies. Radio-tracking was performed as continuous sessions over the daily activity period or by temporary checks over the study duration, and habitat mapping was carried out at a spatial scale from single bird home ranges up to hundreds of hectares of the study area. Both species showed their habitat preferences clearly, agricultural landscapes with open areas for the skylark and mixed agricultural landscapes with vertical structures (hedges, small forests) for the yellowhammer, as well as differences in the preferred foraging crops. Individual home ranges differed considerably and were in general substantially larger during the full duration of the studies, showing inter- but also intra-individual variation that indicates high flexibility in the individual behaviour. Information extracted from this data may allow for better evaluations of the use of relevant agricultural landscapes by farmland bird populations. It could strengthen the risk assessment of PPPs and therefore should be taken into account in the ongoing revision of the EFSA GD. Furthermore, data obtained in these studies on behaviour, spatial and temporal habitat use and feeding ecology of farmland species provide detailed knowledge of general interest for ornithologists, conservation scientists and experts in agri-environmental policy.

TUPC22

Calculating realistic long-term PT values for wildlife risk assessment - insights from telemetry field studies

J. Ludwigs, Rifcon GmbH / Business Development; O. Jacoby, Rifcon GmbH; M. Ebeling, Bayer AG Crop Science Division / Ecotoxicology - Terrestrial Vertebrates Expert Team; M. Foudoulakis, Corteva Agriscience, The Agriculture Division of DowDuPont / CPRS; T.B. Fredricks, Bayer CropScience / Global Regulatory Sciences; S. Haaf, ADAMA Deutschland GmbH; R. Murfitt, Syngenta Ltd / Environmental Safety; J. Nopper, BASF SE

The current EFSA guidance document on risk assessment for birds and mammals assumes, if no specific data is available, that animals feed exclusively on pesticide-treated fields. One important recommended and frequently used refinement of the risk to birds and mammals from pesticide exposure is a more realistic estimation of the "portion of food animals obtain from treated fields". This so-called PT factor is equalized (according to EFSA B&M Guidance Document 2009) as the portion of time an animal spends potentially foraging over the course of a day within potentially treated fields, i.e. within the respective crop of interest. Radio-tracking is the best method to generate PT values, for long-term risk assessments. Due to time and resource constraints, such empirically recorded radio-tracking data are typically restricted to single or few daily activity PT values per tracked animal, and do not cover long-term periods (e.g. 21 days). Accordingly, intra-individual variability in daily PT values over an extended time period can often not be taken into account for the calculation of a long-term PT. Through analyses of multiple field studies, we further assess the applicability of a Monte Carlo probabilistic approach to simulate 90th percentile 21-day PT values, as presented in Ludwigs et al. (2017). We analyse different original and relevant radio-tracking data sets, which cover a range of different numbers of individuals and sessions per individual of common farmland species like skylarks, wagtails and brown hare. Our general approach of modelling 21-day PT values thus covers intra- and inter-individual variability of farmland species foraging in cropped habitats. We demonstrate how the different data sets from telemetry field studies can result in more appropriate 21-day PT values for use in pesticide risk assessment. These modelled PT values are compared to the current regulatory standard within the evaluation process, where PT refinement is typically restricted to the 90th percentile of the empirical data. It is proposed that this method is considered in the revision of the current EFSA B&M Guidance Document (2009).

TUPC23

Distinctive patterns in the cumulative probability distribution of PT values of several bird species. Significance of the 90th percentile - How to reach a realistic PT value for long-term exposure?

R. Dittrich, Tier3 Solutions GmbH / Wildlife Ecology; I. Hotopp, Tier3 Solutions GmbH / Regulatory Science; M.M. Benito, B. Giessing, Tier3 Solutions GmbH

Refinement steps in the higher tier risk assessment include the PT value, defined as the Portion of diet obtained from a Treated area and ranging from 0 (diet portion= 0%) to 1 (diet portion = 100%). EU regulatory authorities recommend the 90%ile of the measured PT data to be used in the refinement. However, using this single value only neglects valuable information about the studied bird populations. We analysed the cumulative frequency distributions of PT values of several species in the same crop type (orchard or cereal) in two countries (ES and UK). Interestingly, three types of distribution patterns represent the relevance of the crop for the studied population, respectively. Type I distribution follows a quadratic function, where the 90%ile of the PT value is representative for the population. For example, blackbirds in citrus orchards show a 90%ile PT (= 1) close to the median (0.9) and is thus representative for this species in this habitat. Type II follows a linear function where the 90%ile represents half of the population. Type III follows a root function, where for the majority of individuals the actual PT is much lower than the 90%ile, so the crop is the feeding habitat of only few individuals. For example, tit species in pome fruit orchards show a great difference between the 90%ile PT (0.74) and the median (0.19). In the case of type III distributions the 90%ile PT does not describe the foraging behaviour of the population in the crop appropriately. These insights are important, since the 90%ile is used for long-term risk assessment as a representative value of the **mean** exposure of 90% of the population over a longer period (e.g. 21 days). This assumption would only be correct if individuals with a 1-day PT value around the 90%ile were similarly exposed every single day in the whole period. Instead, both literature and our own data shows that PT values of the same individual differ considerably among days. Thus, over any given period of time, the PT of 90% of the population is clearly lower than the 90%ile of 1-day, especially when the frequency distribution follows type II or type III. In such cases, a realistic 90%ile PT can be estimated based on repeated sessions of individuals. As long as no such data is available, the 90%ile should be reassessed by taking into account the difference to the median. This approach, validated by published data of repeated individual sessions, gives a more appropriate PT value for long-term risk assessments.

TUPC24

The Minimum detectable differences - a way to estimate the power of a small mammal field effects study a posteriori

I. Hotopp, Tier3 Solutions GmbH / Regulatory Science; O. Fuelling, Tier3 Solutions GmbH / Field study

Before conducting a field study it is sensible to find out the number of fields necessary to find a specified effect, so that the study can be planned accordingly. This power analysis requires reliable data from previous or pilot studies that provide the necessary means and standard deviations. For field effects studies these data often does not exist. The Minimum Detectable Differences (MDD) can be used to calculate the smallest detectable effect of the study *a posteriori.* The calculation designed for a t-test by Brock et al. (2015) can be modified for statistical methods adequate for analyzing field study data such as Generalized Linear Mixed Models (GLMMs) (Peters et al., 2016, Supporting Information). One possible example is a field effects study focussing on the influence of a Plant Protection Product (PPP) application on common vole populations. For the common vole it is especially difficult to get reliable standard deviations as the voles undergo multi-annual population cycles with huge differences between low and peak years. The guidance document for aquatic organisms by EFSA (2013) provides a ranking with four MDD classes. The best achievable class is class IV with MDD < 50% and defined as “Small effects can be determined statistically”. This < 50% threshold was used to assess the MMD% for four field data sets as there is no such ranking for terrestrial field effects studies provided by EFSA or any other regulatory authority. All together MDD% for 31 trapping sessions were calculated with only one session above the 50% threshold and a mean of 18%. Compared to a 50% threshold for aquatic studies this is a very acceptable result. To get an idea what this difference means in common vole populations, the deviation from the mean between control site populations within the four example studies was calculated. These differences aggregated to values between 17 and 110%. Compared to this natural variation in population density the detection of an average of 18% difference between treated and untreated populations is a promising result.

Can We Demystify Machine Learning for Environmental Chemistry and (Environmental) Toxicology? (PC)

WEPC01

Advancing machine learning in environmental toxicology via information sharing and transfer learning

X. Sui, University of St. Thomas / School of Engineering; C. Lai, University of St. Thomas / Graduate Programs in Software; C. Dusek, St. Thomas University

In early development of Machine Learning (ML) and Artificial Intelligence (AI), there was a strong skepticism on how to interpret the prediction results, and how to generalize the results to more complex situations. To respond to the skepticism, more data such as images and texts were collected and shared in standard formats to strengthen the training of the ML/AI systems. Through extensive training on wide variety of sharable data, many systems such as IBM Watson or Google Alpha Go nowadays can outperform human precision in many fields. In toxicology, if wide variety of data can be shared in standard formats, we can train the ML/AI systems to generate high-confidence hypotheses to guide toxicologists focusing their studies on significantly smaller subsets of targets. Luechtefeld’s 2018 study echoed the similar vision, and analysts in other fields have been using the similar approach in guiding their search for the bank or medical frauds. Sharing datasets in standard formats can also allow scientists to train more generalizable and reliable ML/AI systems. For example, over years of collecting videos in standard formats, self-driving cars can now recognize complex driving conditions with high precision. Similar but limited successes in toxicity prediction have been reported in *DeepTox* and *InSilico*. We can greatly expand the successes to broader applications with larger sharable datasets. For the interpretability issue, many techniques have been developed to help users to identify important features that lead to certain ML/AI predictions. The reliability of such feature identification methods can be improved with wide varieties of large datasets. For example, the LASSO method can compute the positive or negative weights of each predictor in influencing the prediction results. The “attention” method also has potentials in identifying the important “toxicophores” that lead to toxicity or disease. As discussed above, large-scaled information sharing in standard formats will enable scientists to train more sophisticated ML/AI systems that are more generalizable and reliable. More importantly, the trained systems can again be shared and quickly be retrained using much smaller datasets by other scientists for different but related toxicology analyses. This new promising concept of ***transfer learning*** is our current research focus. We plan to expand the AOP prediction systems that we presented in recent SETAC meetings and make those transferable to other toxicology studies.

WEPC02

A machine learning approach for (transcript-)omics data in ecotoxicology to improve consistency of microarray sample sets of chemically treated fathead minnows

S. Kraemer, Helmholtz Centre for Environmental Research - UFZ GmbH / Molecular Systems Biology; W. Busch, A. Schuettler, Helmholtz Centre for Environmental Research - UFZ GmbH / Bioanalytical Ecotoxicology

Omics technologies are applied more and more in ecotoxicological research. One challenge in omics research is to establish consistency between different studies. The present study investigated, whether comparability of microarray data sets can be improved using a machine learning algorithm. Nineteen GEO-sample sets were used to train an universal ecotoxicogenomic map for hepatic tissue of adult male fathead minnows exposed to either waste water or single chemicals or mixtures of chemicals. The unsupervised learning approach reduces the dimensionality of the data set without losing information by clustering genes to nodes according to their similarity in expression behavior. The 54 projections on the ecotoxicogenomic map showed unique patterns. Nevertheless, it is possible to group reduced profiles by their similarity of patterns. In the data sets of an interlaboratory study, a common EE_2-pattern could be identified with 12% of significantly regulated nodes in common and a mean pairwise overlap of 62%. In comparison, We could show that differential expression of microarrays across six different laboratories is more congruent using the application of a machine-learning approach than using single genes. A combined filtering for differential expression of nodes ($p < 0.05$; $|logFC| > 1$) improved consistency in comparison to the results within the interlaboratory study (5% total overlap and 59% mean pairwise overlap). A further coarsening of transcriptomic units by hierarchical clustering as second reduction to the ecotoxicogenomic map, enabled us to determine a combination of estrogenic specific differentially expressed units in this interlaboratory study and two further profiles of microarray experiments that examined estrogenic treated fathead minnows.

WEPC03

Computational tools for in silico multi property profiling of chemicals

E. Papa, University of Insubria / Department of Theoretical and Applied Sciences; A. Sangion, University of Insubria / Department of Theoretical and Applied Sciences (DiSTA); N. Chirico, L. Bertato, University of Insubria; I. Casartelli, University of Insubria / Department of Theoretical and Applied Sciences DiSTA; P. Gramatica, University of Insubria

In the last decade the high economic and social costs of experiments necessary to support the timely identification and management of potential risks associated to chemicals, has pushed the use of *in silico*, i.e. computer-based, alternatives to animal testing, onwards. Machine learning methods based on linear and non-linear approaches as well as data mining techniques have been widely applied to this end. Nowadays thousands of *in silico* models based on structure-activity relationships (i.e. QSARs) are available to predict different endpoints of interest for the scientific and the regulatory community. OECD and ECHA guidelines provide support for the correct development, validation and application of these tools, however not all models are equally transparent, interpretable or have a clearly defined domain of applicability. These issues may limit the application of these models as well as negatively affect the potential benefits associated to the use of alternatives to animal testing. This is particularly important considering the large amount of resources invested worldwide over the last years for the development of these alternative approaches. In the last 20 years, our research group has developed many validated QSARs to predict different physico-chemical properties and biological activities useful for the hazard assessment of legacy chemicals and contaminants of emerging concern, using linear and non-linear approaches. The experience gained in these two decades of research was used to develop the software QSARINS, which is suitable for experienced model developers, and the recently released QSARINS-Chem, for models application only, which is dedicated to all users, i.e. with or without previous modelling experience. In this presentation, we provide step-by-step examples of how these tools can be transparently used to generate multiple linear regression models as well as predictions for various endpoints. The proposed results show that these tools are useful to fill data gaps and profile/prioritize chemicals according to multiple endpoints of interest, also in combination with predictions generated by other software and literature models.

WEPC04

Graph edit distance as molecular similarity measure for virtual screening

C.G. Hernandez, Universitat Rovira i Virgili / Departamento de Ingeniería Química; A. Fernandez, Universitat Rovira i Virgili / Departament dEnginyeria Química; F. Serratosa, Universitat Rovira i Virgili / Departament dEnginyeria Informàtica i Matemàtiques

Graph edit distance has been used for more than 40 years to compare objects in machine learning when these objects are represented by structures, such as attributed graphs, instead of vectors. In some applications, attributed graphs have more ability to represent the intrinsic properties of the elements than a vector of global features. This is because the local parts of the object can be explicitly represented by nodes and edges. Given two graphs, the graph edit distance between them is defined as the minimum number of modifications that are required to transform one graph into the other. To do so, it is needed to define these modifications, which are called edit operations. Basically, six edit operations are defined: insertion, deletion and substitution of both nodes and edges. Edit costs are defined to quantify the amount of distortion that each edit operation introduces. Thus, they are selected according to how similar the nodes and edges are. For instance, it is logical to think that the cost of substituting a hydrogen-bond donor with a joint hydrogen-bond donor-acceptor should be less penalized than the cost of substituting a hydrogen-bond donor with an aromatic ring system. In chemistry, attributed graphs (for instance *reduced graphs*) have been used to represent chemical structures using pharmacophore-type node descriptions to encode the relevant molecular properties. Nevertheless, the comparison has always been carried out by first converting the graphs into a vector of elements (for instance *fingerprints*) and then comparing the vectors using *Tanimoto distance*. In this paper, we propose to directly compare the reduced graphs through the graph edit distance, with the aim of keeping the structure and local information of the compared compounds. In the experimental evaluation, our method is applied to ligand-based virtual screening applications, where an estimation of bioactivity for a chemical is provided based on the bioactivity of similar compounds. Results obtained for graph edit distance show to have a better performance than other previous methods used on reduced graphs, using array representations. Overall, it is shown that reduced graphs along with graph edit distance is a widely applicable combination of methods, capable of identifying bioactivity similarities into a structurally diverse group of molecules.

Advances in Soil Ecotoxicology and Risk Assessment - Impact, Ecotoxicity Tests, and Concepts for a Retrospective Environmental Risk Assessment (PC)

WEPC07

A new method for evaluation of soil ecological toxicity using vibration sensors and earthworms

W. Lee, Research Institute of Natural Science / Geology; S. Lee, Department of Geology and Research Institute of Natural Science Gyeongsang National University / Dept of Geology and Geography; S. Kim, Department of Geology and Research Institute of Natural Science Gyeongsang National University / Geology

The methods suggested by OECD and ISO have been widely used for evaluation of soil ecological toxicity (SET), but their major disadvantages are to focus on only toxic substances and to requrie a relatively large amount of soil samples and large numbers of target species. To overcome those problems, this study conducted to develop a new method via detecting the movement of earthworms using vibration sensors. In order to establish the new method, the various conditions were optimized in terms of soil properties, biological aspects, and device specifications. After optimization, the method was verified by the evaluation of SET using soils contaminated with zinc (Zn). In optimization experiments using clean (uncontaminated) soils, the effects of soil properties [water holding capacity (WHC) and degree of consolidation (DOC)], the number of earthworms used, monitoring time and duration, and device specifications (shape and size) were investigated. On the other hand, in verification experiments using optimized conditions, the farm soils were tested after artifically contaminating with Zn concentrations. Based on the results of optimization experiments, 50% and 1.09 were investigated be most relevant for WHC and DOC, respectively, with consideration of movement and weight change of earthworms. The larger the number of earthworms used, the more frequent movement of earthworms detected. The height and radius of device were proven to be another crucial factors controlling the performance of the method. After testing the efficiency of several heights and radii, the optimal height and radius were proposed 5 cm and 6–10 cm, respectively. In addition, the leave and movement of earthworms decreased with increase in monitoring duration, and it might be caused by detrimental environments on vibration of soil particles and feeding of earthworms as a result of decreasing WHC. Accordingly, the relevant monitoring duration was proposed to be 3~6 days. The results of experiment on verification suggest that the movement of earthworms was decreased with increase in Zn concentrations, and it could be attributed to that earthworms minimized dermal contact with contaminated soils and the quality of soils as feeding media were degraded. Based on the detected movement of earthworms, EC50 was estimated and it was very similar to existing ones. Consequently, the movement of earthworms detected by vibration sensors can be applied to evaluate SET.

WEPC08

Terrestrial ecotox studies with difficult substances - A comparison of different application techniques

C. Maeß, O. Buttler, J. Frenkel, K. McVean, A. Rathke, Noack Laboratorien GmbH

The OECD Guidance document no. 23 identifies different classes of so-called difficult substances. Dependent on the physico-chemical properties of these substances, non-standardized test designs are presented and recommended. No such guidance is available for terrestrial ecotoxicity studies in soil although testing of different classes of chemicals and supporting analytical measurements become ever more important. We compared different techniques of soil application for three representatives of difficult substances. All combinations were supported by analytical measurements of the spiked soil. The analytical results were compared and discussed regarding recovery in soil, homogeneity of distribution and the overall usefulness of the different application techniques for difficult substances.

WEPC09

New soil test method for assessing contaminants using oribatid mites - Results from an international ring test

J. Princz, H. Lemieux, Environment and Climate Change Canada / Biological Assessment and Standarization Section; R. Scroggins, Environment and Climate Change Canada / Biological Assessment and Standardization Section

The use of oribatid mites has been steadily increasing in the assessment of chemical substances in soils, in addition to contaminated site soils. Oribatid mites represent a unique ecological niche within terrestrial systems, are among the most abundant species within surface soils, contributing to nutrient cycling through litter break-down. Efforts within the last several years have led to the development of a new test method within Environment and Climate Change Canada, using the oribatid mite species, *Oppia nitens* (CL Kock, 1839). The new method describes a 28-d test, using age-synchronized test organisms amenable to assessing the effects on adult mortality (if present) and juvenile production. Furthermore, efforts have also been directed to the inclusion of this new test method as part of the International Organization for Standardization (ISO) series of standards within Technical Committee ISO/TC 190 for Soil Quality. As part of standardization efforts, an international ring test was completed, involving 8 participating laboratories from Canada and Europe. Three rounds of testing were completed: (i) performance testing in artificial (AS), agricultural (VSL) and forest soil (FS) (for laboratories to become familiar working with the test species) (Round 1); (ii) a chemical test using boric acid in a field (VSL) soil (Round 2); and (iii) a chemical test using boric acid in the standard LUFA 2.2 test soil (Round 3). The results of the ring test will be presented from all three rounds, wherein, together with performance test data conducted by ECCC Canada using 13 soil types and horizons, the test validity criteria for this species and test method were finalized. The new test method is the first standardized effort for oribatid mites; the method will complement an existing suite of soil test methods (e.g., earthworms and collembolan), with applicability to both forest and agricultural soils.

WEPC10

Soil metal-contamination meets global climate change: effects on soil properties and toxicity risks to soil biota

M. González-Alcaraz, Department of Biology & CESAM - University of Aveiro / Biology & CESAM; C. Malheiro, University of Aveiro / Biology Department and CESAM; D. Nunes Cardoso, University of Aveiro / department of Biology & CESAM; A.R. Silva, University of Aveiro / Dept.of Biology & CESAM; C. Quintaneiro, Department of Biology & CESAM - University of Aveiro; A. Ferreira, University of Aveiro / Biology; M. Alves, University of Aveiro / Department of Biology & CESAM; I. Silva, University of Aveiro / Departmento of Biology; J. Alvarez-Rogel, Escuela Técnica Superior de Ingeniería Agronómica. Universidad Politécnica de Cartagena / Ciencia y Tecnología Agraria; R.A. Verweij, J. Mariën, D. Roelofs, Vrije Universiteit Amsterdam / Department of Ecological Science; C. van Gestel, Vrije Universiteit Amsterdam / Ecological Science; I. Henriques, University of Aveiro / CESAM; S. Loureiro, University of Aveiro / department of Biology & CESAM

Anthropogenic activities have been inducing alterations on Earth's climate system. The Intergovernmental Panel on Climate Change (IPCC) predicts major changes towards the 21st century (e.g., higher frequency/intensity of floods and droughts; increasing global air temperature). These alterations may impair the biotic and abiotic components of terrestrial ecosystems, affecting their functioning and sustainability and thus the services they provide. This scenario may worsen in anthropogenic-degraded areas where soil biota has to deal with already multiple stressors (i.e., multi-stressed environments) and where the behaviour/distribution of the contaminants present may change depending on the prevailing climate conditions and therefore their toxicity too. So far most of the studies dealing with climate change and soil toxicity risks have been focused on the effects of single climate factors on chemical-spiked soils, while less attention has been paid to climate factors combinations and/or anthropogenic-degraded field soils. In order to overcome this issue a new research line has been created in the Dept. Biology & CESAM from Aveiro University (Portugal) through the performance of the following research projects: GLOBALTOX (Marie Sklodowska-Curie programme; 704332), METOXCLIM (FEDER, COMPETE 2020 and Portuguese FCT; POCI-01-0145-FEDER-029557) and MICROCLIM (French CNRS/INEE via OHMI). The overall goal of the research line is to assess how biotic and abiotic components of field metal-contaminated soils may be affected under the current global warming perspective, by using toxicity (measured by means of soil invertebrates) and the associated changes in functional soil parameters (physico-chemical, microbiological) as indicators of ecosystem services. A inter/multi-disciplinary ecotoxicological approach is being applied to field metal-contaminated soils, using different invertebrate species and expositions to single/multiple climate factors (soil moisture content, air temperature, UV radiation and atmospheric CO_2). Climate factor combinations are be based on IPCC future climate predictions. The research line considers changes in key soil parameters (e.g., pH, organic matter, metal availability, microbiology) and soil invertebrates (e.g., body metal content, enzymatic biomarkers, gene expression) to understand the effects at organism/population level (e.g., survival, avoidance behaviour, reproduction).

WEPC11

BioNem Mulch Project - Assessing the efficiency and non-target effects of bionematicide delivery systems

S. Chelinho, CFE Centre for Functional Ecology / Department of Life Sciences of University of Coimbra; T. Natal-da-Luz, CFE - Centre for Functional Ecology / Department of Life Sciences; M.E. Braga, CIEPQPF Chemical Process Engineering and Forest Products Research Centre / Department of Chemical Engineering, University of Coimbra; J. Cardoso, R. Chim, CFE Centre for Functional Ecology / Department of Life Sciences University of Coimbra; A.M. Dias, CIEPQPF Chemical Process Engineering and Forest Products Research Centre / Department of Life Sciences University of Coimbra; I. Esteves, I. Abrantes, CFE Centre for Functional Ecology / Department of Life Sciences University of Coimbra; J. Sousa, University of Coimbra / Department of Life Sciences; H.C. Sousa, C. Maleita, CIEPQPF Chemical Process Engineering and Forest Products Research Centre / Department of Chemical Engineering, University of Coimbra

The use of synthetic nematicides is one of the most frequent and efficient strategies to control plant-parasitic nematodes (PPN). Root knot nematodes (RKN, Meloidogyne spp.) are among the PPN with higher economic impact worldwide, as they affect crop productivity, quality and value. However, due to increasing concerns on the risks posed by chemical nematicides, the development of environmentally friendly bionematicides has been stimulated. Recent studies have demonstrated that several phytocompounds have nematicidal activity but their applicability on RKN management should be explored. Currently, mulching plants with polyethylene plastic is a common practice to manage weed/soil-borne plant pathogens, although the waste disposal of such non-biodegradable mulches raises several environmental problems. The BioNem Mulch project, comprises a multidisciplinary approach and focuses on the development of fully degradable-in-soil bionematicide delivery systems (BDS) for RKN management on tomato crops. More specifically, this project aims to: 1) evaluate the impact of nematicidal compounds, in tomato crop and RKN life cycle; 2) develop BDS based on biodegradable plastic mulches and bionematicides; 3) assess BDS biodegradability and efficiency on RKN management; and 4) evaluate the effects of BDS field applications on non-target soil mesofauna. Soil quality indicators, such as mesofauna diversity (e.g. non-target nematode and microarthropod communities), microbial functional parameters (microbial biomass and soil basal respiration), and BDS degradation will be analyzed, under pot and field scenarios, to fully monitor the associated soil impacts.

WEPC12

Comparing effects of fludioxonil on non-target invertebrates using ecotoxicological methods from single-species bioassays to model ecosystems

A. H�gerb�umer, R. Raschke, Bielefeld University / Animal Ecology; N. Reiff, Ecossa; W. Traunspurger, Bielefeld University / Animal Ecology; S. Höss, Ecossa / Animal Ecology

Lower tier toxicity testing used for risk assessments of plant protection products (PPPs) is conducted with single species. Informations from such toxicity tests are, however, limited to direct effects of the respective tested substances. Although the uncertainties regarding the protectiveness of these tests for *in-situ* communities are known, informations on effects of PPPs on community-level of non-target organisms are scarce. Model ecosystems, i.e. microcosms, are suitable to bridge this gap between single-species tests and field studies since they provide controlled experimental conditions and are able to demonstrate direct and indirect effects of the respective substances. In the present study, single-species toxicity tests and soil-spiked microcosms were used to comparatively investigate the toxicity of the non-systemic fungicide fludioxonil (FDO) on non-target soil organisms, i.e. nematodes. Regarding soil invertebrates, nematodes are among the most abundant metazoan organisms and are considered as important components of the soil food web. Since nematodes are suitable for risk assessments via various assay tools ranging from single-species toxicity tests to field studies, potential effect of FDO on these non-target organisms were assessed using standardized toxicity tests with *Caenorhabditis elegans* (ISO 10872) in spiked soil exposure and *in-situ* nematode communities, sampled from microcosms with FDO-spiked soils. In the standardized toxicity tests, FDO inhibited the reproduction of *C. elegans* dose-dependently, with a chronic 96-h EC50 of 209.9 mg FDO/kg soil dry weight (dw) and a 96-h No Observed Effect Concentration (NOEC) of 63.0 mg/kg soil dw, which is comparable to the 28-d NOEC of *Chironomus riparius* in sediment (40 mg/kg sediment dw) and within the range of the 56-d NOEC of *Eisenia fetida* (20 mg/kg soil dw) and 28-d NOEC of *Folsomia candida* (125 mg/kg soil dw). In the spiked microcosms, distinct effects on *in-situ* nematode communities could be measured, with significantly lowered abundances in spiked soils, (40% and 50% reduction of nematode abundance in soils spiked with 259.3 and 476.4 mg/kg dw. Overall, this study provides new insights into the impact of the non-systemic fungicide fludioxonil on non-target soil organisms and demonstrated the general suitability of standardized toxicity testing on *C. elegans* in protecting *in-situ* communities.

Recent Approaches in Establishing Linkages between Exposure Science and the Environmental Effects of Trace Organic Contaminants (PC)

WEPC13

Monitoring estrogenic activities of waste and surface waters using an in vivo zebrafish embryonic assay: comparison with in vitro cell-based assays and determination of effect-based trigger values

F. BRION, INERIS / Chronic Risk Department; V. De Gussem, INERIS; S. Buchinger, German Federal Institute of Hydrology / Department G Biochemistry Ecotoxicology; B. Piccini, INERIS; H. Hollert, RWTH Aachen University / Institute for Environmental Research; V. Dulio, INERIS; E. Simon, Centre Ecotox / Aquatic Ecotoxicology; I. Werner, Swiss Centre for Applied Ecotoxicology / Department of Anatomy Physiology and Cell Biology; R. Kase-Pasanen, University of applied sciences Muttenz FHNW; S. Ait-Aissa, INERIS / UMRI SEBIO ECOT

Monitoring of environmental estrogens has become a major concern to assess the quality of water bodies. In that respect, the use of *in vitro* reporter gene assays to monitor estrogenic activity has proven relevant as it enables an integrative and quantitative assessment of ER-active contaminants. However, *in vitro* cell assays may not necessarily reflect the estrogenic activity observed *in vivo* in fish, raising the question of the relevance of *in vitro* measurement of estrogenic activity to predict risk for aquatic species and ecosystems.In this context, our objective was to determine 1) whether estrogenic activity measured *in vitro* led to an *in vivo* response in a fish biological model, and 2) on the basis of such an *in vitro* / *in vivo* comparison, whether there exists an *in vitro* threshold value above which an *in vivo* effect is detected/evidenced. This study reports the use of the zebrafish-based EASZY assay to assess *in vivo* estrogenic activity of 33 surface (SW) and waste water (WW) samples collected across Europe and that were previously well-characterized for estrogen hormones and *in vitro* estrogenic activity (Könemann et al., 2018). We showed that 18 out of the 33 SW and WW samples induced estrogenic responses in transgenic zebrafish embryos leading to significant and concentration-dependant dependent up-regulation of the ER-regulated cyp19a1b gene expression in the developing brain. The in vivo 17β-estradiol-equivalents (EEQs) were highly correlated with both the chemical analytical risk quotient (RQ) based on steroidal estrogen concentrations and EEQs reported from 5 different in vitro assays. Based on in vitro vs. in vivo comparison, regression analyses allowed to determine for each in vitro assay an optimal cut-off value which was defined as an effect-based trigger values (EBTs) above which in vivo responses were observed. The definition of these *in vitro* assay-specific EBTs values allowed to improve the sensitivity and specificity of the individual *in vitro* assays for predicting a risk associated with substances acting through the same mode of action within environmental mixtures. Altogether, this study provides experimental demonstration of the toxicological relevance of in vitro-based assessment of estrogenic activity and recommends the use of such *in vitro/in vivo* comparative approach to refine and validate EBTs for mechanism-based bioassays.

WEPC14

Combined analytical and effect-based monitoring of EU Watch List water samples

E. Simon, Centre Ecotox / Aquatic Ecotoxicology; A. Duffek, German Environment Agency- Umweltbundesamt; M. Frey, Steinbeis Innovations Center; M. Scheurer, TZW DVGW-Technologiezentrum Wasser / Analysis and Water Quality; K. Swart, P.A. Behnisch, Biodetection Systems BV; J. Tuerk, Institute of Energy and Envionmental Technology eV IUTA; J. Bachmann, German Environment Agency (UBA) / Section IV2.2 Environmental Risk Assessment of Pharmaceuticals; R. Kase-Pasanen, University of applied sciences Muttenz FHNW; E. Vermeirssen, Swiss Centre for Applied Ecotoxicology EawagEPFL / Aquatic Ecotoxicology; I. Werner, Swiss Centre for Applied Ecotoxicology / Department of Anatomy Physiology and Cell Biology

Three steroidal estrogens, 17α-ethinylestradiol, 17β-estradiol, and estrone, and the cyclooxygenase (COX) inhibitor pharmaceutical, diclofenac have been included in the first Watch List of the Water Framework Directive. This means that more Union-wide monitoring data are required on these potential water pollutants before they can be considered for inclusion in the list of priority substances. However, it is a challenge to detect these chemicals at bioactive concentrations (low pg/L) with existing routine analytical methods. Effect-based methods are promising bioanalytical tools that could circumvent such detection challenges by measuring total estrogenic activity or COX inhibition in the aquatic environment in a cost-efficient way at very low concentrations exerted by the above mentioned substances. To investigate the applicability of effect-based methods for monitoring specific groups of substances under the WFD a monitoring project was initiated by the Swiss Centre for Applied Ecotoxicology (CH) and the German Environment Agency (DE). Furthermore, the project aimed at providing high-quality monitoring data for these Watch List substances. Surface waters from Watch List sampling stations in 14 EU member states and 4 Swiss cantons were analyzed for steroidal estrogens and diclofenac by LC-MS/MS and screened *in vitro* for estrogenicity by the human cell-based ERα-CALUX and the yeast estrogen screen, AYES, and COX inhibition. The presentation aims to summarize the major results and conclusions of this large monitoring project: All together high-quality monitoring data were produced and the applicability of effect-based methods was shown to complement targeted monitoring of specific groups of substances in the aquatic environment under the EU WFD. The applied effect-based method of steroidal estrogens is more sensitive than chemical analytics pointing out its good screening potential. At the same time, it also implies that analytical methods are faced with detection challenges of the target analytes at low concentrations. Chemical analytical and effect-based methods can be combined in order to get the benefits of both: to receive indication on substances and their contribution to the measured effects, to study variable chemical exposure, to exclude false negative measurements, to monitor specific groups of substances in the aquatic environment.

Identification of chemicals in contaminated sediments with the support of bioassays

C. Gallampois, Umea University / Chemistry; S. Buchinger, Federal Institute of Hydrology / Department G Biochemistry Ecotoxicology; T. Hamers, VU

University Amsterdam / Department of Environment and Health; S. Örn, Swedish University of Agricultural Sciences / Department of Biomedical Sciences and Veterinary Public Health; G. Reifferscheid, Bundesanstalt für Gewässerkunde; M. Tysklind, P. Haglund, Umea University / Department of Chemistry
Over the last decades, an increasing number of pollutants have been detected in the environment. Even at trace levels, certain of these contaminants pose an increasing environmental, human health and economic risk. The identification of toxicants is a crucial step to protect aquatic environment and is an on-going challenge that may be addressed by toxicity profiling for environmental quality assessment. The Baltic Sea has been exposed to an extensive use of chemicals from the very beginning of the industrialization of the region and its marine environment has one of the longest histories of contamination in the world. The city of Sundsvall has an industrial history of over 150 years, associated with major pulp and paper industry as well as chemical and aluminum manufacturers. As a result, coastal sediments in the area are polluted by trace metals and organic compounds of industrial origins. *Aim*: Assessing the toxicity of the sediments in Sundsvall area and identifying chemicals responsible for the observed effects. *Methods:* Sediment samples were taken in connection to the different industries located in the Sundsvall Bay (river estuary S1, fiber bank S2, oil depot S3, primary aluminium producer S4, residential area under the influence of the aluminium factory and river current S5, wood finishes and surfactants production S6 and further away residential areas S7 and S8). The battery of bioassays includes, mutagenicity with different strains of Salmonella, fish embryo toxicity, DR-CALUX (total extract and purified extract), ER-CALUX and TTR-binding. The chemical identification is done by GCxGC-HRMS and LC-ion mobility-HRMS. *Results:* Plausible presence of amino compounds in all sediments samples, except for S1 and for S2 (fiber bank sample is cytotoxic). In general, samples S2, S3 and S4 (fiber bank, oil depot and aluminium production) exhibit most of the positive responses towards the different bioassays. The results for the fish embryo assay show mainly malformation when exposed to S2. In details, nitro-PAHS are expected in samples S3, S4 and S5, high amount of PAHs in S4 and compounds such as PCBs, dioxins and furans can be present in S3. Possible presence of estrogenic active compounds in S2, S3 and S4 (e.g. natural and synthetic steroids, surfactants, pesticides …). Finally, compounds like OH-PBDE, triclosan, nonylphenols or musk for instance could also be present in S2 and S4.

WEPC16

Successfully interlinking temporally- and specially- explicit fate and effect modelling within an agricultural field

A. Agatz, IBACON GmbH / Ecological Modelling; R. Ashauer, University of York / Environment; P. Sweeney, Syngenta / Environment Product Safety; C. Brown, University of York / Environment Department
The development of efficient and sustainable molecules for plant protection is characterized by extensive requirements for the environmental risk assessment. Proof of efficiency is part of the risk assessment procedure and can influence the development and registration process for new molecules and products. The proposed placement strategy (application type and application rate) derived from efficacy trials and the resulting environmental load (driving the Predicted Environmental Concentration (PEC)) are the basis for the risk assessment for non-target organisms. Particularly for substances used to control root damaging pests, the assessment of efficacy is demanding and costly due to the complex interplay of system components and the limited options for investigating interaction between roots, pests and substances without disrupting the system. Here we present a new temporally- and spatially-explicit modeling concept called COMPASS (Comprehensive Model for Pesticide Activity in SoilS) that simulates the interaction between roots, pests and substances in the soil profile and allows investigation of the efficiency of different placement strategies. The modeling concept consists of an individual based population model for the pest, an agent based root growth model that can be affected by the pest, a water and substance transport model that is linked to the root growth model, and a toxicokinetic/toxicodynamic model that converts individual exposure of moving organisms in the soil profile to their survival. The concept was developed using the corn rootworm *Diabrotica virgifera* as model species and it was evaluated using 125 field studies conducted in four regions of Illinois (USA) over a period of ten years where substance efficacy was found to be highly variable. The field studies used for evaluation of the model framework span 11 commercial products containing one of three active substances (chlorpyrifos, clothianidin, tefluthrin) and applied as seed, band or furrow application at sowing. The model simulates efficacy in agreement with the observed efficacy in 94% of all field studies tested. We discuss how a model following the new concept can be used to a) develop new molecules and products, 2) optimise application timing, application type and application rate to support integrated pest management, and c) in the future assess the interplay between control of the target pest whilst minimising risk to non-target species within a field.

WEPC17

pH-dependent toxicity due to protonophoric uncoupling

A. Ebert, Helmholtz Centre for Environmental Research UFZ; K. Goss, Helmholtz centre for environmental research - UFZ / Analytical Environmental Chemistry
When researching the linkages between exposure conditions and toxic effects for ionisable compounds, pH-dependence of toxicity is an important factor. One such pH-dependent effect is protonophoric uncoupling, where a weak acid shuttles protons H^+ across the inner membrane of the mitochondria, and thereby decreases/dissipates the proton gradient created by proton pumps of the respiratory chain. This gradient is essential for ATP-synthesis, and its dissipation leads to a toxic effect. Due to recent advances in the prediction of anionic permeation through lipid bilayers, we were able to develop a purely mechanistic biophysical prediction model of pH-dependent uncoupling toxicity. Our model describes a steady state situation, where the net flux of the protonophore across the membrane is zero. At the same time, we assume a toxic effect to occur once the flux of shuttled H^+ reaches the same order of magnitude as the opposing flux of H^+ created by the proton pumps. Important input factors are physiological data, like the pH- and potential-gradient across the mitochondrial membrane, as well as the fractionation (pKa) and the permeability of the weak acid. The core input is the anionic permeability of the uncoupler. At this point, our mechanistic model is well suited to predict minimal toxicities of ionisable compounds, as well as pH-dependencies and their direct cause (like ion trapping or limitations by the neutral permeability). But to avoid underestimation of toxicity due to uncoupling, heterodimer permeation will have to be included in the model. The advantage of our model over already existing quantitative structure-activity relationships (QSARs) is the ability to account for pH- or potential- gradients across the membrane. Also, the mechanistic nature of the model allows to draw direct conclusions on the factors that limit the uncoupling activity.

Disinfection Byproducts and Oxidation Byproducts: Analysis, Fate, Toxicity and Treatment (PC)

WEPC19

Toxicological Assessment of Disinfection By-products using Zebrafish Embryo Bioassays

R. Chaves, ISAMB- FMUL/EPAL/CIIMAR; C. Guerreiro, Faculty of Medicine, University of Lisbon; V. Cardoso, EPAL- Empresa Portuguesa das Águas Livres, S.A. / Direção Laboratórios e de Controlo da Qualidade da Água; M.M. Santos, CIIMAR/FCUP / Biology/Endocrine Disruptors and Emerging Contaminants
Disinfection of drinking water is crucial to protect human health from pathogens and to prevent their regrowth during water supply, but the reaction of disinfectant agents with organic matter can lead to the formation of disinfection by-products (DBPs). Given their widespread occurrence, the potential human health impacts and (eco)toxicity associated with exposure to DBPs are of particular interest due to their potential carcinogenicity and vary non-carcinogenic effects. Understanding the public health implications of this emerging compounds in drinking water and their unclear biological mechanism is crucial for societies, decision-makers and water safety plans. The main aims of this project are (a) to implement and validate analytical methods to detect, identify and quantify new and unregulated DBPs such as Haloketones and Aldehydes, in drinking water, in order to contribute for enhancing the effectiveness of EPAL's water safety plans and improve the knowledge on the risk of DBPs in a drinking water supply system (b) In order to assess health risk of DBPs in drinking water, a high-throughput embryo bioassay approach based on OECD 236 toxicity test with the model animal Zebrafish (*Danio rerio*) was employed. We present here the preliminary results based on the toxicological approach with zebrafish embryo bioassays, using 7 unregulated compounds, including Haloketones, Aldehydes, Alcohols and Nitrosamines. The preliminary results point to significant differences on total abnormalities, mortality and sensorimotor reflexes after 96h post-fertilization, which were compound and concentration dependent. The human health risk of the tested compounds will be discussed and integrated with the current knowledge in the field. **Acknowledgement** FCT- Fundação Ciência e Tecnologia for funding grant PDE/BDE/122649/2016

Assessing the occurrence of trihalomethanes, haloacetic acids and halophenols from chlorinated industrial discharges at sea and their toxicity on Paracentrotus lividus

K. Lebaron, Université Aix Marseille; S. COUPE, Université Toulon; C. Demelas, L. Vassalo, J. Boudenne, Université Aix-Marseille
Chlorination, one of the most widely used techniques for water disinfection, is also considered to be one of the most effective available treatments for the control of micro- and macrofouling. However, chlorine is very reactive towards natural organic matter, ammonia and bromide present in seawater. The reactions of chlorine with these species lead to the formation of several brominated or chloro-brominated by-products, whose nature, levels and eco-toxicities are poorly documented in the literature. This study aims at evaluating the levels and impacts of chlorinated discharges in a heavily industrialized area, located in a semi-enclosed bay in South East of France. In this area, the total amount of daily releases is estimated to reach up around 6 million cubic meters of chlorinated waters. Five sea sampling campaigns were carried out between 2017 and 2019. Physico-chemical parameters were recorded on-site. Water samples were also collected using 1L bottles and stored at 4 °C after the addition of ascorbic acid or

ammonia chloride. These water samples were used for the analysis of several classes of chlorination by-products including THM, HAA and HP. Samples treatment consisted of liquid-liquid extraction with MTBE. All extracts were analyzed using GC-ECD (Clarus 580, Perkin Elmer, Norwalk, CT, USA). Limits of detection were 0.01 μg/L for THM and HP, and 0.1 μg/L for HAA. Additionally, individual and mixture acute toxicity and genotoxicity were measured on larvae of Mediterranean Sea urchin: *Paracentrotus lividus*. The toxicity test was based on abnormal growth rate to characterize the developmental effect, biochemical analysis to evaluate DNA damage and how each geographical group of urchins respond to this kind of pollution. Individual molecule toxicities were plotted on a dose-response curve, and toxicities on two population of sea urchins, either chronically exposed or not, were compared. This work showed the occurrence of THM, HAA and HP, with predominance of bromoform, tribromoacetic acid and tribromophenol in the industrial gulf. The synergic acute toxicity and genotoxicity of these three molecules on *Paracentrotus lividus* larvae has been demonstrated for concentrations significantly higher than the environmental ones, and a local adaptation was demonstrated with different molecular responses. **Acknowledgements**: This work was included in the project "Fos-Sea" funded by the French Research Agency (ANR-16-CE34-0009). *PARTICIPATION IN THE YSA*

Analytical method development for the determination of the emerging chlorination by-products bromobenzoquinones in seawater.

M. Verlande, Laboratoire Chimie Environnement; E. Quivet, A. Durand, Université Aix Marseille; J. Dron, Institut Ecocitoyen pour la Connaissance des Pollutions; J. Boudenne, Université Aix-Marseille

After the first discoveries of disinfection by-products (DBPs) formation during chlorination in the 1970s, research has been conducted to understand processes of formation and identification of DBPs. Up to now, more than 600 DBPs have been identified in various water matrixes. Among them, halobenzoquinones (HBQs) were first identified and confirmed as an emerging group of halogenated DBPs in 2010. Quantitative structure toxicity relationship analysis predicted HBQs to be potential bladder carcinogens. Their occurrence in seawater has been poorly studied until now, while the potential sources of their production increase. Indeed, the brominated-HBQs may be formed by chlorination of organic matter present in sweater. They could be thus found in the marine discharges of wastewater treatment plants, in ballast waters, in the outlets of industrial plants using seawater, and in the outlets of desalination plants. Analytical methods for the determination of brominated HBQs in seawater is poorly documented in the literature. In the present study, four bromated HBQ have been analyzed, according the frequent occurrence of their chlorinated analogues in treated tapwater at ng/l levels: 2,5-Dibromo-1,4-Benzoquinone, 2.6-Dibromo-3,5-Dimethyl-1,4-Benzoquinone, 2,6-Dibromo-3-Chloro-5-Methyl-1,4-Benzoquinone, 2,3,5,6-Tetrabromo-1,4-Benzoquinone. As a first step, their stability in seawater has been studied. The results show HBQs in seawater are not stable over time, with a degradation rate of 93% in 19 hours at 20 °C for three of them.To stabilize them in seawater, it is necessary to transform them into their redox congeners, *ie* bromohydroquinones by adding ascorbic acid. To reach a low level of detection, it is then necessary to optimize a preconcentration step. In this way, we developed a new method of solid phase extraction (SPE) for these compounds by implementation of an experimental design, allowing the optimization of several factors (nature of sorbents and of solvent, extraction and elution rates).\n\nTo validate the whole analytical procedure (SPE-GC-MS analysis), real samples, coming from a heavily industrial area where 6 millions m^3 of chlorinated are discharged daily, have been analyzed. *\n Acknowledgments: This work was included in the project "Fos-Sea" funded by the French Research Agency (ANR-16- CE34-0009). M.Verlande thanks The C.R SUD-PACA and the Institut Ecocitoyen pour la Connaissance des Pollutions for his doctoral scholarship.*

Evaluation of the relevance of disinfection byproducts (DBPs) for the environmental risk assessment of biocides

M. Hüben, Fraunhofer IME / Ecological chemistry; M. Diehle, RWTH Aachen University / Institute of Environmental Engineering; M. Herrchen, M. Klein, Fraunhofer IME / Ecological chemistry; S. Hahn, Fraunhofer ITEM / Chemical Risk Assessment

Disinfectants are widely used biocidal products. Their scopes of applications are quite broad and include different fields such as (drinking) water, health care, food processing or construction industry. Among the active ingredients used, highly reactive substances like chlorine, peroxides or ozone are common. During their application, numerous disinfection by-products (DBPs) are formed, especially if organic matter is present. Depending on the specific use, the reaction conditions such as presence of water, pH, temperature and application duration differ significantly and may influence the formation of DBPs. The intended use also determines possible releases of the formed DBPs into the environment. This complex situation is not adequately considered within the European biocides regulation at the moment. The authorisation of biocidal products is regulated by the EU Biocides Regulation 528/2012 which also requires the assessment of possible DBPs. The existing Guidance on Disinfection By-Products is limited to halogen-containing biocides and, selected product types and includes only general scientific strategies for the risk assessment of DBPs. A detailed European guidance for an environmental risk assessment (ERA) of DBPs is missing. On this basis a harmonized ERA of biocidal products within the EU is questionable. In order to fill this regulatory gap and develop a feasible regulatory toolkit, the German Environmental Agency (UBA) launched a research project for the consideration of DBPs within the environmental risk assessment of biocidal products (FKZ 3718 65 403 0). The project aims are a literature search based identification of DBPs relevant for the ERA of biocides and the conditions of use influencing their formation as well as the identification of active ingredients and product types. Moreover possible entry pathways of the DBPs into the environment are investigated. The obtained results are finally complemented by an experimental validation via chemical analysis of simulated product applications.

Microbiological analysis and genotoxicity assessment of sewage effluents treated by advanced oxidation processes

L.R. Sommaggio, Sao Paulo State University - UNESP / Biologia; D.E. Mazzeo, Sao Paulo State University - UNESP / Department of Biochemistry and Microbiology; J.A. Malvestiti, R.F. Dantas, University of Campinas / Technology; F.A. Oliveira, C.E. Levy, University of Campinas UNICAMP / Department of Clinical Pathology; M. Marin-Morales, Unesp - Institute of Biology / Biology

Among the processes for effluent treatment in Wastewater Treatment Plants (WWTP), advanced oxidation disinfection, such as ozonation (O_3) and ultraviolet radiation in conjunction with the hydrogen peroxide ($UV+H_2O_2$), can be highlighted. These processes generate hydroxyl radicals (OH·), which promote the oxidation of the pollutants and the disinfection of effluents. As the oxidative processes can generate toxic compounds and metabolites, bioassays are a crucial tool to evaluate the elimination of the toxicity, before these effluents are reused or discarded in hydric bodies. The application of new technologies to the effluent treatment requires a validation of the efficacy of the process to avoid any impairment of the ecosystem associated with the receiving water body. Thus, this study aimed to asses the genotoxic potential of sewage effluent samples, before and after the disinfection treatment by advanced oxidative processes, by the micronucleus (MN) test on HepG2/C3A cells, as well as the microbiological assessment of these effluents. Samples from a WWTP in Limeira (São Paulo State-Brazil) were collected after the conventional treatment process. The samples were exposed to treatments with ozone (O_3) and $UV+H_2O_2$ for periods of 20 (T1) and 40 (T2) minutes. The results showed a significant rate of MN induced by the effluent before and after the treatment with $UV+H_2O_2$ (T1). Regarding the nuclear buds, significant results were observed for the treatments $UV+H_2O_2$ (T1 and T2). The presence of multiple nuclear alteration was significant for the treatment $UV+H_2O_2$ (T1) and, when considered all the previous alterations combined (MN, nuclear bud and multiple alterations), the treatments $UV+H_2O_2$ (T1 and T2) were the ones that showed significant results. In relation to the microbiological characterization, the effluent before the treatment showed 8 bacteria genders. After the treatment with O_3T1 and O_3T2, 7 and 5 microbial genders were observed, respectively. After the treatment with $UV+H_2O_2$ (T1), only one gender was detected, which one was eliminated after $UV+H_2O_2$ (T2). Therefore, this study revealed that the treatment performed with $UV+H_2O_2$ induced more genotoxic damages to the cells, independently of the disinfection period assessed. In contrast, it was more efficient to eliminate the microorganisms. So, we must consider not only the disinfection power of the treatments, but the possible negative impacts that they may cause to the environment.

Effect-directed analysis for the determination of genotoxic products formed during ozonation of wastewater containing significant industrial inputs

T. Manasfi, Eawag - Swiss federal Institute of Aquatic Science and Technology / Environmental Chemistry; A.J. Bergmann, Oekotoxzentrum Eawag-EPFL / Environmental Molecular Toxicology; U. von Gunten, Eawag, Swiss Federal Institute of Aquatic Science and Technology; J. Hollender, Eawag / Environmental Chemistry; E. Vermeirssen, Swiss Centre for Applied Ecotoxicology EawagEPFL / Aquatic Ecotoxicology; C. McArdell, Eawag / Department of Environmental Chemistry

Organic micropollutants (MPs) such as pharmaceuticals and biocides cause undesired effects in the aquatic environment when present above certain concentrations. Discharges from wastewater treatment plants (WWTPs) are one of the major sources of introduction of MPs into watercourses. While conventional WWTPs are efficient at the removal of organic material and nutrients, their removal of MPs is insufficient. As a result, upgrading technologies in WWTPs are crucial to minimize the discharge of MPs into watercourses. Ozonation is one of the measures to remove a broad range of MPs from wastewater (WW). In Switzerland, a new water protection act, which entered into force in January 2016, requires the reduction of MP discharges from WW. To comply with this requirement, several Swiss WWTPs have been (or are being) upgraded with ozonation treatments. During ozonation, most MPs react either directly with ozone or with hydroxyl radicals formed from ozone decomposition processes, leading to the formation of ozonation transformation products (OTPs) and byproducts (OBPs), which may also be toxic. Although some of the formed OTPs and OBPs are removed in biological post-treatments, there are still concerns about those that persist. Additionally, the impact of the presence of significant industrial WW discharges into municipal WWTPs remains an issue of concern, since previous and recent own investigations highlighted increased toxicities during ozonation in such WWTPs in some cases. The present study aims at optimizing and implementing a diagnostic bioanalytical strategy integrating toxicological and chemical analyses based on effect-directed analysis (EDA). This approach combines *in vitro* genotoxicity assays, fractionation, and high-resolution mass spectrometry (HRMS) for the detection and identification of genotoxic compounds formed during the ozone treatment of wastewater rich in industrial inputs. Based on the obtained results, thorough investigations of the formation mechanisms of genotoxic compounds will be conducted to characterize their precursors and understand the conditions which affect their formation.
